ABSTRACT

A study of the National Accident Sampling System (NASS) found an increase in upper extremity injuries when drivers were restrained by a seat belt and air bag as opposed to a seat belt alone. These injuries were attributed to forces from the air bag deploying or the air bag projecting the arm into vehicle components or the upper body of the driver. Two evaluation methods were used to assess the extent of injury and aggressiveness of different driver side air bags. The RAID, developed by Conrad Technology, and the Hybrid III instrumented arm, tested at the Vehicle Research and Test Center, were used in static testing to evaluate the effect of air bags on the arm.

The positions of the RAID and the Hybrid III arm simulated the arm in four different turning positions with the forearm across the center of the wheel. Both devices recorded arm moments and accelerations. Film analysis determined the cause of the peak resultant moment for each bag in the four configurations. The Hybrid III was able to attribute half of the moments that surpassed the Injury Assessment Reference Values (IARV) to forces from the air bag when deployed in close proximity to the forearm, while the other half of the moments that surpassed the IARV were from contact with the head, neck and chest of the dummy. In contrast, the RAID only recorded accelerations and moments due to the air bag but was unable to account for contact between the arm and the occupant or vehicle's interior. The Hybrid III instrumented arm and the RAID gave similar rankings of the severity of the different air bags.

INTRODUCTION

The main goal of the initial phase of the arm/air bag program was to determine if the RAID and Hybrid III instrumented arm led to similar conclusions regarding the arm injury potential of different air bag systems. To do this, testing was performed with the Hybrid III instrumented arm at the Vehicle Research and Test Center (VRTC) using the same testing configurations and air bags as those used with the RAID testing device.

BACKGROUND

ARM INJURY/AIR BAG INTERACTION STUDIES - A recent NHTSA study (conducted by Conrad Technology) found a higher incidence of arm injury in National Accident Sampling System (NASS) cases in accidents involving air bags. When drivers were restrained by only a three-point belt, about 1% experienced upper extremity injuries. Of those drivers restrained by both three-point belts and air bags, 4% suffered arm injuries. A more detailed NASS study of 36 specific cases of upper extremity injury to drivers found that half occurred in low impact collisions ($\Delta V<24$ km/hr), half occurred while turning, and half resulted in injuries with an AIS>3. Seventy percent of the injuries with an AIS>3 were inflicted on the radius and ulna. The increase in upper extremity injuries was attributed to two possible mechanisms. The first are direct forces from the air bag deploying on the arm. The second mechanism involves the air bag throwing the arm with high velocity into the driver body or vehicle surroundings.[1]

Another study conducted by the University of Michigan, Transportation Research Institute (UMTRI), has shown that upper extremity injuries usually occur in the form of abrasions, contusions, sprains and fractures in the forearm, wrist and fingers. It was found that these minor injuries occur in approximately 20%-25% of their sample data. These injuries were contributed to the forces afflicted by the air bag as it deploys (where the bag reaches velocities of 160-320 km/h), and contact with the occupant and vehicle surroundings. [3]

RAID

The RAID arm simulator was developed by Conrad Technologies Inc., to evaluate air bag severity relative to arm injury in a static laboratory setting. A drawing of the device appears in Figure 1. Its basic structure consists of an 46 cm aluminum tube and weighs 1.6 Kg (not including the weight of the hand mass of .5 Kg). The connecting end of the RAID consisted of a double pivoted joint which allowed rotations in two directions. The free hanging end of the RAID consists of a concentrated hand mass. The length of the RAID was extended

to 46 cm to protect the pivot attachments from the deploying air bag. This is longer than the Hybrid III forearm (approximately 28 cm), but is shorter than the entire length of the Hybrid III instrumented arm (approximately 58 cm).

Five strain gage "stations" permit moments in two directions along the length of the RAID, as seen in Figure 1. To conduct laboratory testing of different air bags, the steering wheel is mounted vertically to a test fixture. The RAID pivot is connected to a crossbar located above the steering wheel, so it hangs vertically and represents an arm positioned across a steering wheel. The distance between the RAID and steering wheel can be controlled by moving the crossbar.

HYBRID III INSTRUMENTED ARM - The Hybrid III instrumented arm [2] was developed to allow evaluation of air bag severity with a dummy in a vehicle setting. As illustrated in Figure 2, the structure of the device is the standard Hybrid III dummy forearm and hand which weighs approximately 1.5 Kg. The instrumented arm was equipped with four sets of strain gages and two accelerometers (as seen in Figure 2).

RAID/HYBRID III INSTRUMENTED ARM STRUCTURAL COMPARISON - Because of structural differences between the RAID and Hybrid III instrumented arm, the kinematics and measured responses of the two systems are expected to be different. The Hybrid III arm can bend at both the elbow and the shoulder, while the RAID testing device has only one joint at a location relative to a human arm about halfway between the elbow and shoulder. If we view each device as a beam in bending, the differences in length, diameter, material, and end conditions will lead to different responses to the same input.

Figure 3 shows the RAID and Hybrid III instrumented arm in a scaled comparison. The devices are lined up relative to how they are positioned to the steering wheel rim during testing. For the RAID, the hand mass is centered over the rim, while the junction of the Hybrid III hand and thumb is the approximate rim location of the Hybrid III instrumented arm. The side-by-side comparison indicates that none of the strain gage stations on the RAID line up with those of the Hybrid III instrumented arm.

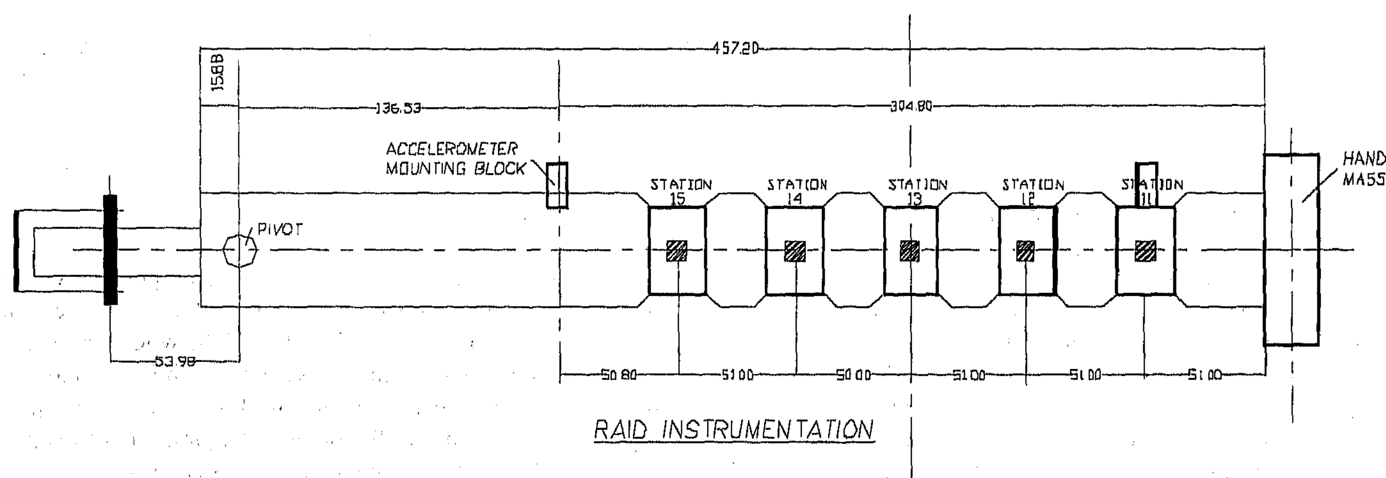

Figure 1. RAID testing device (dimensions in mm)

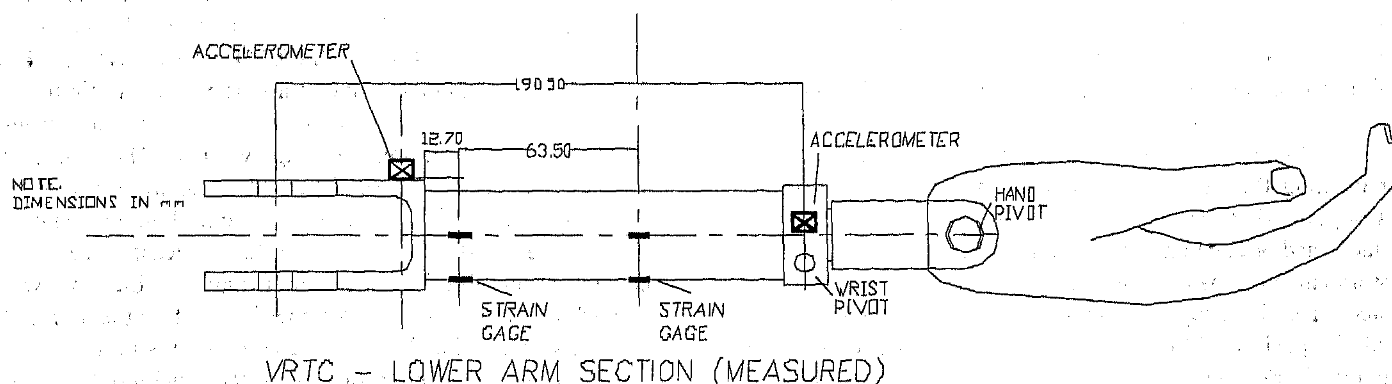

Figure 2--Hybrid III instrumented arm (dimensions in mm)

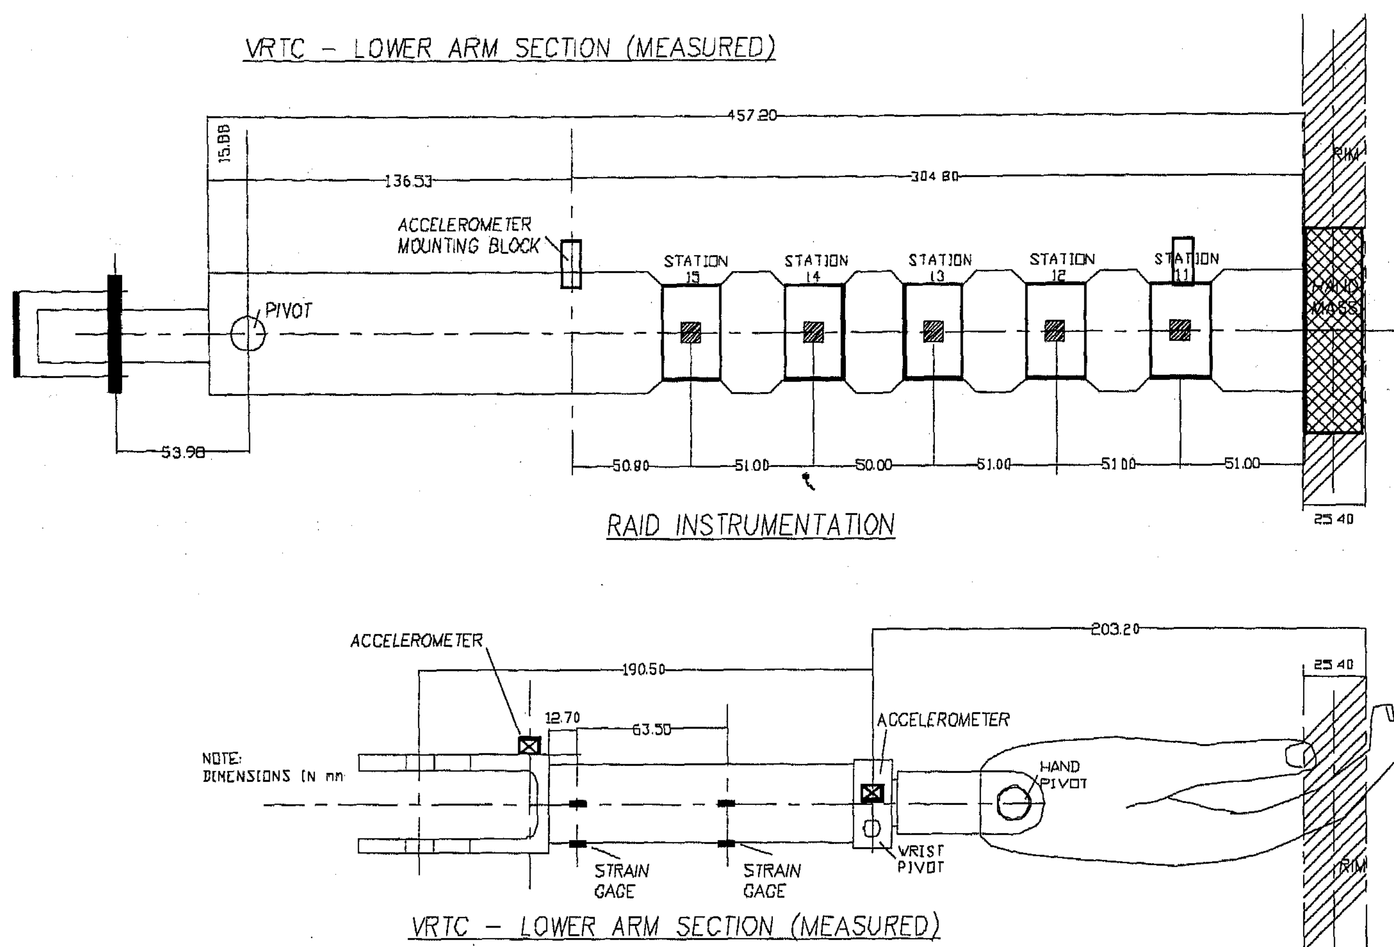

Figure 3. Comparison of RAID and Hybrid III instrumented arm (dimensions in mm)

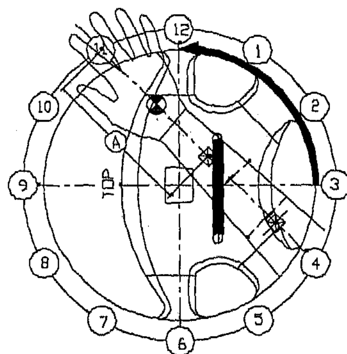
ARM INJURY CRITERIA - An IARV was estimated in both the RAID and Hybrid III instrumented arm initial testing programs. The total dynamic bending moment for the arm was estimated to be 115 N*m for the RAID device.[1] A similar estimate was completed at VRTC to find a range for the peak load for males and for females. For the VRTC estimate, the female bending moment tolerance was 70-90 N*m, while the male tolerance was 120-150 N*m.[2]

PROCEDURE

TEST CONFIGURATIONS - The RAID was tested in a variety of different configurations that varied the orientation of the arm device relative to the steering wheel, and the distance between the arm and the air bag module. Four of the RAID configurations were selected for comparison testing with the Hybrid III instrumented arm, and were designated V-1, V-2, V-3, and V-4 as described in Table 1.

As mentioned before, the RAID testing protocol called for hanging the device from a pivot in front of the steering wheel. The wheel was turned and shifted to achieve the desired distance and orientation relative to the arm. Since the Hybrid III instrumented arm was being evaluated on the dummy seated in a sled buck, the setup was limited by how close the upper arm could be positioned to the dummy's torso without twisting the dummy. For example, the RAID hand/elbow was placed in the 12 and six o'clock positions in configurations V-2 & 3. With the dummy sitting centered in front of the wheel, it was not possible to place the elbow at the six o'clock position without moving the dummy's torso. Instead, the elbow was placed at a feasible angle (elbow at four o'clock) and the wheel was rotated to position the air bag seam relative to the arm in the same way it was positioned relative to the RAID. The same type of adjustment was done in the other configurations to keep the forearm and air bag seam orientations consistent with the RAID test conditions.



Figures 4, 5, and 6 illustrate specific examples of Hybrid III instrumented arm and RAID testing configurations. The arm positions are shown together with the amount of wheel rotation required. In all figures, the Hybrid III instrumented arm position is on the left and the RAID configuration on the right. The details regarding each setup are also included in Table 1, as are the configuration designations used by Conrad Technologies.

HYBRID III INSTRUMENTED ARM TEST MATRIX- In addition to using four of the same configurations from the RAID testing, the Hybrid III instrumented arm program also used four of the same air bag systems. The four air bag systems have been arbitrarily labeled H, J, K and L followed by the model year. For example, a 1995 model J would be noted as J-95. The RAID system was tested at least once in each configuration with four different air bags. Table 2 shows the Hybrid III instrumented arm test matrix. Each of the four air bag systems was tested in the V-1, V-2 and V-3 positions. Only the K-93 and the J-95 were tested in the V-4 position, because the RAID data indicated lower measured moments for this configuration

The J-95 air bag was tested with the Hybrid III instrumented arm four times at in the V-1 position to determine repeatability. In addition, some questions were raised regarding the Hybrid III thumb position on the steering wheel. Therefore, the thumb was placed under the rim for the first three tests and over the rim on the fourth test.

Table 3 summarizes additional tests performed in the V-1 and V-3 positions. Each bag was tested once in each configuration. The results generated by the 1994 air bags were compared with the corresponding 1996 models' results to assess any improvement in the later year model.

TEST PROTOCOL - The Hybrid III instrumented arm tests were conducted statically using a sled buck as the test fixture. The setup is shown in Figure 7. The dummy was positioned on a generic metal seat which could be shifted toward or away from the steering wheel. The steering wheel was attached to a column that allowed adjustment of the column and steering wheel angles. For the initial part of this program, the same steering wheel angle and column angle were used since the difference in vehicle measurements for the four air bags tested was minimal. The steering wheel and the column angles were set at 25°. Two ventilators were placed in front of the buck to contain the post-test air bag exhaust.

Prior to each test, a series of measurements were taken to ensure consistent placement of the dummy. Before each test, the dummy's face was painted with chalk to indicate the points of contact between the dummy's face, arm, air bag and the test buck. The event was captured on high speed film and high speed video. Still pictures also were taken before and after each test.

Table 4 reflects the channels recorded in each test and the channel filter class at which the data was computed.

RESULTS

This section summarizes test results of the Hybrid III instrumented arm and the RAID comparison in the V-1 through V-4 configurations, the fleet air bag results in the V-1 and V-3 configurations and the J-95 repeatability test summary.

Neck moments in the x and y directions	600

There are two main events that occurred in the following tests which contributed to moments surpassing the IARV. The first was caused by direct contact between the air bag and the Hybrid III instrumented arm at the time the air bag was deployed. This event usually occurred within the first 15 msec of each test (referred to as an 'air bag injury'). The second event that contributed to moments that surpassed the IARV was caused by contact between the Hybrid III arm and body (referred to as a 'contact injury'). This usually occurred at times greater than 20 msec. Table 5 contains a summary of the RAID and Hybrid III instrumented arm data, followed by the times at which the data was recorded.

HYBRID III INSTRUMENTED ARM/RAID COMPARISON

CONFIGURATION V-1 - Films reviewed of configuration V-1 showed very little contact between the dummy's arm, face or chest for all air bag systems. In all tests, the forearm seemed to rotate away from the wheel while the upper arm stayed still until later in the event. As seen in Table 6, the injury summary shows moments exceeding the IARV occurred from air bag contact, while one isolated case actually occurred when the arm was thrown to the side causing and excessive inertial load from the elbow locking. All of the peak wrist accelerations occurred in the first 10 msec and were therefore results of the air bag deployment.

CONFIGURATION V-2 - Contact injuries were evident in two of the four tests in the V-2 position. In the J-95 and H-91 air bags, the arm contacted the chest and continued upward into the chin and neck. These moments caused by contact were not severe enough to surpass the IARV, but the forces afflicted by the air bag at deployment exceeded the proposed female IARV (as indicated in the first two columns of Table 6). The L-92 and K-93 air bags on the other hand, caused the arm to travel in an upward direction directly contacting the chin. These moments surpassed the proposed male and female IARV.

CONFIGURATION V-3 - Configuration V-3 had the same hand, elbow and steering wheel position as configuration V-2. However, in configuration V-2 the forearm was placed 7.6 cm from the module and in configuration V-3, the forearm was placed at a distance of 1.3 cm from the module. This decrease in distance subjected the arm to some higher forces when the air bag was deployed.

Unlike configuration V-2, where the Hybrid III arm contacted the chest of the dummy in each case, chest contact was only evident in one of the vehicles (K-93). The other three vehicles (J-95, L-92 and H-91) experienced direct contact between the Hybrid III arm and the head and neck (without contacting the chest). This seemed to produce higher moments than the cases in which the arm slid up the chest.

The resultant moments for the V-3 position were a little more severe than the results from the V-2 position. The proximal placement to the point of air bag deployment increased the magnitude of the moments. As seen in Table 6, configuration V-2 registered two moments that exceeded the proposed female injury criteria. On the other hand, configuration V-3 registered one moment that exceeded the proposed male IARV and two that exceeded both the male and female proposed IARV.

CONFIGURATION V-4 - The K-93 and the J-95 air bags were the only bags tested in the V-4 position due to nonessential findings at Conrad Technology compared to the other configurations. Contact between the arm and the dummy was evident in each test, although the highest injury potential moment was caused by the air bag (as indicated by the second and third columns of Table 6). The K-93 forced arm contact high on the chest, then upward to the face. The J-95 caused direct contact between the hand and the face of the dummy resulting in a moment which exceeded the proposed male IARV.

The resultant moments registered portray the more mild characteristics of this configuration compared to the other three positions. The K-93 arm test obtained the most force from the air bag and not from contact in this position. The J-95 results were a little more severe than they were in the V-1 and V-2 positions simply because there was contact with the J-95 bag in this configuration and not in the others.

HYBRID III INSTRUMENTED ARM/RAID DISCUSSION

Table 6 reflects the peak resultant moments (N*m) relative to the proposed IARV, and the events that caused the peak moment. Values are from the ARM/RAID comparison testing only. A ✔ represents a moment that would be equivalent to the IARV for a fifth percentile female (70-90 N*m), an ✗ represents a moments that would be equivalent to the 50th male IARV (120-150 N*m) and a ✚ represents any moment that exceeds 150 N*m. The first column represents air bag injuries and the second column represents contact injuries. The third column represents moments created when the arm is projected horizontally to the side of the dummy and the elbow is in a locked position. The location of the maximum moment as recorded at the proximal or distal moment strain gage locations (Figure 2) is also noted.

The Hybrid III instrumented arm/RAID peak resultants for configuration V-1 through V-4 are listed in Table 5. For comparative purposes, only the first 20 msec of the Hybrid III arm data is considered here. This eliminated responses occurring due to dummy contact and thus provided a better comparison with the RAID.

For each of the following configurations some trends between the Hybrid III instrumented arm and the RAID data are evident. The peak resultant moments for the RAID configurations measured much higher and surpassed the IARV for both men and women in every case. On the other hand, the Hybrid III moment measurements surpassed the female IARV in each case but less than half the time for male IARV. Since women seem to be the subject of arm injury more often then men, the Hybrid III injury assessment may be more representational before any scaling factors are applied to either device.

The difference in wrist velocities can be accounted for by analyzing the differences in the two testing devices. The RAID velocities were recorded at values almost twice as high as Hybrid III instrumented arm values. This is most likely due to the difference in the weight, kinematics and set up of the two different test devices. As the air bag deployed, the Hybrid III forearm generally moved while the upper arm remained stationary. This allows us to contribute higher accelerations in the Hybrid III testing to the mass of the lower arm being less

Table 5. Air Bag Assessment

		ARM				RAID			
		K-93	L-92	J-95	H-91	K-93	L-92	J-95	H-91

than that of the RAID. This difference in weight would produce the different accelerations experienced by each of the test devices. Another source of discrepancy may result from the time at which the velocity values were recorded. The RAID velocities were taken from the maximum velocity reached by the device after losing contact with the air bag (generally at 30 to 40 msec). On the other hand, the Hybrid III maximum velocities were recorded at an earlier time because of the contact that occurred between the arm and the dummy's head and body (at 15 msec).

The difference in results can also be attributed to different kinematics between the two systems. The Hybrid III arm cannot move freely in any direction because its motion is dependant on the movement of the rest of the dummy. If the arm is moving, the elbow and upper arm and body will restrict some of its motion while also moving backwards to absorb some of the initial force from the air bag. On the other hand the RAID is attached to an immobile support so the arm reacts to all of the force applied to it.

Despite the difference in kinematics some parallel conclusions do exist in the air bag assessment rating between the Hybrid III instrumented arm and the RAID. The RAID and the Hybrid III arm device ranked configurations V-2 and V-3 exactly the same while V-4 was able to differentiate between the most and least aggressive bags. For configuration V-1 the air bag ratings were very similar. The L-92 and the J-95 bags were found to be the least aggressive bags while the K-93 and the H-91 were found to be the most aggressive bags. The evaluation methods used to assess the air bags used with the Hybrid III arm were not stringent. The Hybrid III arm tests were ranked by the magnitude of the resultant moments, accelerations and velocities. For example, the bag with the highest resultant moment was

ranked #4, or most aggressive. The bag with the lowest moments and accelerations was ranked #1, or least aggressive. There is some ambiguity to the ranking system, and other parameters could slightly sway the ranking of the bags. Nevertheless, the two systems were able to accurately differentiate between the most and least aggressive systems.

FLEET AIR BAG RESULTS

The fleet air bag testing was conducted on 1994 and 1996 systems. For three of the systems, tests were conduced on both 1994 and 1996 models, while the remaining units were tested only for the 1996 model. The 1994 and 1996 model year air bag module performances were compared to assess improvements. In the charts which follow, the injury reference ranges for the male (Male IC, M-Max IC) and female (Female IC, F-Max IC) IARV are indicated by the straight horizontal lines.

FLEET VEHICLES IN POSITION V-1 - The charts that follow show the peak resultant moments for the fleet vehicles in the V-1 position. Figure 8 depicts the improvement between the A, F and E, 1994 and 1996 air bags. Each vehicle's aggressiveness improved in the more recent model year. The 1994 models all surpassed the peak male IARV while the 1996 model year was decreased. The E vehicle's moments had the most dramatic reduction form 1994 to 1996, but still exceeded the female IARV.

The other vehicle performances ranged from very aggressive (exceeding the peak male criteria) to non-aggressive (not exceeding the lowest female IARV). As seen in Figure 9, the G-96 and the H-96 both surpassed the IARV substantially while the I-96 and the D-96 fell within the maximum male IARV. The B-96 moments created during the test did not exceed either the male or female IARV.

FLEET VEHICLES IN THE V-3 POSITION - The following results show the Fleet air bags in the V-3 position. As illustrated by the bar graphs (Figures 10 & 11), this is a much more severe position than the V-1 position. Figure 10 indicates a significant improvement for the 1994 model year air bags. The 1994 model year air bags all exceed the peak male IARV. The 1996 model year air bags for these three models all registered slightly within the male injury range or midway between the maximum and minimum female IARV. The remaining 1996 air bag systems all exceeded both the male and female IARV as shown in Figure 11.

REPEATABILITY

CONFIGURATION V-1 - The following tests were done to demonstrate consistency in the test results for a given test configuration. Four tests were run using the same air bags, configuration and set up. The dummy was placed in the V-1 position, with its arm in the 11 o'clock and four o'clock position. The steering wheel was rotated 90° CCW. Table 7 describes the events seen on film.

Table 8 shows the magnitude of the resultant accelerations for the four J-95 repeatability tests. The first three tests were performed with the thumb placed under the steering wheel. In order to check the effect of the thumb position on the wheel, test #4 was conducted with the dummy's thumb placed above the wheel. There was no significant difference in the data to indicate that the thumb affected the test results. Test #2 registered higher in most of the accelerations and the lower arm elbow resultant moment because the dummy's arm contacted the dummy's face during the test. In test #1, 3 and 4, the arm was thrown from the bag and the hand was very close to experiencing contact with the dummy's face and head. Therefore, any slight variation in the air bag or test set up could have caused the contact and was not considered in the repeatability aspect of the testing. For comparison, the point of contact was filtered out of the data in order to obtain a better comparison of the data. The following table reflects the moments with the contact point filtered out for Test #2, but the graphs of the moments do not. The point of contact was left in to show the magnitude and time at which it occurred.

The following graphs (Figure 12) show that the tests were very consistent with the exception of the moment created by contact in the second test. When the hand brushed the chin creating a moment at about 30 msec, an increase in the velocity can be noted on the graph. If this event were omitted from the analysis, the graphs of the distal and proximal moments and the velocity curves track each other very well. The distal moments all peak just before 10 msec and are all going back to zero by 20 msec. The proximal moments also peak before ten msec and return to zero at the same times.

DISCUSSION & CONCLUSIONS

The Hybrid III instrumented arm and the RAID were fairly consistent in differentiating between the severity of the different air bag systems. The RAID and the Hybrid III moments and velocities registered at different magnitudes, but each measured the same bags as having the highest moments at given velocities relative to the other systems. Both devices recorded the K-93 and the H-91 as the bags with the highest peak moments and the J-95 and the L-92 with the lowest peak moments. A moment vs. velocity scatter graph was used to portray the severity of each air bag system as measured by the Hybrid III (Figure 13) and RAID (Figure 14) devices. Each air bag model and year labels are preceded by its configuration designation (for example, J-95 in the V1 position is designated V1-J-95). The K-93 and H-91 were found to be the most severe air bags in the V-3 position, since they measured both the highest moments and velocities. In addition, the graphs also show that each device was able to correlate the severity of the moment with the velocity. Both graphs show a somewhat linear relationship between an increase in velocity and an increase in the moment recorded.

Both the Hybrid III and RAID devices recorded moments and accelerations resulting from deployment of the air bag systems. The Hybrid III was also able to detect moments created when the arm contacted the dummy's head, neck or chest. The RAID could assess severity of the bag based solely on the moments and accelerations applied by the air bag and could not account for any injury potential resulting from contact.

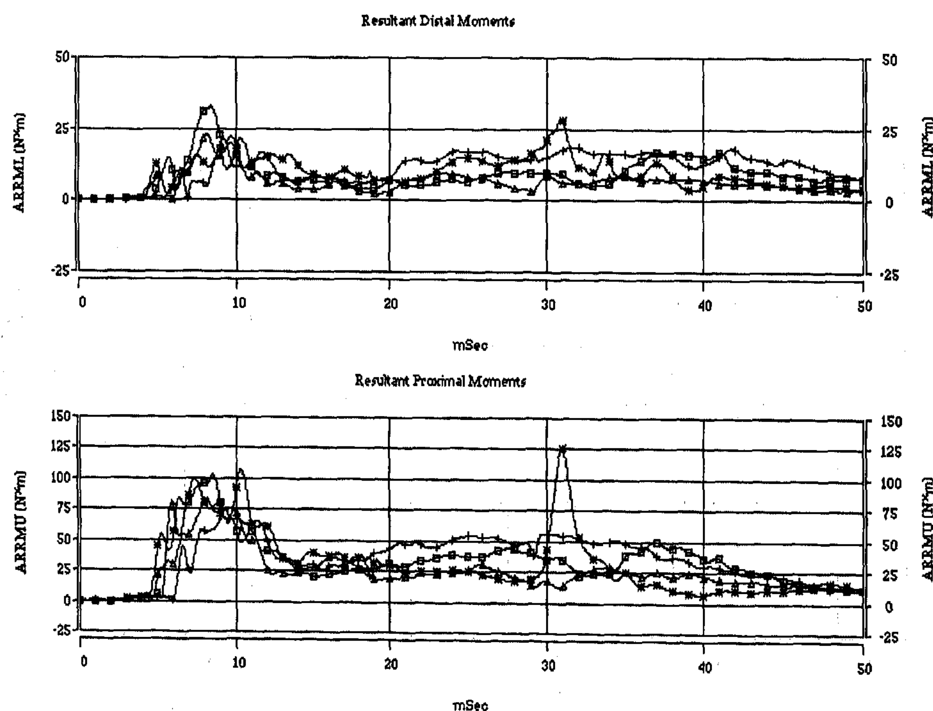

Figure 12. Proximal and distal moment curves for J-96 repeatability

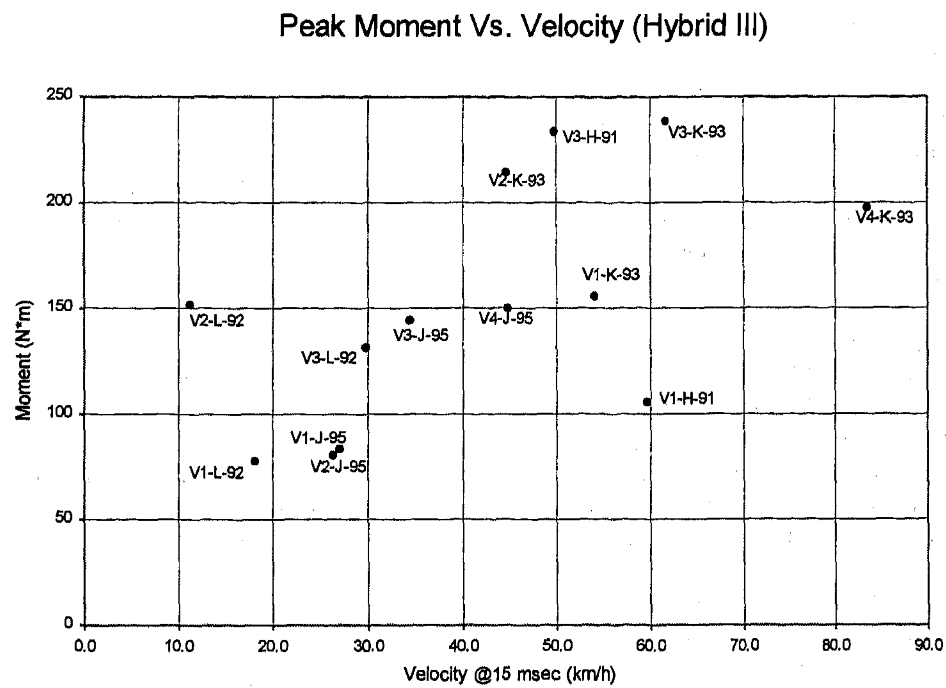

Figure 13. Hybrid III Moment Summary

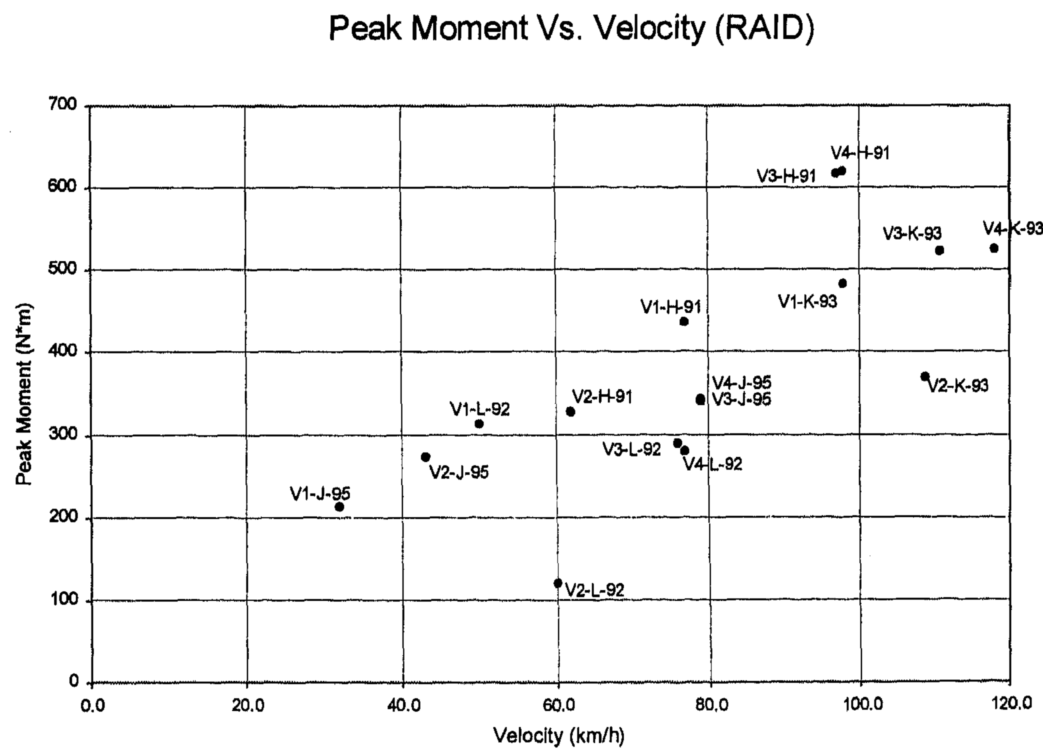

Figure 14. RAID moment summary

The RAID and the Hybrid III did not share the same kinematics, therefore, the moment and velocity magnitudes differed from each other. The RAID was an aluminum structure which made it somewhat lighter (2.1 Kg) than the Hybrid III arm (4.5 Kg), and connected at a joint acting as the elbow. The Hybrid III was heavier and was able to move at the elbow and the shoulder. The Hybrid III movement was also governed by the dummy which played a role in how the arm moved and inevitably created different moments and velocities than the RAID.

The Hybrid III moment measurements were the same order of magnitude as the proposed IARV. The Hybrid III testing mostly exceeded the female injury IARV of 70-90 N*m, but not always the male IARV of 120-150 N*m. The RAID moments registered rather high, and would have implied a high likelihood of forearm fracture in all systems for both male and females, suggesting that the arm IARV's may not be applicable to the RAID.

Based upon these results, the Hybrid III instrumented arm was selected for testing of fleet air bag systems. While both the RAID and Hybrid III devices appeared capable of distinguishing air bag deployment severities, the Hybrid III device offered two advantages over the RAID. First, the Hybrid III device provided the potential for assessment of arm interaction with the occupant and vehicle interior which was more realistic than the RAID. Secondly, the moment measured with the Hybrid III was of generally the same magnitude as the proposed arm IARV. This was felt to be more consistent with the available accident data.

Transient Aerodynamic Simulation in Crosswind and Passing an Automobile

Kenji Okumura and Toshihiko Kuriyama

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The one-box type automobile's stability on the highway is often influenced by encountering crosswinds or when passing large automobiles such as trucks and buses. This causes the automobile to behave unexpectedly. Many experiments for improving this situation have been carried out. In this respect, the analysis of transient aerodynamic characteristics is important for automobile safety and stability on the highway. Conventional transient aerodynamic simulations require a supercomputer and about million grid points. Also there were few case studies that dealt with situations such as plunging into crosswind and passing an automobile.

In this paper, a transient aerodynamic simulation by using a sliding mesh of discontinuous interface and the Arbitrary Lagrangian-Eulerian (ALE) method is presented. This method uses the k-ε turbulence model and the third-order upwind scheme, which is introduced to the convective term of the Navier-Stokes equation to improve the flow field and pressure distribution. It takes 100 hours to get the total transient results by using an engineering work station (EWS). Calculated yaw characteristics in a crosswind are in good agreement with experimental results.

Furthermore, we have simulated the effect of an active spoiler in a crosswind, and the aerodynamic characteristic of passing a one-box automobile are carried out.

INTRODUCTION

The RV (Recreational Vehicle), which was created to meet contemporary user needs, is now establishing itself as a new category of automobile. The wagon-shaped one-box automobile, for example, is one type of RV. This type of automobile, however, is said to be aerodynamically sensitive when hit by a gust of wind upon emerging from a tunnel at high speed, when overtaking a large automobile or when passing a large on-coming automobile. One of the reasons for this sensitivity, according to many previously published experiment reports[(1)-(5)] is the yawing movement acting on the one-box automobile. In our previous paper[(6)], we carried out a crosswind analysis method within a steady flow and reported on a wind-tunnel experiment using a crosswind (active) spoiler, the verification of the experiment and the spoiler's effect in the crosswind. This steady flow analysis, however, is not capable of grasping the actual phenomenon and is therefore insufficient for the analysis of the behavior and dynamics of an automobile driven on the road.

In this paper we will discuss a new method that we have developed for predicting the transient aerodynamic characteristics of an automobile, in which transient aerodynamic phenomena are calculated using a discontinuous interface grid and moving boundaries. Our simulations of yawing moment variations, which influence the high-speed driving stability of an automobile, were in good tendency with the results of our experiments. We have also verified the effect of a crosswind spoiler. In this paper we will also report on the simulations of one automobile passing another and the analysis of the influence of the transient aerodynamic characteristics of two automobiles.

COMPUTATIONAL METHOD

For computation, we used a commercial fluid analysis solver, SCRYU V1.7,and in order to calculate the k-ε turbulence model, separation and reattachment with high accuracy, we used the third-order upwind scheme, MUSCL, for the convection term of the discretization method of the Navier-Stokes equation. This solver applied the first-order Euler-backward scheme for the temporal term to get implicit solution. All variables are colocated. Solution algorithm is SIMPLE or SIMPLEC. In our previous crosswind steady analysis method[(6)] we sought to compute the steady aerodynamic characteristics of a constant direction flow such as that inside a wind tunnel, but the real phenomena encountered during driving, such as a gust of wind or unexpected passing by another automobile, are unsteady.

Therefore, in order to predict transient aerodynamic phenomena, we have developed a computational method using a

$$\frac{\partial (u_i - v_i)}{\partial x_i} = 0$$

Equation 1. Mass-Conservation Equation

$$\frac{\partial \rho u_i}{\partial t} + \frac{\partial (u_j - v_j)\rho u_i}{\partial x_j} = -\frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j}\mu\frac{\partial u_i}{\partial x_j} - \rho g_i \beta (T - T_0)$$

Equation 2. Momentum-Conservation Equation

discontinuous interface grid and the ALE (Arbitrary Lagrangian-Eulerian) method[7], which is capable of expressing moving boundaries.

Fig. 1 shows the concept of a discontinuous interface grid. In this method, as long as the edge points of a discontinuous surface match, the mass and momentum of the discontinuous surface are conserved by interpolation. The overlaped or separational ratio of this method allows in a half of element size. By establishing groups of elements that are movable relative to each other across this discontinuous surface, moving meshes can be rendered.

Equation 1 is a mass-conservation equation and equation 2 is a momentum-conservation equation according to the ALE method, which is capable of expressing moving boundaries. These equations are different from those used in the static coordinate system in that moving velocity components Vi,j are introduced. By treating the energy-conservation equation and the k-ε equation in the same manner, the movement and deformation of the meshes can be handled.

This concept is shown in Fig. 2. The trouble with this method is that if the areas of the interfaces at a moving boundary differ greatly, the resolution of the larger surface influences the computational accuracy, resulting in low interpolation accuracy. In order to avoid this problem, in our computation we concentrated a computational mesh around the automobile, in the positions where a crosswind hits and the positions most influenced by passing automobiles, so as to minimize area variation of the interfaces during movement.

Using a computational method based on the above concept, we defined meshes that expand and shrink as they move on a discontinuous surface, thereby expressing the movement of the automobile.

COMPUTATIONAL CONDITIONS

The computational conditions used in the present analysis are shown in Table. 1. We used a 1:1 scale one-box model for verification. To simulate the automobile's behavior into a crosswind, we set the automobile velocity in the driving direction at 27.8 m/s (100 km/h) and the crosswind velocity at 13 m/sat right angle as in the case of the crosswind evaluation. For the Reynolds number we employed a value of 2 x 10^6 using the automobile height as the representative length, and for the initial computational condition we assigned a crosswind of 13 m/s over the entire area from the crosswind generator region to the outlet. We set the computation time unit ΔT as 5 x 10^{-4}. For the kinetic energy k we assigned a value of 1 x 10^{-4} m^2/s^2, and for the dissipation rate ε we assigned a value of 1 x 10^{-4} m^2/s^3 over the entire area for the stablity of computation. For the boundary conditions, we set an inlet velocity regulation of 13 m/s in the crosswind generator region as the inlet condition, and defined the entire area of the downstream side of the wind generator region as the outlet and provided a pressure regulation. For the automobile surface and the road surface we used the logarithmic law for the wall conditions, and to make the proper wall conditions, we generated an initial grid around the surface so that Y^+ of the boundary layer is between 100 and 500. All other boundary surfaces were made symmetrical and assigned a free sliding condition. In this computation, tire rotation is not taken into account. The third order upwind scheme, MUSCL, used in our computation features a stable computation performance in that when the computation overshoots and tends to diverge, it automatically switches to a first order scheme. The computation time when the number of elements was 250,000 was 400 seconds per step using SGI's INDIGO 2 SOLID IMPACT R10000 engineering workstation. It took 900 steps from the automobile's plunge into the crosswind to its recovery to a steady running condition, making the overall computation time approximately 100 hours.

In the case of passing, the running velocity of the preceding automobile and the passing automobile were set as 22.2 m/s (80 km/h) and 33.3 m/s (120km/h) respectively. For the boundary conditions, 22.2 m/s of inlet velocity regulation was assigned as the inlet condition at the upstream side, and a pres-

CPU Time	100 hours	220 hours

sure regulation was assigned to the downstream side, which was defined as the outlet. To provide the initial conditions, we conducted a steady flow analysis at the starting position (2 times the automobile length behind the preceding automobile), and performed a transient moving computation after obtaining the steady flow field. For the moving conditions, an automobile velocity difference of 11.1 m/s was assigned to the passing automobile. Other conditions were the same as those in the case of a plunge into a crosswind.

With approximately 270,000 elements, it took about 220 hours to calculate a simulation of the passing automobile from the position two automobile lengths behind to the position four automobile lengths ahead of the overtaken automobile on the above-mentioned engineering workstation.

COMPUTATIONAL MODEL

In order to reduce the mesh generating time, a boundary fitting coordinate (BFC) is used for each block constituting the mesh. For the automobile body mesh, the half model computational mesh used in the steady flow analysis has been converted to a full model and partially used, thereby reducing the computation time. Fig. 3 shows the computational mesh for a crosswind plunge in this analysis, and Fig. 4 shows the concept of a computational mesh for passing. The mesh for the crosswind plunge consists of four basic blocks: acrosswind generator block and a running automobile block, where the mesh forms are maintained, and an expandable block and a shrinkable block, where the meshes are deformed using the ALE method. These blocks are discontinuously connected along the interface of the gap between the crosswind generator and the automobile, and express the movement of the automobile as the blocks corresponding to the automobile itself and its front and rear slide while shrinking and expanding. Similarly, the computational mesh for passing also comprises four basic blocks, in which the preceding automobile's meshes are maintained as they are and the overtaking automobile's meshes deform as they move.

We assigned a space of 53 m x 26 m x 5.5 m (Length x Width x Height) for the analysis of the crosswind plunge. As the automobile moves ahead a wake is generated in the rear, and a separation vortex is generated on the leeward portion of the automobile's sides in response to this wake and the crosswind. The above dimensions are to ensure a sufficient space for capturing the separation vortex. The dimensions of the space with reference to the automobile dimensions are 3 times the automobile length for the spatial area from the automobile front to the crosswind generator region, 9 times the automobile length for the crosswind generator region itself, 3 times the automobile length for the space behind the automobile, 1.8 times the automobile width for the distance between the automobile side to the crosswind generator, 15 times the automobile width for the distance between the leeward portion of the automobile's sides and the outlet downstream, and 3.5 times the automobile height for the height of the space. In order to ensure accuracy, the computational meshes were concentrated on the entrance to the crosswind generator region and around the automobile itself. Fig. 5 shows the mesh around the automobile used in this analysis. The number of elements was approximately 250,000. Using the commercial pre-processor, PROSNER, for generating and correcting meshes while applying the mesh data for aerodynamic analysis of the

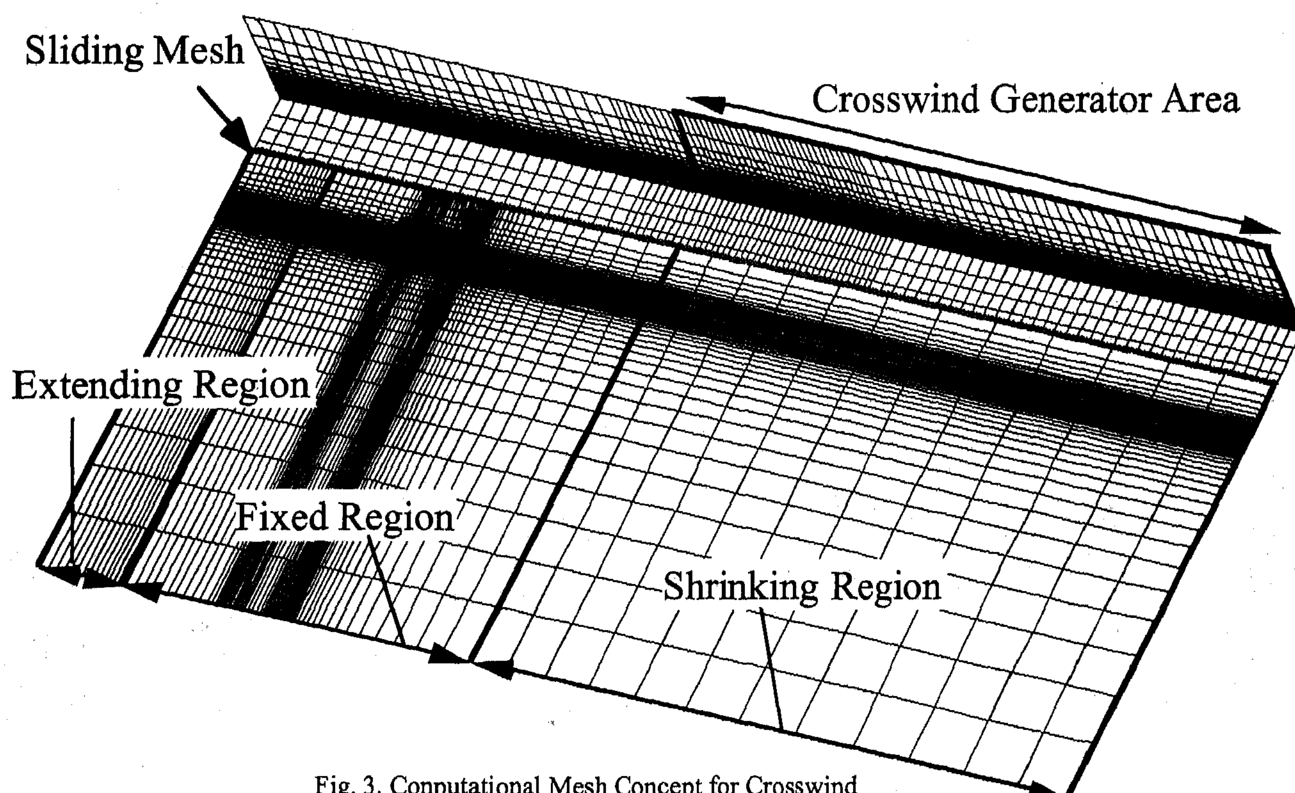

Fig. 3. Conputational Mesh Concept for Crosswind

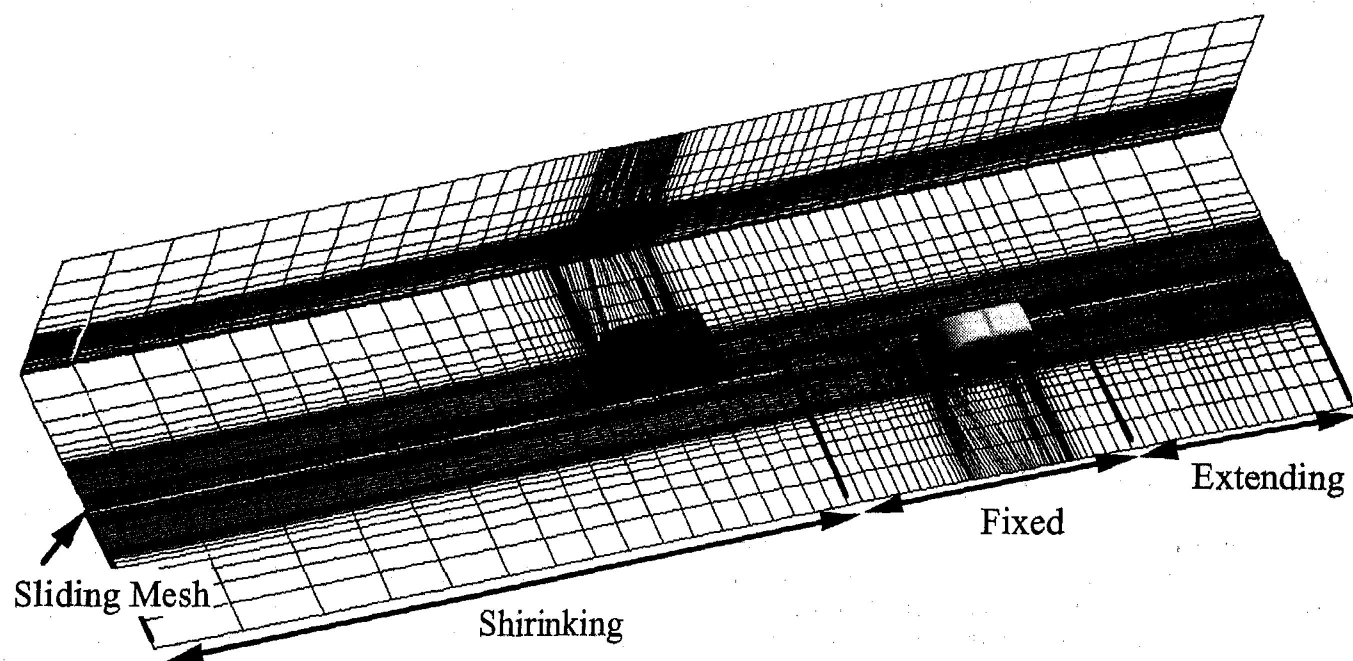

Fig. 4. Conputational Mesh Concept for Passing

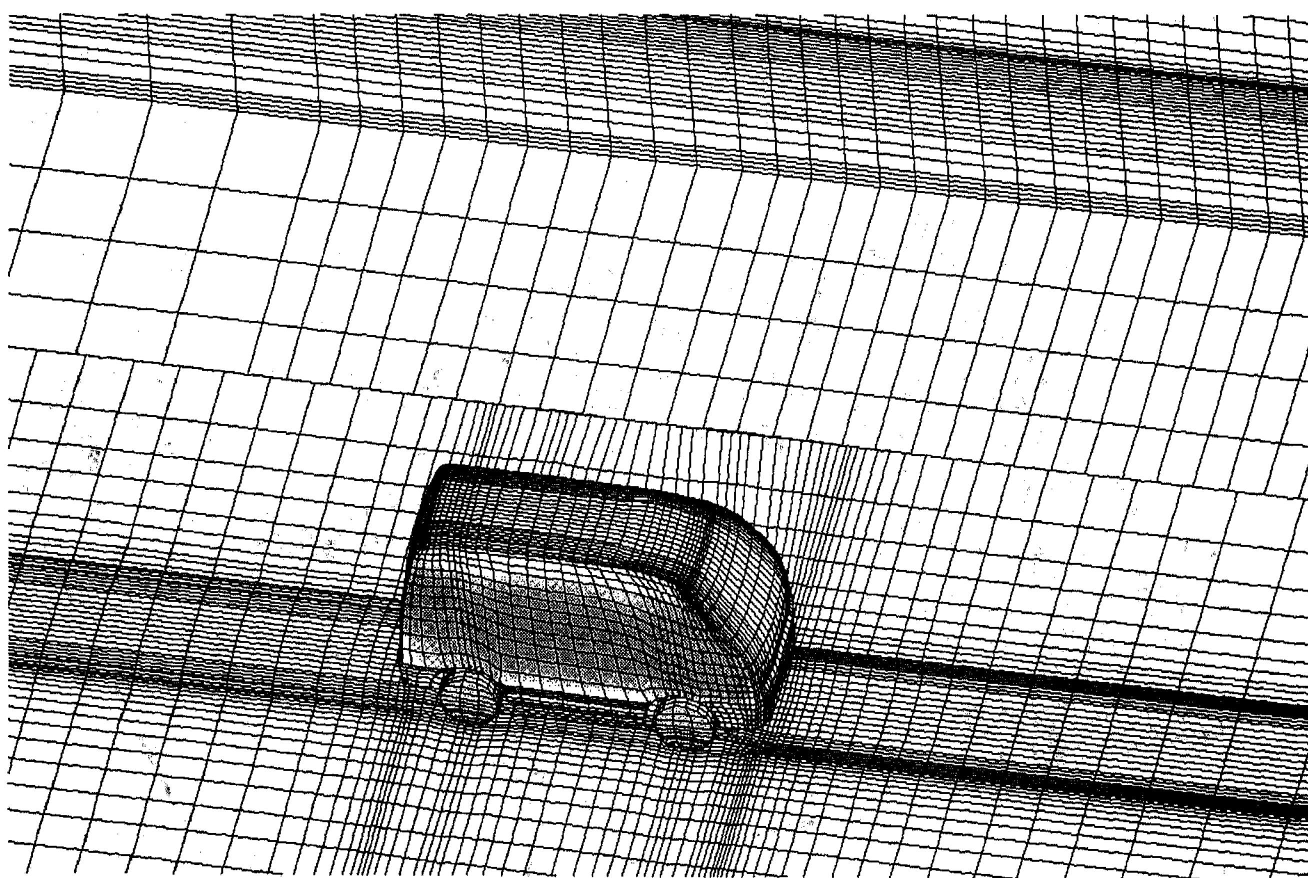

Fig. 5. Mesh around Body for Crosswind

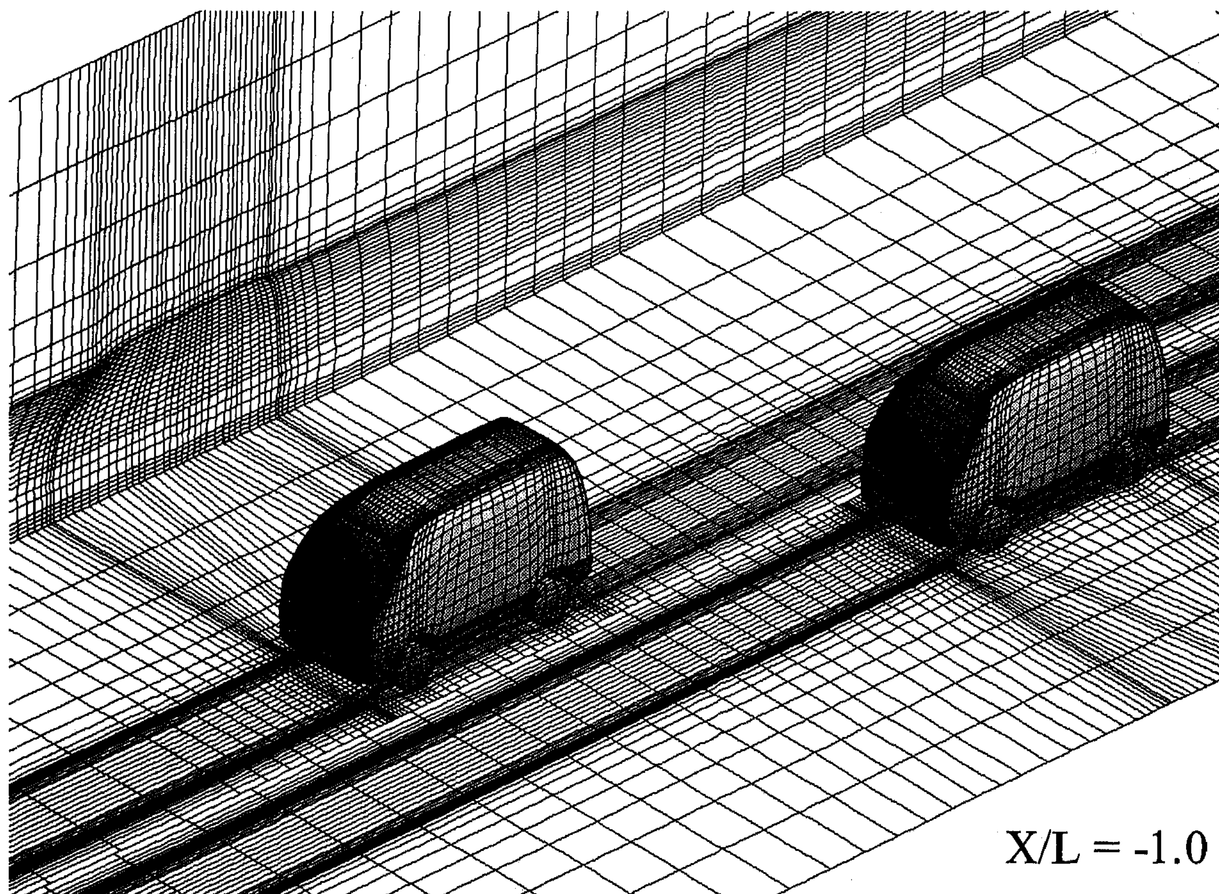

Fig. 6. Mesh around Body for Passing

steady flow, it took approximately five hours to complete the computation. Computation transferred from CAD shape data would have taken approximately 25 hours.

The analytical space for the computational mesh for passing measures 40 m x10 m x 5.5 m (Length x Width x Height). The automobiles are presumed to be of the same one-box type with a distance of 1/2 width between them. The dimensions of the space with reference to the automobile dimensions are: 5 times theautomobile length for the spatial area from the preceding automobile to the inlet, twice the automobile length for the automobile-to-automobile distance, 3 times the automobile length for the space between the passing automobile and the outlet, 2.5 times the automobile width for the exterior space on either side of the automobile, and 3.5 times the automobile height for the height of the space. Fig. 6 shows the mesh around the automobile. The number of elements is about 270,000. It took about the same time to generate the mesh for the plunge into the crosswind.

UNSTEADY COMPUTATION RESULTS FOR THE PLUNGE INTO A CROSSWIND

The yawing moment that acts on the one-box automobile when it enters into a crosswind reaches its maximum value immediately after it enters the crosswind and then transiently changes to a steady value as shown in Fig. 7. When the relative angle of the composite wind is 30 degrees, the yawing moment reaches its maximum value when the automobile has moved 1.3 times the automobile length into the crosswind, regardless of the automobile shape, according to the experimental study by Yamada, et al[1].

In our study, we conducted a simulation of a plunge into a crosswind in an attempt to discover the mechanism of yawing-moment generation through visualization. We used a commercial fluid post-processor, FIELDVIEW in order to shorten the post-processing time.

YAWING MOMENT COEFFICIENT (C_{YM}) - As shown in Fig. 8, the automobile is divided into four blocks that border each other at the center of theautomobile. The results of obtaining the yawing moment generated in each block are shown in Fig. 9. In order to average out the transient data, an ensemble average is taken from ten serial steps.

Because of the diffusion of the flow from the wind generator region, the automobile begins to come under the influence of the crosswind when it has moved approximately one automobile length from the entrance to the wind generator region. When this position is set as X/L=0 in figures, the yawing moment reaches its maximum value when the automobile has moved approximately 1.4 times the automobile length into the

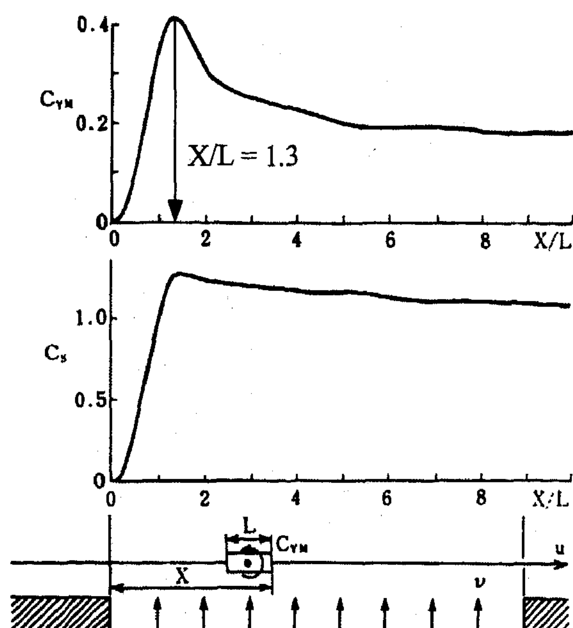

Fig. 7. Variations of Experimental CYM and Cs plunge into a Crosswind (quated from Kobayashi's SAE paper 881878)

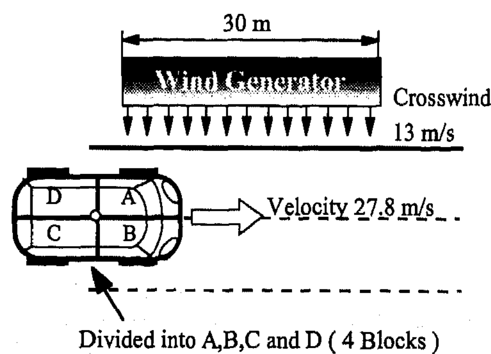

Fig. 8. Automobile devided into 4 Blocks

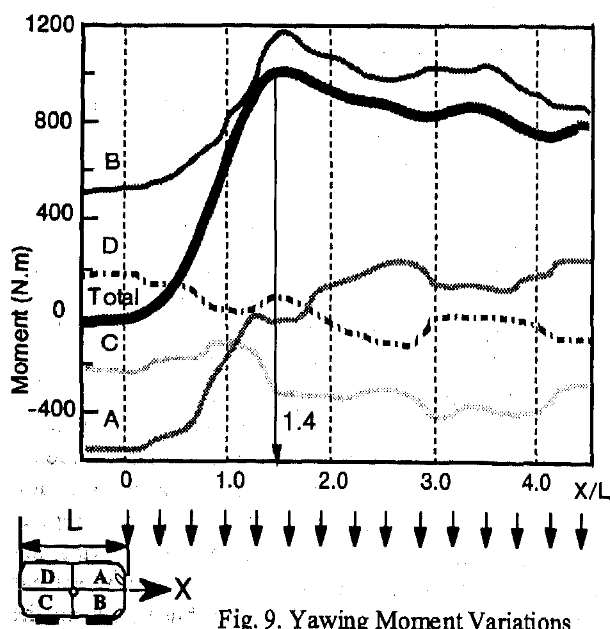

Fig. 9. Yawing Moment Variations

crosswind (X/L=1.4). The composite angle between the automobile velocity (27.8 m/s) and the crosswind (13 m/s) is approximately 28 degrees, and this finding agrees with Fig. 8.

From the changes in each block it has been found that the increase is most evident on the leeward front portion B, of the automobile, then in the windward front portion A of the automobile. In other words, the leeward portion B and the windward portion A of the front part of the automobile are the blocks that contribute to the generation of the yawing moment. This tendency agrees with our steady flow analyses(6),(8). We will now discuss the drag force, side force, lift force and pressure distribution.

DRAG FORCE (CD) - Fig. 10 shows the variation in the drag forces. We have found that the total drag force slightly decreases at first and then increases after the automobile moves one length into the crosswind. Drag force variations in each block show that the drag force on the windward front portion A of the automobile suddenly increases right after the automobile's plunge into the crosswind, but the drag force on the leeward front portion B of the automobile suddenly decreases, so that the two forces cancel each other. Whereas the drag forces on the rear parts of the automobile, C, D, decrease at first and then increase gradually, showing the same tendency as the total drag force.

These results indicate that the total drag force is dependent on thestructure of the wake that forms toward the rear of the automobile.

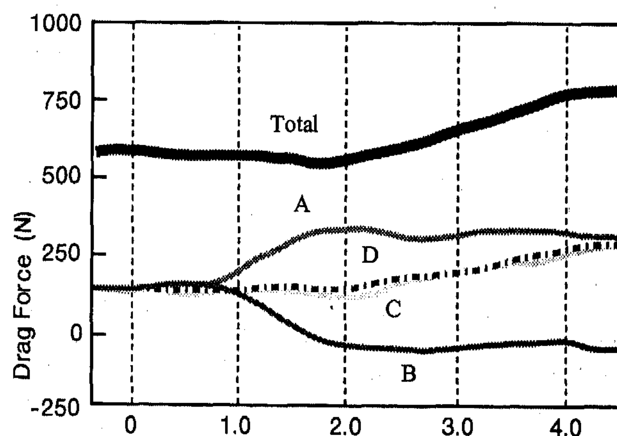

Fig. 10. Drag Force Variations

SIDE FORCE (Cs) - Fig. 11 shows the variation in the side forces. We have found that the total side force increases at the moment when the automobile moves into the crosswind, and there is no noticeable peak. The variations in each block indicate that the leeward portion B and the windward portion A of the front of the automobile influence the side forces greatly. The negative pressure regions formed on both sides of the front part of the automobile as it proceeds are transformed into a positive pressure in the upstream side and anegative pressure in the downstream side. Like the yawing moment, it can be concluded that the front parts A and B of the automobile play an important role in the formation of the side force.

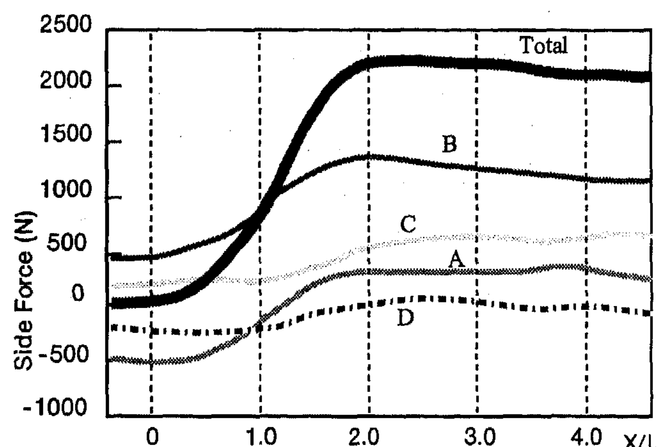

Fig. 11. Side Force Variations

LIFT FORCE (CL) - Fig. 12 shows the variation in the lift forces. We have found that the total lift force turns into a down force when the automobilemoves into the crosswind region, but suddenly increases when the automobile proceeds further into the crosswind. The lift-force variations in each block indicate that while a down force is generated in the windward front portion A of the automobile, a lift force suddenly increases in the leeward front portion B of the automobile. The lift force tends to increase in the leeward rear portion C of the automobile too. The reason for the generation of the down force is that in the windward front portion A of the automobile, stagnation points are created by the composite flow of the crosswind and front wind, and a strong negative pressure due to separation is generated under the floor of section A. The reason for the increased lift force is that a separated flow reattaches to the underfloor on the leeward sides B and C after plunging into the crosswind, so the pressure recovers and increases.

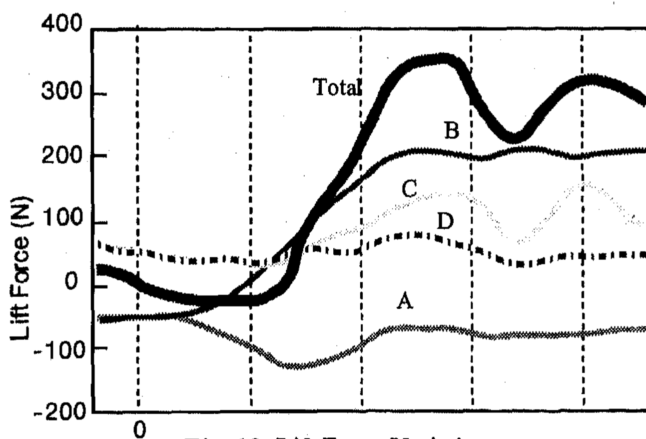

Fig. 12. Lift Force Variations

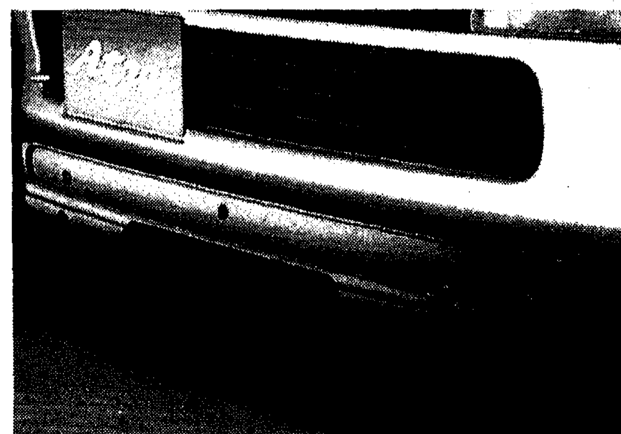
THE MECHANISM OF YAWING MOMENT GENERATION - Fig. 13 shows the variation in the automobile surface pressure distribution and in the 3D negative pressure isoplethic surface (Cp = -1.5) and positive pressure isoplethic surface (Cp =+0.8) immediately before the automobile's plunge into the crosswind (X/L = 0, X: moving distance, L: automobile length), at the automobile's plunge into the crosswind by 1.4 times the automobile length (X/L = 1.4), and at the automobile's plunge into the crosswind by 4 times the automobile length (X/L = 4.0).

At X/L = 0, it is evident that positive pressure is concentrated in the center of the automobile front and that stagnation point exist at the tip of the front bumper. Negative pressure areas generate symmetrically on both sides of the automobile front end, cancelling out the yawing moment.

At X/L = 1.4, the stagnation points are concentrated in the corner of the windward front portion A of the automobile. In the leeward front portion B of the automobile the negative pressure area expands greatly. These phenomenon contribute to the sudden increasement of yawing moment of block A and C as shown in Fig. 9. This is the reason why the yawing moment reaches its maximum value.

At X/L = 4.0, the negative pressure in the leeward front portion B of the automobile recovers, and a negative pressure is also generated in the leeward rear portion C of the automobile. In addition a crosswind hits the leeward rear portion D of the automobile, cancelling the yawing moment.

From the above observation, we have found that the yawing moment reaches its maximum value immediately after the automobile's plunge into the crosswind.



THE EFFECT OF A CROSSWIND SPOILER FOR THE PLUNGE INTO A CROSSWIND

Fig. 14 shows the view of a crooswind spoiler. Fig. 15 shows the pressure isoplethic surface of an automobile equipped with a crosswind spoiler. The stagnation point pressure increases slightly at X/L = 0, but at X/L = 1.4 the strong negative pressure on the leeward front potion B substantially decreases. At X/L = 4.0 the same tendency as that of a standard automobile is exhibited.

The computation results of the yawing moment with the crosswind spoiler are shown in Fig. 16.

These data indicate that a crosswind spoiler can reduce a dynamic yawing moment by approximately 20%, because of the reduction effect of the leeward front portion B.

The yaw rate variations in the crosswind generator region

Fig. 14. Close View of Crosswind Spoiler

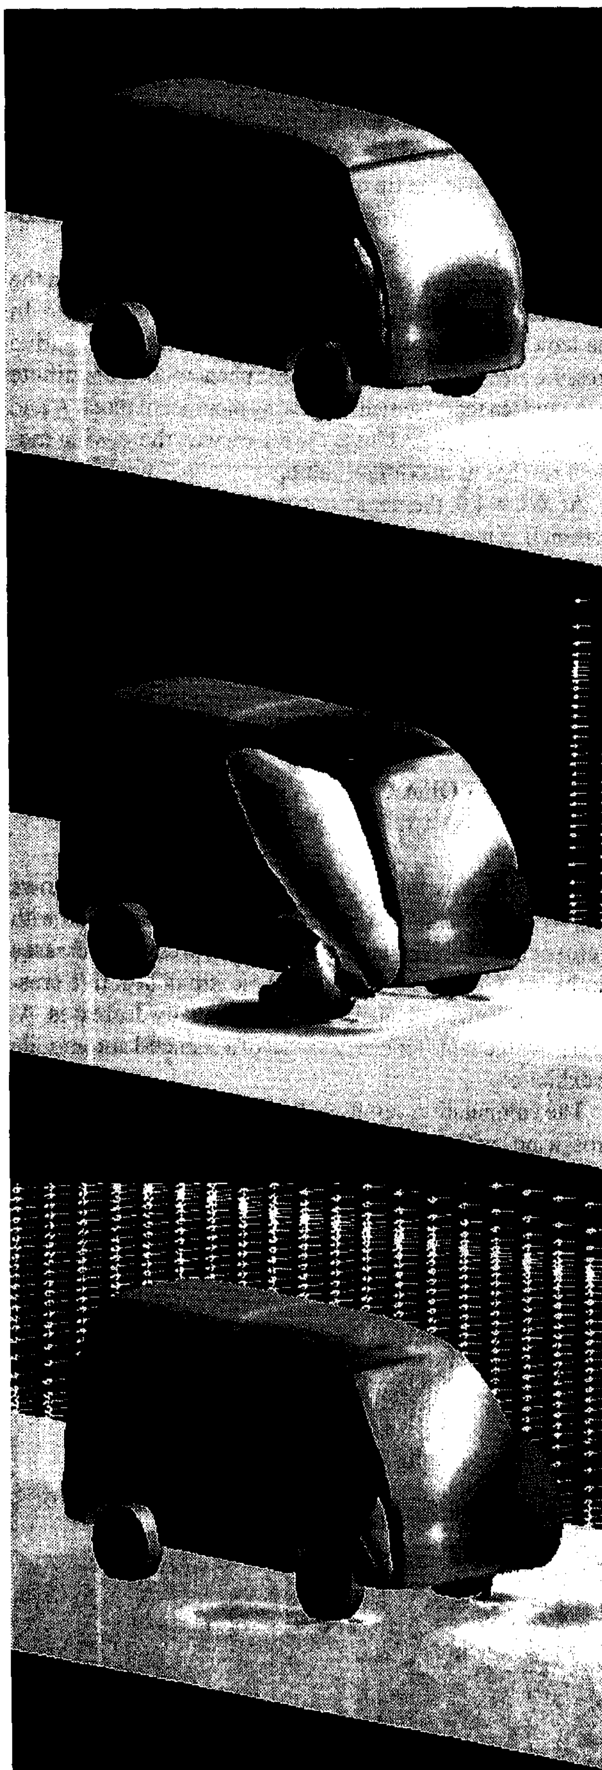


Fig. 13. Pressure Iso-Surfaces of Standard Automobile

Fig. 15. Pressure Iso-Surfaces with Crosswind Spoiler

during an actual evaluation are shown in Fig. 17. The dynamic yaw rate was found to be consistently reduced by the crosswind spoiler by more than 20% within the wind generator region.

Fig. 18 shows a comparison of the total lift forces acting on automobiles with and without a spoiler. In the case of an automobile with a crosswind spoiler a down force is obtained even after the automobile enters into the wind generator region. As a result no sudden increase in the lift force is observed, as opposed to the case of a standard automobile without a spoiler. This is because the spoiler cuts the underfloor flow, creating a stable and strong negative pressure area under the floor. This reduced lift force and the above-mentioned yawing moment reduction effect contribute greatly to the driving stability under actual running conditions.

UNSTEADY COMPUTATION RESULTS IN PASSING PHENOMENON SIMULATION

It has been reported that the maximum values of the aerodynamic forces (drag force, side force and yawing moment) that apply on the automobile being passed depend on the position of the passing automobile, and that among these forces the yawing moment has the greatest effect on the automobile's behavior[(4),(5),(9)].

In this section we will report on the simulation of a passing phenomenon, in which we visualized a generation mechanism for transient aerodynamic forces.

Yamamoto et al report that when the difference between the velocity of the passing automobile and the passed automobile is relatively small (5.6 m/s or less), static aerodynamic characteristics can explain the passing phenomenon[(4)]. In our study, we attempted computations of a steady flow with two automobiles running at 22.2 m/s with a 0 m/s velocity difference between them and also of a situation in which there is a velocity difference of 11.1 m/s (22.2 m/s and 33.3 m/s respectively) at which a dynamic effect begins to appear, and we identified the difference between these two situations.

YAWING MOMENT (CYM) - Fig. 19 shows a comparison between experiment (the one-box automobile passed by a large bus, which is quated from Yamamoto's report[(4)]) and computation (the one-box automobile passed by one-box automobile) of preceding automobile in a static condition. The computional results are good tendency with experiment. But those are smaller than experimental data. Because the pressure around bus is stronger than one-box automobile and its force is larger.

Fig. 20 shows a comparison between a static computation and a dynamic computation. In order to average out transient data, an ensemble average is taken from ten serial steps. At X/L = 0 (X: moving distance, L: automobile length), the passing automobile catches up with the preceding automobile. It is known from a static passing experiment[(4),(9)] involving a large bus and a one-box automobile in a wind tunnel that the drag force, side force and yawing moment have qualitative maximum values regardless of the shape of the passing automobile. The maximum values for the drag force, side force and yawing moment are seen between X/L = 0 and X/L = 0.5, with that of the drag force and side force approaching closer to X/L = 0, and that of the yawing moment approaching closer to X/L = 0.5.

According to the static computation result of Fig. 20, the waveforms representing the yawing moments are of the same shape on either side of X/L = 1.0 at which the two automo-

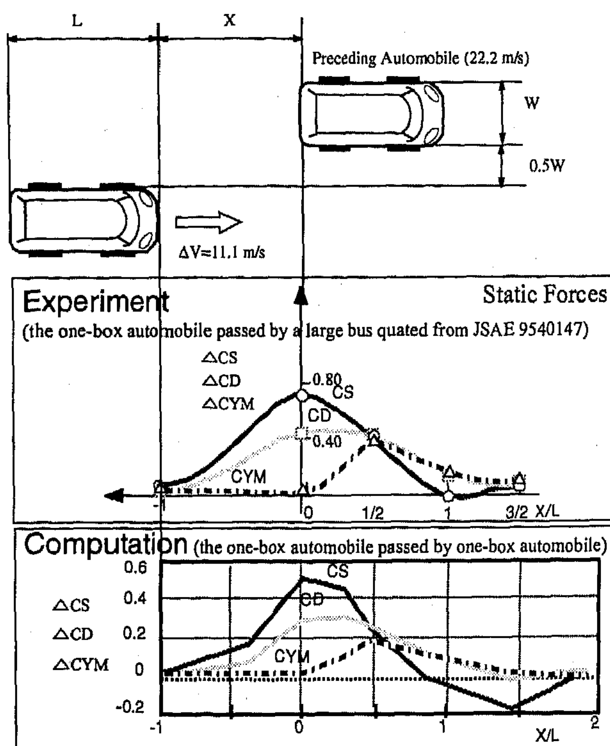

Fig. 19. Comparison of Static Aerodynamic Static Forces of Preceding Automobile

biles run abreast. Whereas in the dynamic computation result, in which there is a difference of 11.1m/s between the velocity of the two automobiles, the passed automobile receives a yawing moment that is almost twice as large as in the case of the static computation. Accordingly the waveforms received by the preceding automobile and the passing automobile are asymmetrical. We believe the reason is that the pressure wave of the passing automobile influences the preceding automobile, and that the greater the velocity difference between the two, the greater the difference between the yawing moments received by the two.

From the above findings it can be concluded that when the velocity difference between the two automobiles is substantial the preceding automobile receives the greater moment and its waveform and that of the passing automobile are also asymmetrical to each other, so it is difficult to evaluate the aerodynamic forces dynamically acting on an automobile using a steady flow analysis.

The waveform of the preceding automobile shows a strong peak when X/L = 0.5 regardless of static or dynamic analysis, and this agrees qualitatively with the above-mentioned experiment reports[(4),(5),(9)]. Fig. 21 is one example of the measured dynamic yawing moment of station wagon passed by a bus (quated from SAE 700037). This result shows a strong peak about X/L = 0.5 too.

Fig. 22 shows dynamic computation results of 3D pressure isoplethic surfaces at X/L = -1.0, 0.25, 0.5, 2.4. Fig. 23 shows 3D isoplethic velocity magnitude surface at 10 m/s.

From X/L = 0 to 0.25, the positive pressure wave from the passing automobile pushes the interference rear side of the

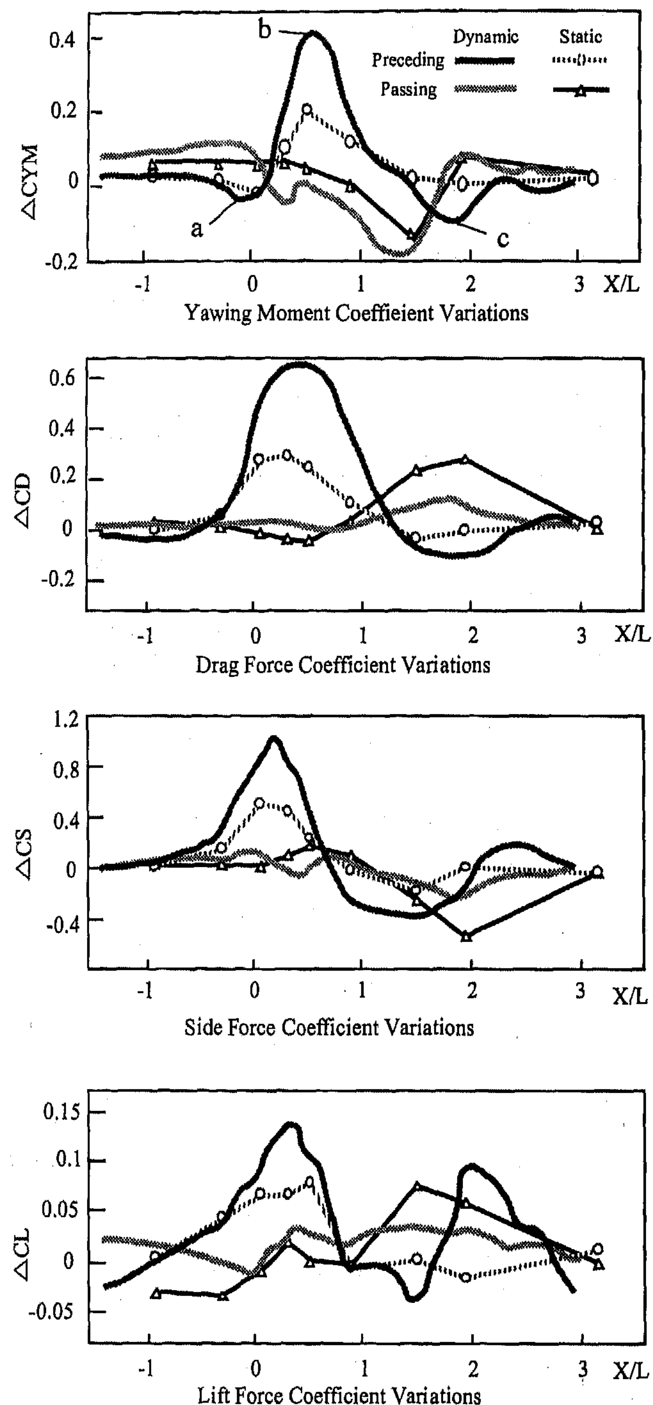

Fig. 20. Computed Static and Dynamic Aerodynamic Forces

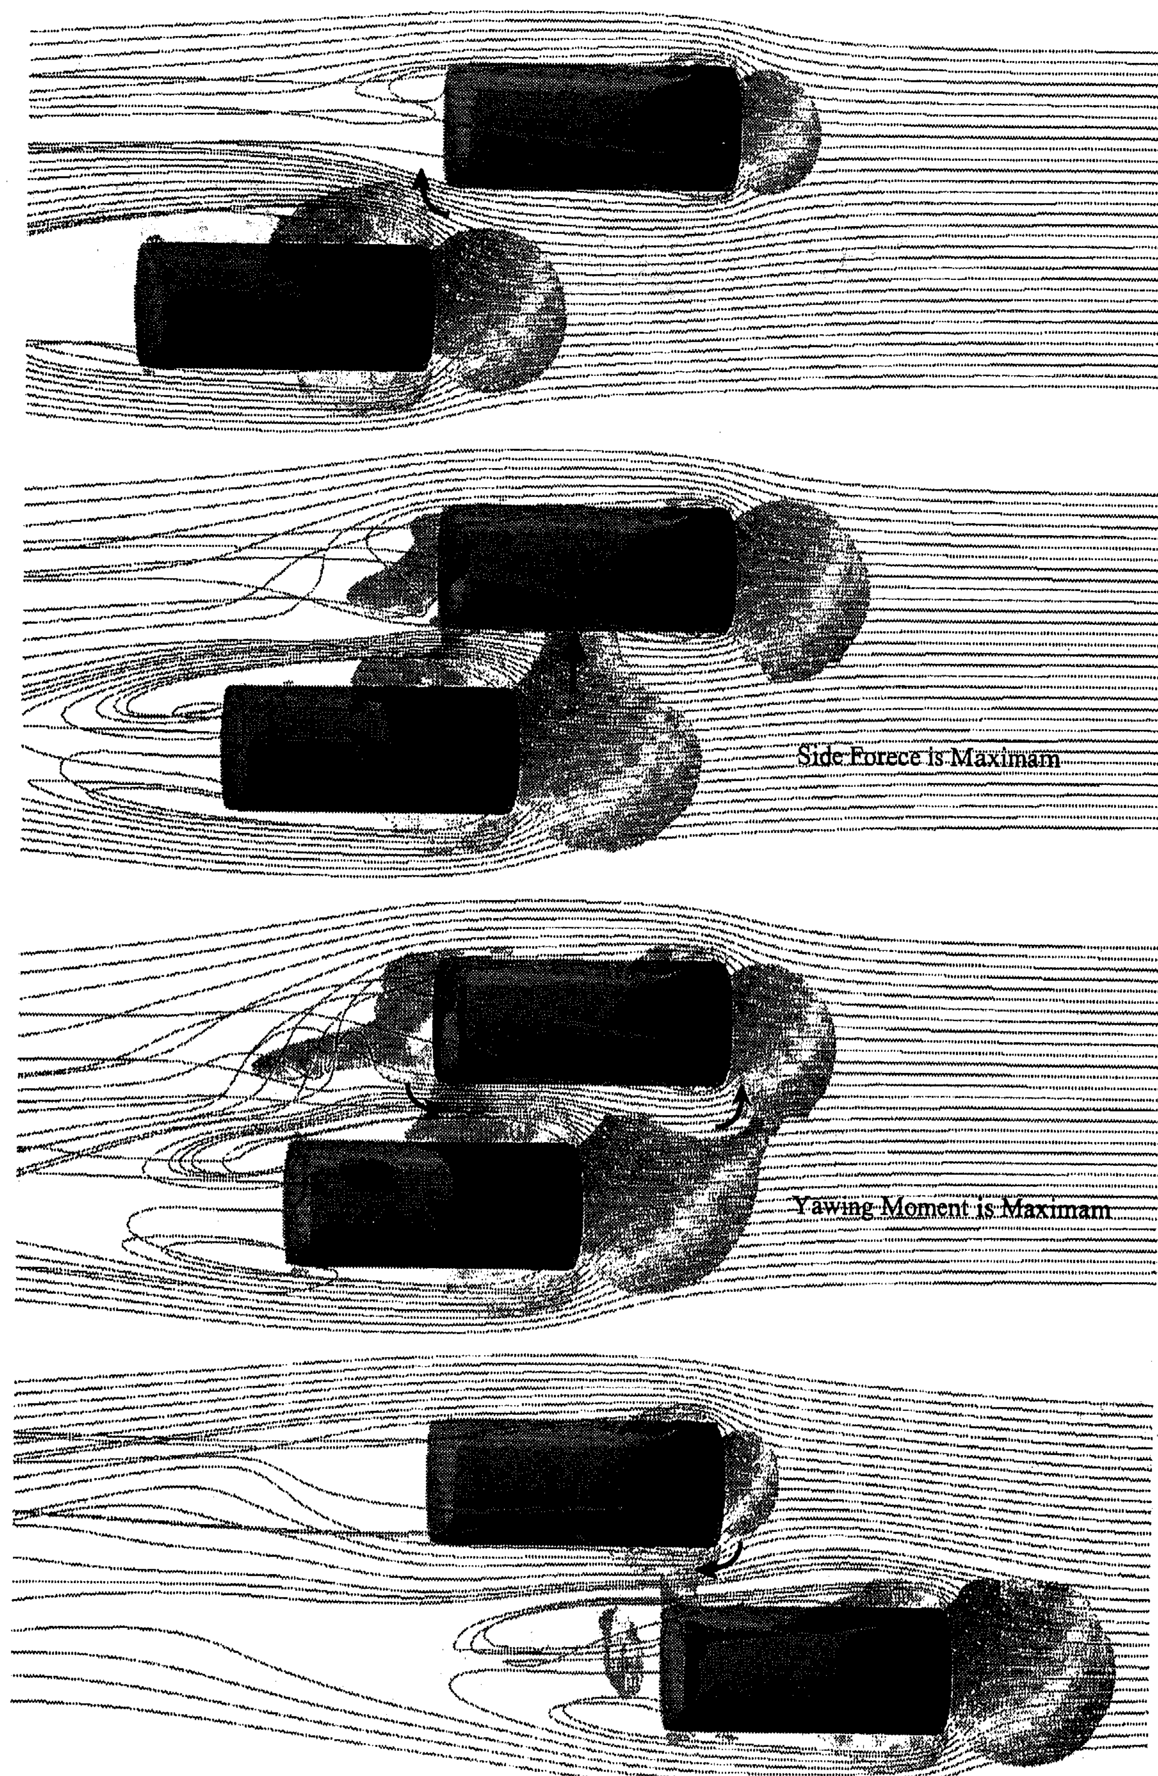

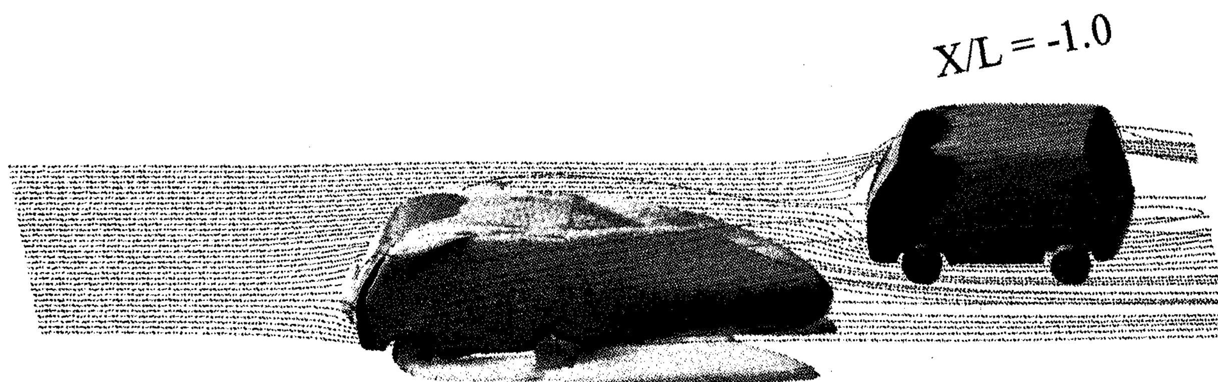

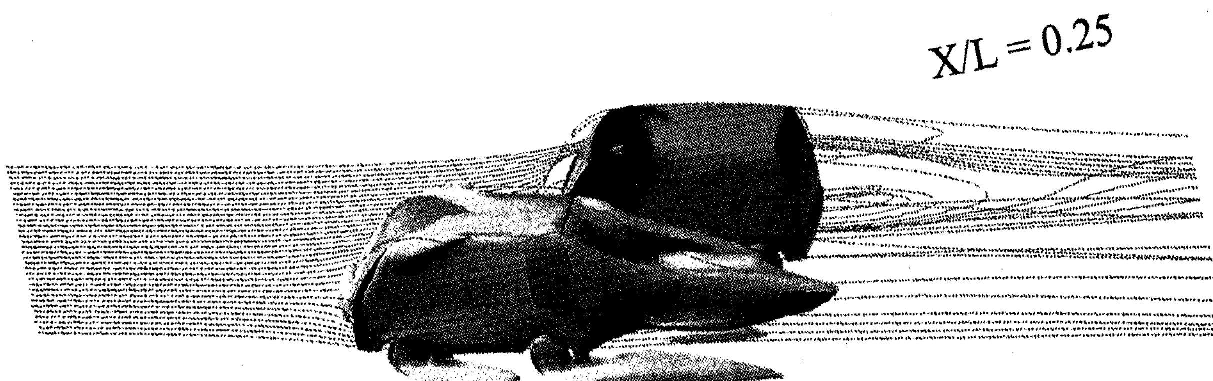

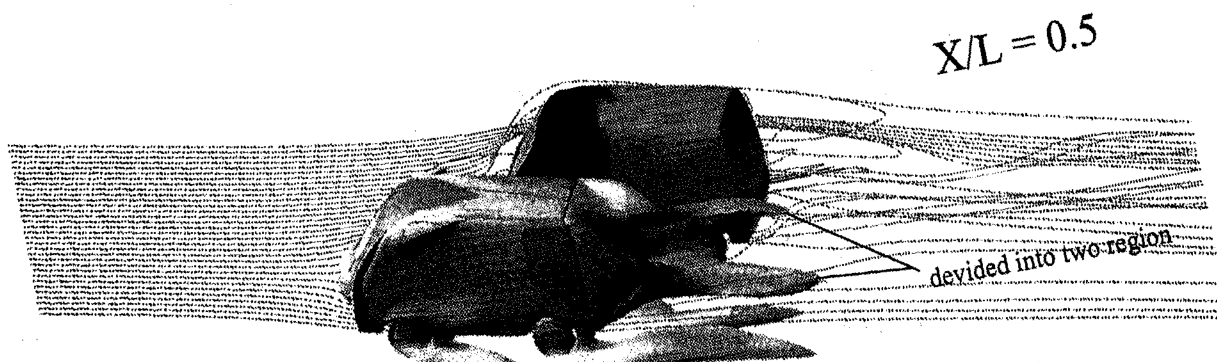

Fig. 22. Pressure Iso-Surfaces from Top View

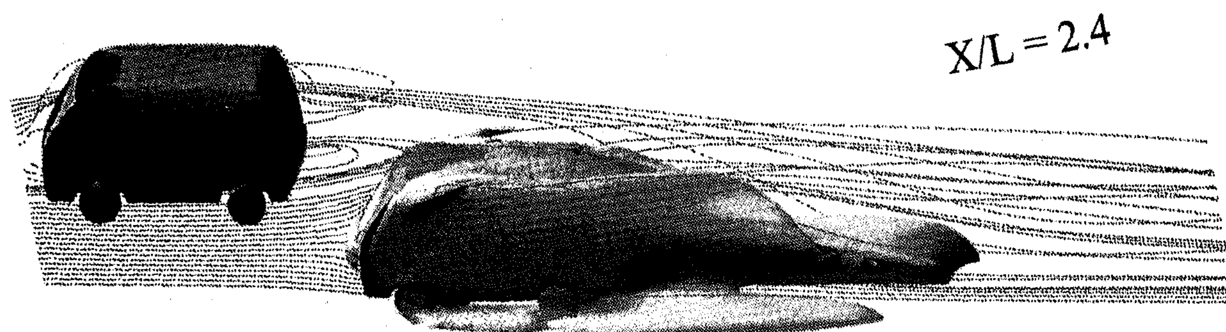

Fig. 23. Velocity Magnitude Iso-Surface of Preceding Automobile at 10 m/s

preceding automobile. This force generates a small clockwise yawing moment as shown "a" in Fig. 20 ,21.

Near X/L = 0.5, the interference side surface of the preceding automobile receives a positive pressure wave and a negative pressure wave from the passing automobile simultaneously, generating a strong counterclockwise moments in the same direction. For this reason the total yawing moment has the maximum value at this positiont as shown "b" in Fig. 20 ,2

From X/L = 1.5 to 2.0, the negative pressure wave from the passing automobile pulls the interference rear side of the preceding automobile. This force generates a small clockwise yawing moment as shown "c" in Fig. 20 ,21.

The preceding and passing automobiles are divided into four blocks that border at the center of each automobile and the results of obtaining the dynamic moments generated in each block are shown in Fig. 24.

At X/L = 0, at which the preceding automobile is caught up by the passing automobile, the moment, which was inclined to decrease at the preceding automobile's rear interference side D due to the positive pressure wave of the passing automobile, suddenly increases as the preceding automobile enters the negative pressure region of the passing automobile.

At X/L = 0.5 the moment at D saturates, but the moment at the automobile front interference side A suddenly decreases.

Consequently, we have found that the yawing moment of the preceding automobile is influenced by the interference sides A and D,depending on the front positive pressure wave and the side negative pressure wave of the passing automobile.

In the case of the passing automobile, on the other hand, a moment acting in the opposite direction from that acting on the preceding automobile increases, and its variation is smaller than that of the preceding automobile because of its higher velocity.

DRAG FORCE (CD) - Fig. 25 shows the variation of the total and each block drag force. In a steady flow the drag forces are symmetrical at X/L = 1.0, but in a dynamic state, in which the velocities of the two automobiles differ, the total drag force of the preceding automobile suddenly increases whereas the

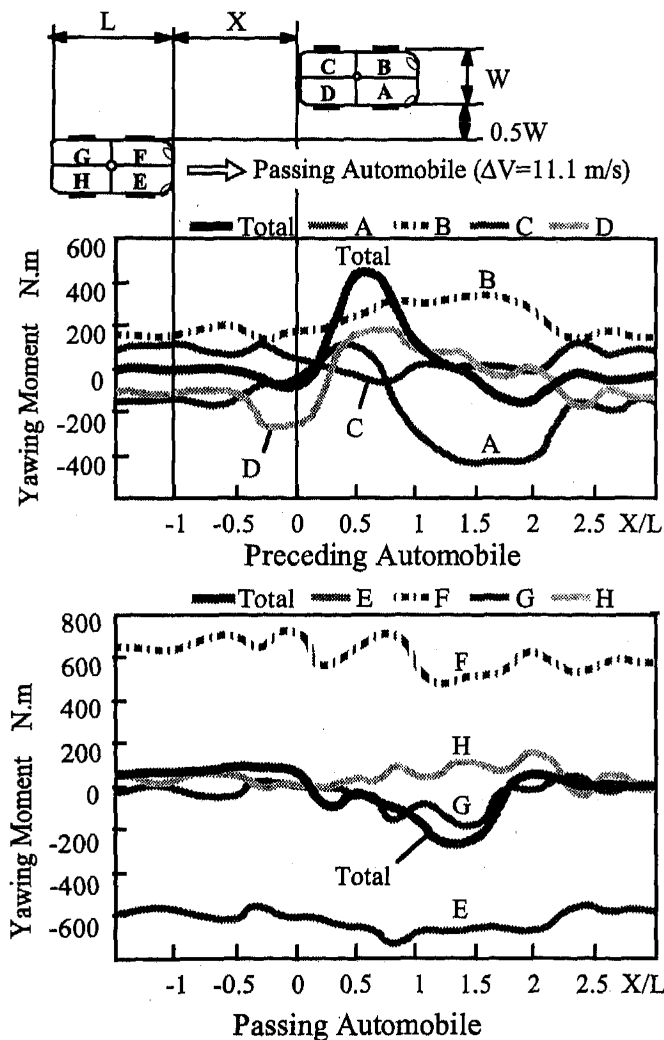

Fig. 24. Daynamic Yawing Moment Variations

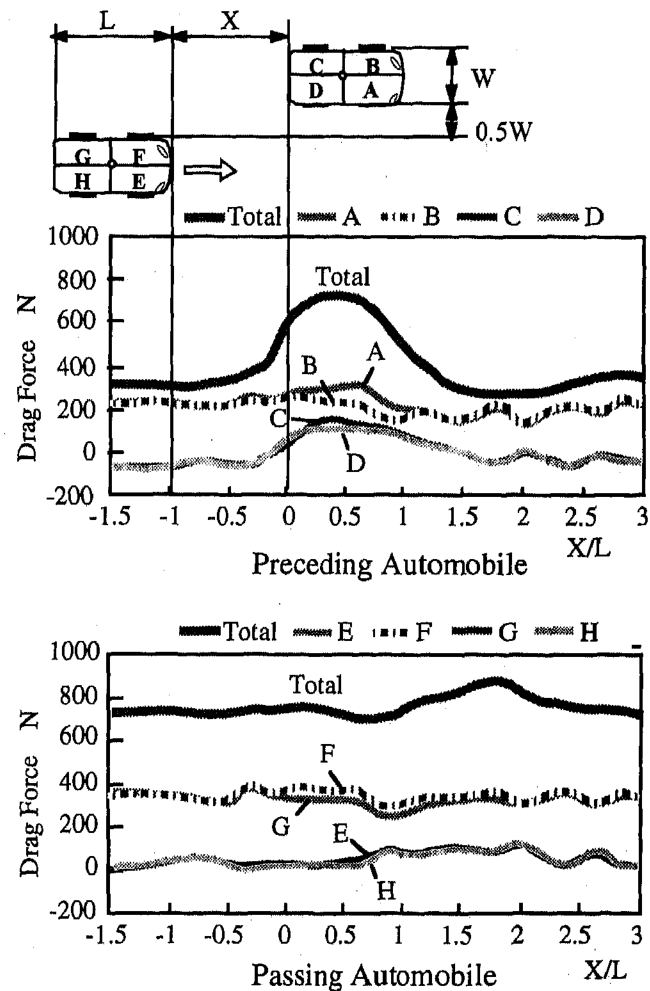

Fig. 25. Dynamic Drag Force Variations

drag force of the passing automobile changes only slightly. The forces applied in the static and dynamic states are apparently different. In either case, however, the maximum values of the drag forces are around X/L = 0 to 0.5, and this agrees qualitatively with the above-mentioned experimental results.

As for each block, the drag forces at C and D in the rear of the preceding automobile increase as the passing automobile approaches, and converge after the passing automobile has passed.

Next, let us focus on the drag forces acting on the preceding automobile. We will examine these forces, which vary remarkably, with reference to the pressure distribution variations (Fig. 22).

Until X/L = 0.5, the positive pressure wave destroys the balance of the wake of the preceding automobile, so the drag force increases gradually.

Near X/L = 0.5, the positive pressure wave recovers a negative pressure on the sides of the preceding automobile. At the same time the negative pressure wave attracts the wake of the preceding automobile and divides into two (Fig.23 at X/L =0.5), so its negative pressure region is expanded into a long, narrow shape. This phenomenon causes a large imbalance of vortices around the automobile, so that the drag force reaches its maximum value.

After X/L = 1.0, the preceding automobile is behind the passing automobile, so the drag force becomes smaller. We found that it converges at X/L = 3.0 or larger.

From the above observations, we have found that the drag force of the preceding automobile depends on its wake shape, which is attracted by the negative pressure wave of the passing automobile.

SIDE FORCE (Cs) - Fig. 26 shows the variation of the total and each block side force. Like the drag forces, the side forces are statically symmetric. Dynamically, while the side force acting on the preceding automobile increases rapidly, the side force acting on the passing automobile changes only slightly. As in the case of moments and drag forces, side forces applied statically and dynamically are different. The maximum values, however, are exhibited at X/L = 0 to 0.25, and this agrees qualitatively with the experimental results.

As for each block, we will focus on the side forces acting on the preceding automobile. We will examine these forces, which vary remarkably, with reference to the pressure distribution variations (Fig. 22).

When X/L approaches 0, first the automobile rear interference side D and then the automobile front interference side A receives a side force.

Near X/L = 0.25 the side force reaches its maximum by the composite force A and B, and when X/L exceeds 0.25 the positive pressure wave of the passing automobile deviates from the center of the preceding automobile, and the flow velocity between the preceding automobile and the passing automobile increases, generating negative pressure. As a result, the side forces at A and D suddenly decrease due to this negative pressure.

Consequently the maximum value of the total side force is shown near X/L= 0.25 and the waveform is peaked.

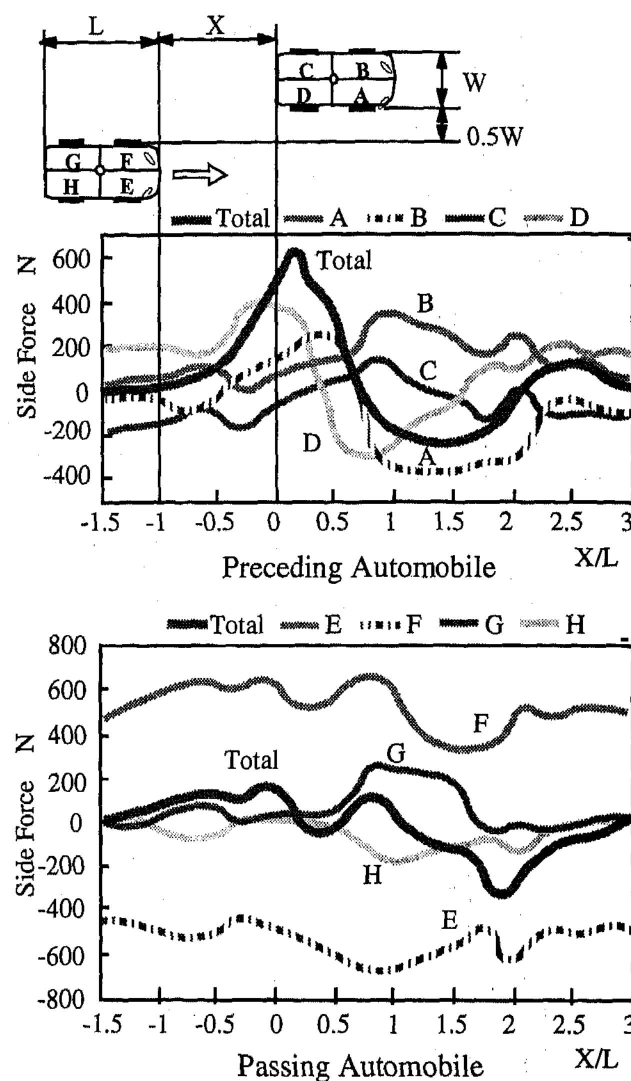

Fig. 26. Dynamic Side Force Variations

Beyond X/L = 0.75 the pressure at D recovers, then the pressure at A also recovers. Beyond X/L = 2.5 the effect of the wake of the passing automobile becomes small, and the pressures converge.

Likewise we have also found that a small counter side force is generated on the passing automobile near X/L = 1.75, which is a symmetrical position of both automobiles.

From the above observations, we have found that the side force of the preceding automobile depends on the pressure variation of the interference side A and D, and is greatly increased by the positive pressure wave of the passing automobile and decreased by the negative pressure generated between the two automobiles.

LIFT FORCE (CL) - Fig. 27 shows the variation of the total and each block lift force. Like all the aerodynamic characteristics so far explained, the lift forces become symmetrical statically at X/L = 1.0, but dynamically the lift forces acting on the preceding automobile vary remarkably while the variations

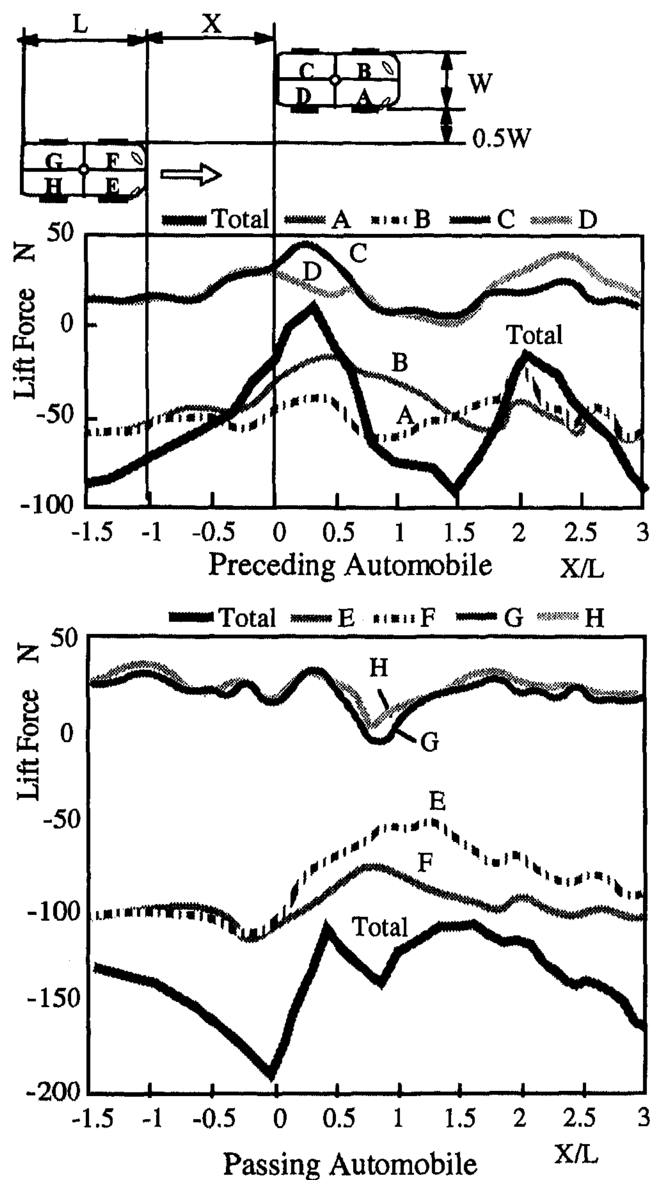

Fig. 27. Dynamic Lift Force Variations

on the passing automobile are small. Different forces are applied depending on whether the relationship between the two automobiles is static or dynamic.

We will focus on the preceding automobile, for which the dynamic forces generated in each block vary remarkably.

Near X/L = 0, only the lift forces acting on the automobile rear interference side D tend to decrease and the lift forces acting on the other areas increase. The increase is the smallest at A, which is the most distant point from the passing automobile, so the positive pressure wave of the passing automobile influences the pressure distribution of the lower part of the automobile. There are two remarkable peaks in the total lift force of the preceding automobile near X/L = 0.25 and 1.9.

Between X/L = 0.75 and 1.75, the negative pressure generated between the preceding automobile and the passing automobile causes the total lift force to decrease.

Near X/L = 2.0, a flow blows up the underfloor, attracted by the negative pressure of the wake of the passing automobile. As the passing automobile becomes distant the values come close to the single driving value.

Consequently, we have found that the lift force depends on the positive pressure wave variation of the passing automobile and the negative pressure variation between two automobiles and the passing automobile's wake.

From these observations of the aerodynamic forces involved in a passing phenomenon, we have found that when the velocity difference between the preceding automobile and the passing automobile is substantial, the preceding automobile receives a larger aerodynamic force than in the static case, and the waveforms are asymmetrical with reference to the moment of the static passing automobile. Furthermore, the force depends on the pressure variation of the interference automobile side.

In other words, static analysis such as wind-tunnel experiments and steady flow simulations are not sufficient to correctly evaluate the aerodynamic forces dynamically acting on an automobile.

CONCLUSION

1) We have developed a computational method using a discontinuous interface grid and moving boundaries which is capable of analyzing transient aerodynamic phenomena (plunge into a crosswind, passing, etc.).

2) The aerodynamic characteristics (yawing moment variations) obtained from our computation results were in good tendency with the experimental results.

3) The yawing moment reaches its maximum value when the automobile plunges into a crosswind by approximately 1.4 times the automobile length, due to the negative pressure on the leeward front portion of the automobile.

4) The preceding automobile receives a larger aerodynamic force than during steady driving when the difference between the passing and preceding automobile's speeds is large and its waveform is asymmetric.

5) The aerodynamic force of a passing phenomenon depends on the pressure variation on the interference side of the preceding automobile, which is influenced by the front positive pressure wave and the side negative pressure wave of the passing automobile.

We believe our development of a dynamic real phenomenon analysis method provides a new possibility for furthering understanding of transient aerodynamic phenomena.

Coast Down Method in Time-Distance Variables

ABSTRACT

The differential equation of motion of a freely coasting vehicle is analysed and its integral solution in the form of an explicit speed-time function and then a distance-time one is derived. The latter form eliminates the traditional speed term from the equation. By making speed or deceleration measurements unnecessary, a whole set of potential error sources is eliminated, thus improving the sensivity and accuracy of the coast down method. By replacing the distance measurements with precision test track markings, the coasting data requirements are reduced to accurate measurements of time only. This simplifies both the method and the test facility, and improves the reliability of the test data. Because of the efficiency of this a significant volume of test data has been gathered, and included in this report, which characterizes vehicle aerodynamic drag and rolling resistance. In addition to smaller vehicles, these data also include trucks, buses, and articulated vehicles in production and under development which are too large and too heavy to be tested in wind tunnels or on tire dynamometers. For the smaller vehicles, road-to-tunnel and road-to-dynamometer correlations are also presented.

NOTATION

a, b, c coefficients for zero, first, and second power of speed, respectively, in vehicle dimensionless total resistance function

B characteristic relationship between parameters of coast down differential equation

c_x aerodynamic drag coefficient of full-size vehicle in road conditions

c_w aerodynamic drag coefficient of full-size vehicle in automotive wind tunnel

$\bar{c}_w$ aerodynamic drag coefficient of full-size vehicle in the aircraft TsAGI wind tunnel

c_D aerodynamic drag coefficient of vehicle scale model in wind tunnel

c_z aerodynamic lift coefficient at zero yaw

d dimensionless drag force of freely coasting driveline with drive wheels

d_0 initial value of d (at V approaching to zero)

F frontal area

f rolling resistance coefficient

f_0 initial value of rolling resistance coefficient (at V approaching to zero)

G vehicle weight

g gravitational acceleration

$h = gb/(2\delta)$

$h_0 = gb/\delta_0$

I_d rotation inertia of the driveline, excluding the wheels of the drive axles

I_w rotation inertia of one isolated wheel

k_a coefficient of speed influence on dimensionless aerodynamic drag χ

k_f coefficient of speed influence on rolling resistance

m number of vehicle drive wheels

n total number of vehicle wheels

p_t tire inflation pressure

r tire rolling radius

s current distance

S residual coasting distance

S_1 total coasting distance

S_Δ distance between adjacent reflective stakes

ΔS_c distance of vehicle coasting conforming to T_c

t real time

t_a ambient temperature

T residual coasting time

T_1 total coasting time

T_c	time of continuous coasting between test segments under time record interruption
V	vehicle speed
V_1	initial coast down speed
z	number of vehicle wheel revolutions
z_1	total number of vehicle wheel revolutions during coasting
β	symbol for speed-dependent term of traditional form time-speed relation for coast down motion
β_1	value of β for initial coast down speed
β_0	value of β for zero coast down speed
χ	dimensionless aerodynamic drag
δ	rotating mass coefficient of the vehicle
δ_0	rotating mass coefficient of driveline with drive wheels
δc_x	significant error of c_x at 0.95 confidence level
$\delta \bar{c}_w$	significant error of $\bar{c}_w$ at 0.95 confidence level
Π	criterion equal to k_a when it is unaffected by vehicle weight changes
ρ	air mass density
σ	length ratio for two successive road test segments

INTRODUCTION

As known, a triangle of correlation links, which is traditional for applied science (Fig.1), has vertices such as physical modelling, mathematical simulation, and full-scale testing in service conditions. But in spite of intensive development of modern aerodynamics, this triangle still remains incompletely closed at the latter vertex.

The reason is that the measurement of external forces for vehicles and railway transport on the real road surface or on the rails, respectively, is a severe problem.

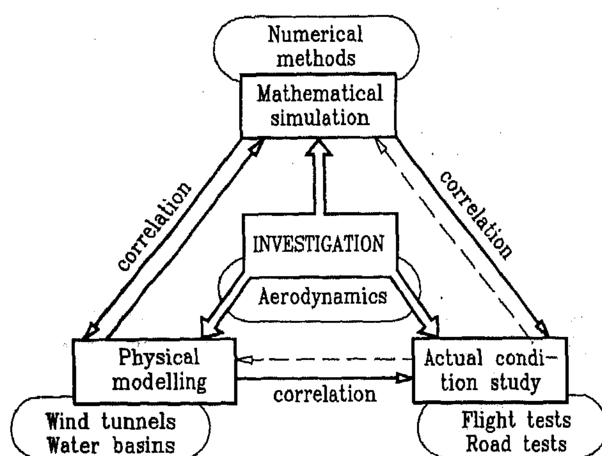

Figure 1: Triangle of applied investigations

So, refinement attempts of the coast down test method for examining vehicle resistance in real conditions are continuing from 1930's up to the present time [1]-[27]*.

The paper that is most often considered to be a pioneer one in coast down test method development is [1]. However, even in 1936 B.S.Falkevitch, in his book [2] published in Russia, described the method being "successfully used in USA" he had called as "Iowa College Method". The main relationship is:

$$S_1 = \frac{\delta G}{2gk_a} \ln\left(1 + \frac{k_a}{Gf} V_1^2\right)$$

(where the notation of the present paper is used).

Taking into account the time of exchanging scientific experience and issuing of that book it may be supposed that the USA method is one of the earliest.

At the present time the significance of this research lead increases due to the impossibility for the full-scale vehicles with frontal area more than 3-4 m^2 to be tested in wind tunnels on account of the stream blockage.

As research practice indicates, the coast down test method also appears most promising for investigation of small values of vehicle resistance in road conditions and even more of its small increments [6][23][24][25], etc.

The main common feature of known varieties of coast down test method is that all of them are based on the measurements of the vehicle speed or deceleration, the latter being extremely small during the coasting. Thus an investigator, independently of his theoretical conceptions, is forced to use one of the following types of speed meters or its combinations: 5-th wheel; Correvit type of device (a noncontact version of 5-th wheel); various light-barrier type devices, or their electro-magnetic analogs; different air-velocity probes, and propeller-vane anemometers. Except for Pitot-static tube and hot wire probes, all the others are operating with the use of division of small measured distance segment by small measured time interval as an algorithm. Meantime the error of measuring the speed and its derivative would always be higher than those for distance and time measurements, being equal to the sum of these correspondent errors.

The replacement of speed or acceleration measurements by distance and time records was not a success until now. Integration of the coasting equation with the function of motion resistance being polynomial, p(V), of the 2^{nd} or higher power yields an implicit function, t=f(V). Consequently, integration of this function instead of explicit one,

* Numbers in parentheses designate references at end of paper

Table 1: Initial relationships for examining motion resistance

Forces reduced to drive wheel circumference	Dimensionless values (forces divided by vehicle weight)		Coefficients of influence of speed V and deceleration $\frac{dV}{dt}$	Formulae of speed influence and motion equations
	Nomenclature	Values at V=0		
Rolling resistance	f	f_0	$k_f\ [s^{-2} \cdot m^{-2}]$	$f = f_0 + k_f V^2$ (1)
Driveline loss	d	d_0	$b\ [s \cdot m^{-1}]$	$d = d_0 + bV$ (2)
Air drag	χ	0	$k_a = c_x \frac{\rho}{2} \frac{F}{G} \left[s^2 \cdot m^{-2}\right]$	$\chi = k_a V^2$ (3)
Total drag	$d + f + \chi$	$f_0 + d_0 = a$	$k_f + k_a = c$	$a + bV + cV^2$ (4)
Inertia of drive wheels and driveline	$-\frac{\delta_0}{g}\frac{dV}{dt}$	d_0	$\delta_0 = \frac{(mI_w + I_d)g}{Gr^2}$	$-\frac{\delta_0}{g}\frac{dV}{dt} = d_0 + bV$ (5)
Vehicle inertia	$-\frac{\delta}{g}\frac{dV}{dt}$	a	$\delta = 1 + \frac{(nI_w + I_d)g}{Gr^2}$	$-\frac{\delta}{g}\frac{dV}{dt} = a + bV + cV^2$ (6)

s=f(t), gives s=f(V,t) where distance is both time and speed dependent. From the mathematical point of view, searching for the problem solution seemed unpromising until now.

INTEGRATION OF THE COAST DOWN EQUATION

An equation of vehicle motion can be formed by means of expressions (1)-(3) as the terms of resistance function (4) represented in Table 1. The resulting equation (6) is most widely used for description of vehicle coasting. Usual consideration of the rolling resistance-speed dependence to be linear at first sight appears like the simplest way of drag component separation, because for such a representation a term proportional to V^2 is an aerodynamic drag. However, relating to the test data obtained by such a simplification no successful repeatability of results was achieved.

The reason is a significant distortion of tire performance because of nonlinear dependence of tire rolling resistance upon speed, as confirmed by [7][8][24] and others. In the paper presented the function f of rolling resistance coefficient is a 2nd power binomial of speed (1) that is fairly adaptable for tire loss description.

The following notation and expressions are used when integrating equation (6) in Table 1.

$$\beta = \arctan\frac{1}{B}\left(\frac{g}{\delta}cV + h\right), \quad (7)$$

$$\beta_1 = \arctan\frac{1}{B}\left(\frac{g}{\delta}cV_1 + h\right), \quad (8)$$

$$\beta_0 = \arctan\frac{h}{B}, \quad (9)$$

where

$$B = \frac{g}{2\delta}\sqrt{4ac - b^2}, \quad (10)$$

$$h = \frac{gb}{2\delta} \quad (11)$$

Then, the traditional integral of equation (6) may be written in the following brief form:

$$t = \frac{\beta_1 - \beta}{B} \quad (12)$$

Defining total coasting time as T_1 (Fig.2) and basing on (12), one can write:

$$T_1 = \frac{\beta_1 - \beta_0}{B} \quad (13)$$

Solving equations (12) and (13) by eliminating β_1 yields

$$\beta = B(T_1 - t) + \beta_0 \quad (14)$$

Introducing a new variable, T, that may be called the residual vehicle coasting time one can write, according to Fig.2

$$T = T_1 - t$$

Then, expression (14) may be written as

$$\beta = BT + \beta_0$$

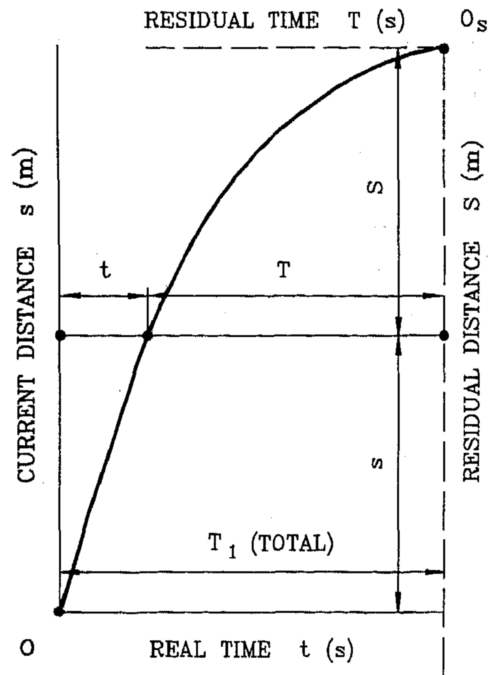

Figure 2: Coasting distance-time plane in coordinate systems of real and residual time

From equality of the angular arguments it follows that its tangents are also equal to each other:

$\tan\beta = \tan(BT + \beta_0)$

Solving this equality and (7) jointly one obtains the following explicit function, V(t)

$$V = \frac{dS}{dT} = \frac{\delta}{gc}\left[B\tan\left(BT + \beta_0\right) - h\right], \qquad (15)$$

where, in accordance with Fig.2, S is the residual coasting distance corresponding to the residual coasting time T. In other words, for the curve S=f(T) the origin of coordinates is shifted from 0 to the stop point 0_S of the vehicle under study.

By integrating expression (15) and by finding the integration constant from S=0 at T=0, the following explicit speed-independent distance-time relationship is deduced

$$\boxed{S = \frac{\delta}{gc}\left(\ln\frac{\cos\beta_0}{\cos\left(BT + \beta_0\right)} - hT\right)} \qquad (16)$$

Formulae (15) and (16) were published in paper [9] for the first time. Similarly, integrating the equation of motion (see Table 1) for the raised vehicle drive wheels and driveline (equation 5) yields:

$$V = \frac{d_0}{b}\left(\exp h_0 T - 1\right), \qquad (17)$$

where

$$h_0 = \frac{g}{\delta_0} b, \text{ and} \qquad (18)$$

$$\boxed{S = \frac{d_0}{b}\left[\frac{e^{h_0 T} - 1}{h_0} - T\right]} \qquad (19)$$

Now it is possible to determine parameters a, b, c for vehicle resistance polynomial from (16), (19) with no coasting speed measurements. In this way a whole set of measurement error sources, as well as the need of correspondent test data processing, is excluded. This suggests that several alternate solutions of the problem under consideration are available.

TOTAL DRAG DETERMINATION METHOD

The most rational way of measurement is the coasting time record starting from four fixed points of the track being marked out and by which two reference distance sections ΔS_{12} and ΔS_{34} are formed (Figs.3a, 3b). Expressing the section length ratio for the general case by σ one can write

$$\frac{\Delta S_{12}}{\Delta S_{34}} = \frac{S_1 - S_2}{S_3 - S_4} = \sigma \qquad (20)$$

where S_i (i=1,2,3,4) - residual coasting distances from the corresponding track points to the vehicle stop point.

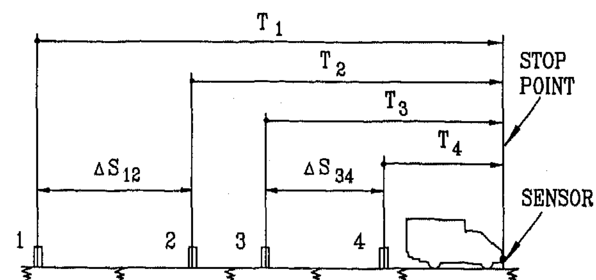

Figure 3a: 4-point time measurement scheme (general case: $\Delta S_{12} \neq \Delta S_{34}$)

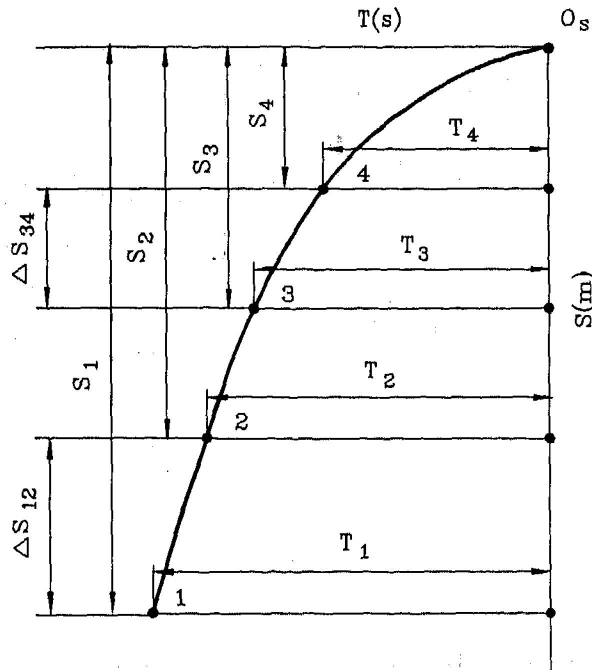

Figure 3b: Distance-time plane for measurement scheme shown in Fig.3a

Having measured the values T_1... T_4 of coasting time and applying (16), one can write two expressions for ΔS_{12} and ΔS_{34} of the form

$$\Delta S_{i,i+1} = \frac{\delta}{gc}\left[\ln\frac{\cos(BT_{i+1}+\beta_0)}{\cos(BT_i+\beta_0)} - h(T_i - T_{i+1})\right] \quad (21)$$

By substituting these expressions into (20) and after simple transformation one obtains

$$\frac{\cos\alpha_2}{\cos\alpha_1}\left(\frac{\cos\alpha_3}{\cos\alpha_4}\right)^{\sigma} = e^{h[T_1-T_2-\sigma(T_3-T_4)]}, \quad (22)$$

where

$$\alpha_i = BT_i + \arctan\frac{h}{B} \quad (i=1,2,3,4) \quad (23)$$

A transcendental equation (22) with (23) having one unknown B is an expression of general form for the method developed. It can be solved by iteration technique.

After calculating B, c can be found from the expression obtained with the help of term-by-term summation of two expressions of the form (21) for ΔS_{12} and ΔS_{34},

$$c = \frac{\sigma\delta}{(\sigma+1)g\Delta S_{12}} \times \left[\ln\frac{\cos\alpha_2}{\cos\alpha_1}\frac{\cos\alpha_4}{\cos\alpha_3} - h(T_1 - T_2 + T_3 - T_4)\right] \quad (24)$$

where α_i is expressed by (23).

With known B and c, parameter a can be found, using (10) and (11):

$$a = \frac{\delta^2}{g^2c}(B^2 + h^2) \quad (25)$$

To apply the expression (25) with (11), the value of b related to the vehicle driveline is needed. On the whole, employment of formulae (22), (24), (25) reduces the parameter measurements to the coasting time only, due to replacement of distance measuring by the track marking being undertaken once per several years.

RATIONAL MEASUREMENT SCHEMES

The simplest scheme of test track marking is that having two adjacent sections of equal length S_Δ (Figs. 4a, 4b), i.e. with three retroreflective stakes in each running direction. For this kind of marking the desirable meanings of S_Δ should lie within the range $(1/3)S_1<S_\Delta<(1/2)S_1$, while its specific values are presented in Table 2.

Overwhelming majority of vehicles were tested by employment of this scheme as applied to which equations (20)-(24) are simplified, because in this case σ=1, T_3=T_2, and T_4 is substituted by T_3.

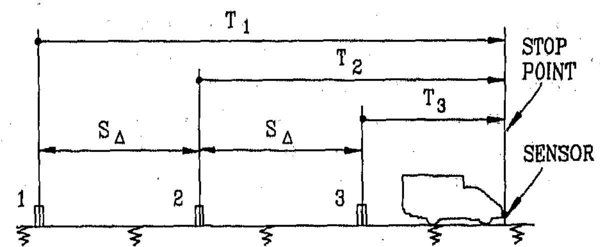

Figure 4a: 3-point time measurement scheme for 2 equal measurement sections

Table 2: Distance S_Δ between reflective marks according to total coasting distance S_1 (a good practice)

S_1 (m) or $z_1 \cdot 10$ (rev.)	850-1100	1100-1300	1300-1500	1500-1700	1700-1900	1900-2100
S_Δ (m) or $\Delta z \cdot 10$ (rev.)	400	500	600	700	800	900

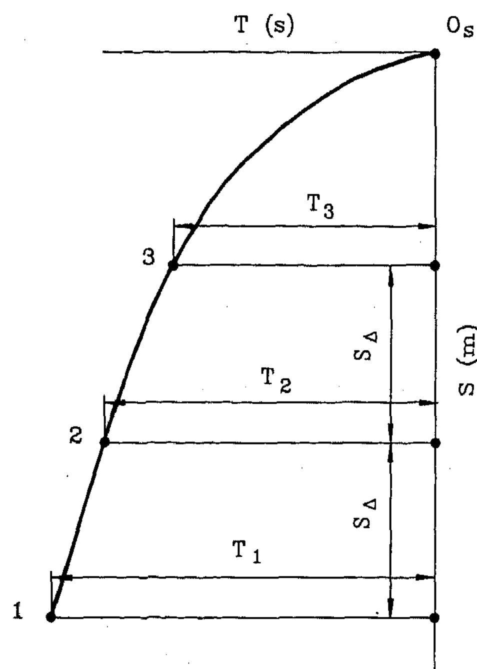

Figure 4b: Distance-time plane for measurement scheme shown in Fig.4a

The scheme with two equal but not adjacent test sections allows the equations (22)-(24) to be simplified, since σ=1.

The scheme with interruption of coasting record is suited for the cases when coasting distance of vehicle or trailer-train exceeds the length of the straight-line horizontal measuring section. It is illustrated by the track having two test sections 1-4 and 4'-7 each of them being marked out into three equal pieces (Fig.5a).

An initial coasting speed on the section 4'-7 is chosen to provide vehicle stopping within section 6-7. An involute of this measurement scheme shown in Fig.5b has an additional unknown time value of record interruption, T_c, in comparison with Fig.3a. Naturally, value of T_c is not a duration of test vehicle U-turn, but it is equal to a magnitude matching both high and low speed segments of curve S=f(T) so that they fall on the common curve. For this case two equations of the form (22) may be related with two unknowns, B and T_c. The

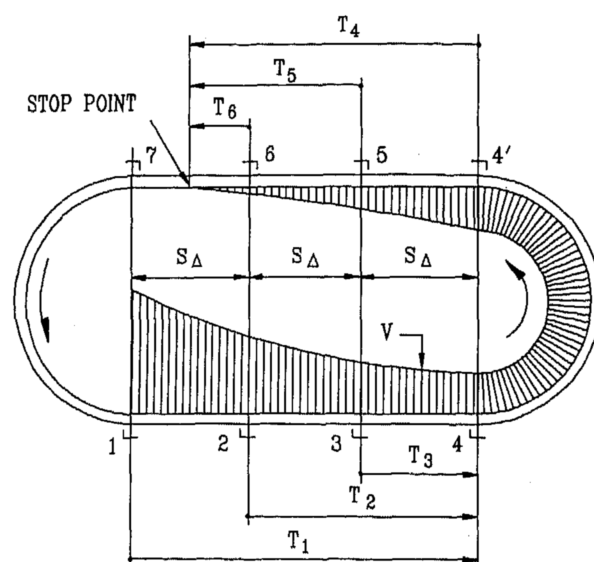

Figure 5a: Time measurement scheme with coasting interruption on U-turns of the annular track

first equation should be composed for two not adjacent but equal track segments 1-3 and 4'-6, when σ=1, and the second one should be written for two unequal segments 2-4 and 4'-5, when σ=2.

By this manner the following set of equations with unknowns B and T_c is obtained, where the coordinates of all six points of the curve S=f(T) are rationally applied:

$$\frac{\cos A_3}{\cos A_1} \cdot \frac{\cos \alpha_4}{\cos \alpha_6} = e^{h(T_1 - T_3 - T_4 + T_6)} \quad (26)$$

$$\frac{\cos A_0}{\cos A_2} \cdot \left(\frac{\cos \alpha_4}{\cos \alpha_5}\right)^2 = e^{h[T_2 - 2(T_4 - T_5)]} \quad (27)$$

where

$A_i = B(T_i + T_c + T_4) + \beta_0$,
(i = 0, 1, 2, 3 with T_0 = 0),
$\alpha_j = BT_j + \beta_0$,
(j = 4, 5, 6).

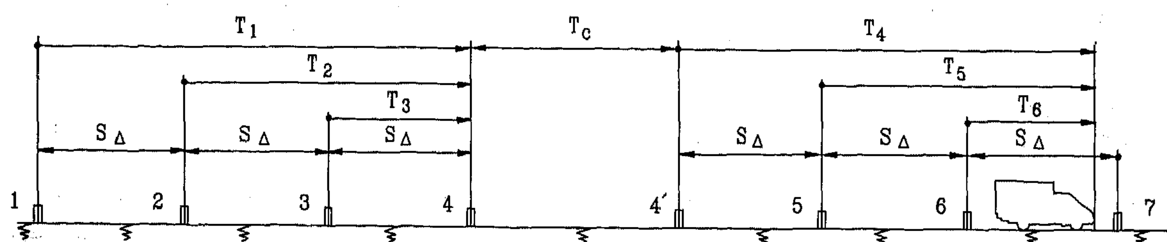

Figure 5b: Involute of measurement scheme with coasting interruption

Thus, each of equations (26) and (27) indirectly incorporates the length of segments of both high and low speed parts of test track. This is the main feature of the set which is solved by iteration method in exterior and interior cycles.

To determine parameter c by utilization of both measuring section data (Fig.5b), equation (24) should be written for extreme coordinates of the segments 1-4 and 5-7. For this case $\sigma=3/2$, $\Delta S_{14}=3S_\Delta$, hence

$$c = \frac{\delta}{5gS_\Delta}\left[\ln\frac{\cos A_0}{\cos A_1}\cdot\frac{\cos\alpha_6}{\cos\alpha_4}\right] - h(T_1 + T_4 - T_6) \quad (28)$$

When applying the measurement scheme shown in Fig.5a and the like (for example, with turn-around loops on the track terminals), the paired runs should be performed in both directions.

Besides that, basing on equations (16) and (21) the variant of determination of parameter a by low speed coast downs and of parameter c by high speed testing is under development now [26][27].

DETERMINATION OF DRIVELINE LOSSES

The simplest variant of the measurement scheme similar to that related to vehicle can be used for determination of neutral driveline losses (see Fig.4b) when raised vehicle' drive wheels and the rotating transmission parts. Using (19), one can write similarly to (21):

$$\Delta S_{i,i+1} = \frac{d_0}{b}\left[\frac{e^{h_0 T_i} - e^{h_0 T_{i+1}}}{h_0} - \left(T_i - T_{i+1}\right)\right] \quad (29)$$

Assuming $\Delta S_{12}=\Delta S_{23}$ and defining $e^{h_0} = x$, one obtains the following expression for determination of x:

$$x^{T_1} - 2x^{T_2} + x^{T_3} = \left(T_1 - 2T_2 + T_3\right)\ln x \quad (30)$$

After evaluation of its root x, parameter searched can be found by the following relation:

$$b = \frac{\delta_0}{g}\ln x \quad (31)$$

Parameter d_0 may be found by summation of two expressions of the form (29) as well as from the total coasting distance value, $S_l=2\pi r z_l$, where z_l is total revolution number of drive wheel, and r is its rolling radius. By summation of two expressions (19) it is easy to obtain

$$d_0 = \frac{2\delta_0}{g}\cdot\frac{S_\Delta \cdot h_0^2}{x^{T_1} - x^{T_3} - h_0(T_1 - T_3)} \quad (32)$$

Inasmuch drive wheel revolution number, z, during the driveline coasting is measured, the value of $S_\Delta=2\pi r\Delta z$ should be substituted into (32), where r is rolling radius of drive wheel, and Δz is revolution number interval to be chosen from Table 2.

SEPARATION OF VEHICLE DRAG SHARES

Through parameters a and d_0, found from (25), (29), the rolling resistance coefficient for zero speed can be obtained as

$$f_0 = a - d_0$$

Separation of aerodynamic drag and rolling resistance that are dependent upon speed to the second power, i.e. terms k_a and k_f, the sum of which is equal to c (see Table 1, column 4, lines 3 and 4), is accomplished by vehicle weight G varying under condition of its aerodynamic configuration invariability and, consequently, of c_x and F constancy. For the pair of tests with different vehicle weights, G_1 and G_2, the following set of equations can be formed.

$$c_1 = k_{f1} + c_x\frac{\rho_1}{2}\frac{F}{G_1}$$
$$c_2 = k_{f2} + c_x\frac{\rho_2}{2}\frac{F}{G_2} \quad (33)$$

As experiments had shown, the difference of 12-15% between values of weight G is sufficient.

If k_f remains unaffected with G changes, then assuming this value as a criterion Π one obtains from the set (33):

$$k_{f1} = k_{f2} = \Pi = \frac{c_2\theta - c_1\nu}{\theta_2 - \nu_2}$$

where $\theta = G_2 / G_1$ and $\nu = \rho_2/\rho_1$.

The searching tests had also demonstrated that more often even for insignificant changes of G parameter k_f is not constant depending mainly on the tire load and temperature. A potential field of these changes is described by the adaptable exponent dependence

$$k_{f2} = k_{f1}\cdot\theta^{\mu}, \quad (34)$$

where μ - exponent.

Solving the set of equations (33) by substitution of (34) obtains

$$k_{f1} = \frac{c_2\theta - c_1 v_2}{\theta^{\mu+1} - v_2}, \quad (35)$$

After that, k_{f2} can be found by (34). Having carried out a test series for three vehicle or trailer-train weight levels, one obtains a set of three equations of form (33) to evaluate μ.

From an experience being accumulated during the tests of significant number of objects a relationship is obtained that allows to calculate parameter μ by varying vehicle weight at two levels, G_1 and G_2:

$$\mu + 1 = 20 \cdot \Pi \cdot 10^4 \quad (36)$$

The latter relation was widely verified by the numerous test series when determining vehicle on-road and wind tunnel aerodynamic drag.

For the passenger cars with relatively small suspension rigidity an additional ballast is placed over the rear axle, and corrector of static deflection (Fig.6) is inserted to the suspension elastic elements.

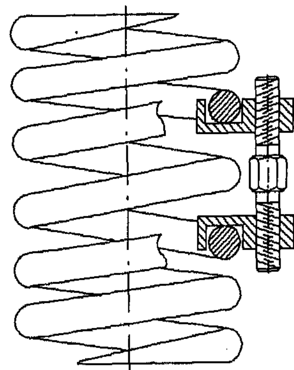

Figure 6: Corrector of suspension static deflection

This corrector readjusts an original body position relative to the road surface. As it is known, the natural frequency of suspended masses is in inverse proportion to the square root from suspension static deflection. Using the correctors like that in Fig.6 additional suspension rigidity is available and equal static deflection of elastic element can be selected for both load values on the rear wheels. Such correction of suspension static deflection is important to provide natural frequency and hysteresis constancy to avoid the additional variables in test series with two vehicle weights. Because of higher suspension rigidity of trucks and many buses, an insignificant change of body height and pitch over the road surface by 12-15% weight increasing may be ignored. For these cases an additional ballast should preferably be located into the centre of mass of such vehicles or close to it. Then, after the certain changes of body position accompanied by vehicle aerodynamic configuration changes, coefficient c_x assumes the meaning averaged for both configurations. For trailer trains it is reasonable to locate an additional ballast in the centre of trailer mass. For the buses with automatic floor level control the conditions of maintenance of invariable body position for two weight levels are the most favourable.

RESEARCH EQUIPMENT

Inasmuch as all variants of the scheme include the record of only one coasting parameter, namely time, the main equipment of the method is essentially simplified taking the form of time interval meter with photoelectric retroreflective sensors (Figs.7, 8).

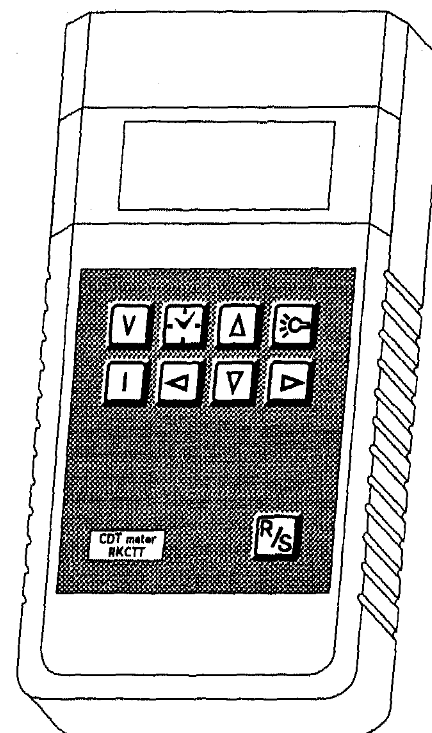

Figure 7: Coast down time meter

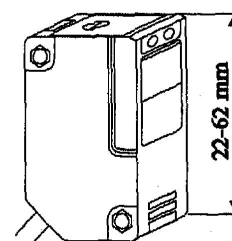

Figure 8: Retroreflective sensor for detection of track marks

As analogy of such time meter, a set of precision stop-watches that are switched on in the moment of vehicle passing by the correspondent distance mark can be conceived of. A photoelectric retroreflective sensor responds to the distance marks in the form of light-reflective stakes (Fig.9). All stop-watches are switched out in the moment of vehicle stopping. So, time data shown in Figs.3a, 4a, and 5a are recorded. For the driveline tests the time meter is equipped by the programmable counter of revolution number of vehicle wheels. At first, an approximate total revolution number, z_1, during the coasting is determined, and then interval revolution number, Δz, is preset providing the condition similar to that presented in the scheme in Fig.4b for the vehicle: $(1/3)z_1<\Delta z<(2/3)z_1$. Recommended Δz values are given in Table 2.

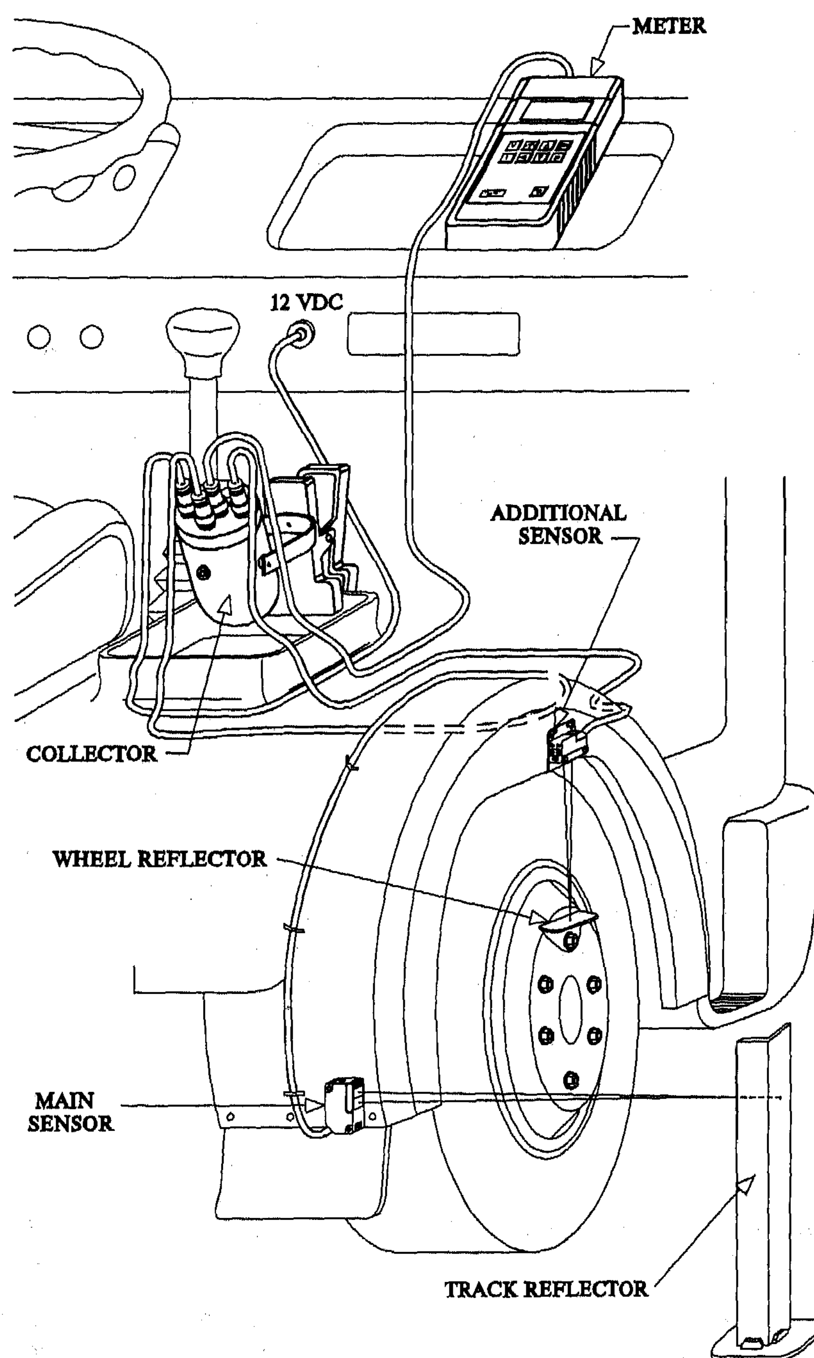

Figure 9: Arrangement of coast down time meter and sensors on the truck

The first specimens of time meter had no built-in memory. The modern time meter with built-in storage capacity 64 Kbyte shown in Fig.8 can transmit data to computer for its processing.

It is designed for simultaneous reception of signals from two retroreflective sensors, one of them being responsive to the track marks, and the second operating as a sensor of vehicle wheel revolution number (Fig.9). It makes possible to measure the wheel rolling radius and to examine carefully an influence of the various factors on it. It also permits to use vehicle tires of high inflation pressure for distance measurements.

An accuracy of coasting time measurements according to the schemes in Figs.3a, 4a is within ±50μs.

The experimental data that are transmitted from the measuring device to computer are processed by use of an adequate software, that was developed on the base of formulae (16)-(36).

In addition, a set of research equipment includes the instruments for measuring tire and final drive temperature as well as tire inflation pressure. It is important to conduct driveline tests at a temperature equal to that of the road tests for proper identification of transmission losses. A portable weather station for atmosphere parameters recording, and vehicle balance or lodometer are also incorporated into the set in use.

It is also essential to mark out the test track with an accuracy of 0.05% or better. For the long tracks, use of the laser geodetic meter that provides marking accuracy of ±1 sm at 1000 m, i.e. ±0.001%, is most efficient.

As a part of research program in Russia two test tracks were marked out and used. The first of them is disposed in the Central Automobile Proving ground (Dmitrov), having the straight-line measuring section of 4.4 km length, and the second 2.2 km length is situated in the GAZ Works Proving ground (Nizhny Novgorod). The marking step of the central part of both tracks is 100 m, while for the rest part it is 200 m. For each particular test series only those reflective stakes were positioned that were required for the measurement scheme selected for the given vehicle.

RESULTS AND DISCUSSION

WIND EFFECT MINIMIZING -Ambient wind is a main potential source of the track data uncertainties.

As known, there are three ways to decrease test errors due to wind action. The first of them is taking into account an influence of wind speed on aerodynamic drag analytically basing on the assumption that wind speed is described by constant vector over a length of the whole test track. Such supposition results in the inadequate model of process in question because uniform wind in the different points of the test track is extremely rare.

The second way which is presented in newer works incorporates into analysis additional simultaneous measurements of the relative airspeed and yaw angle histories by propeller-vane anemometer mounted ahead of the vehicle on the boom. An application of this method is associated at least with four following problems.

1. Aerodynamic interference of the vehicle on the air flow at the anemometer's location and contribution of anemometer to the vehicle drag.

2. Validity of assumption that instantaneous freestream acting on whole vehicle area is adequately modeled by instantaneous relative airspeed and yaw angle which are pointwise estimated by boom-mounted anemometer ahead of the vehicle.

3. The way of introducing a correction for propeller-vane anemometer related to distance constant as well as to vane damping ratio and delay distance.

4. Disregarding the fact that relationship between drag coefficients with yaw angle and at yaw angle equal zero is individual for each vehicle.

Recently, some reports were published with the information about solving the above-mentioned problems and very high drag measurement accuracy reached [23][24][25] that was associated with the need of carrying out up to 20 coastdowns for each vehicle configuration.

The third way of decreasing wind caused variabilities of track data is to limit wind level allowable for test performing as it is regulated by some standards relating to determination of vehicle road fuel consumption and of road resistance parameters for dynamometer simulation.

On the first stage of development it seems rational not to load the method presented by additional methodical constructions and to carry out all the tests at wind speed of no more than 3 m/s as a generalization of experience of standards in action.

As a result, measurement accuracy of parameters c and c_x estimated by the half of significant c_x error at 0.95 confidence level and under 6-fold runs is 2-3% and better for the wind speed up to 1.5 m/s. It may decrease to 5-6% for wind gust speed values of 2-3 m/s. As a rule, a half of significant f_0 error value is not more than 2-5% for the same conditions. The results of numerous road tests are presented below to illustrate these data.

For both above mentioned proving grounds being situated in the wooded middle region of Russia, such wind conditions accompanied by absence of sediments more often occur during the period from April to October and, as a rule,

approximately from 19.30 P.M. to 2.00 A.M. In each month of this period the number of favourable days is sufficient for the intensive experimental working, to be alternated with test preparation and data processing when rainy or windy.

ROAD - TUNNEL CORRELATION OF AERODYNAMIC DRAG - The method was initially applied for the operational development of the passenger cars concurrent to wind tunnel testing. Two types of wind tunnels were used. The first, an aircraft type, was the Central Aerohydrodynamic Institute (TsAGI) subsonic wind tunnel with the open working section and nozzle end cross section area of 38.5 m^2. A car was placed in the flow core on the flat fixed disk screen 6 m diameter and 0.2 m thickness. Supporting plates for the car wheels were connected to the aerodynamic balance by the long holders and positioned in the screen slots. The second, an automotive type, was the wind tunnel of the Central Proving ground in Dmitrov having 26.7 m^2 cross-sectional area and 16 m length working section with slotted walls.

The comparison data obtained by both methods for 4.8 m length sedan are represented in Table 3. By means of an additional drag reducing equipment installed to the vehicle coefficient c_x has been successively diminished. The changes were measured with comparable accuracy both by the aerodynamic balance in the wind tunnel and by the road method. Each vehicle aerodynamic configuration was evaluated by means of 6 runs on the road (three in each direction). An example of the similar comparative tests with the automotive wind tunnel being applied is represented in Table 4.

Notes: * 6 measurements for each configuration;
** No error data.

The testing of additional elements of aerodynamic equipment has shown its small efficiency. An adequate correlation was obtained but, unlike previous example, with about 10% higher c_x for the road conditions.

By the regular utilizing the method developed a significant quantity of test data was accumulated during joint investigation with Russian automotive works. These data characterize correlation between c_x in road condition and the similar coefficients c_w in automotive wind tunnel and $\bar{c}_w$ in TsAGI wind tunnel (Fig.10). Results obtained having very high level of correlation are generalized by the following relations:

$$c_x = 1.12c_w \pm 6.5\% \quad (37)$$

$$c_x = \bar{c}_w \pm 2\% \quad (38)$$

This expression means that all data scatter excluding rough errors (as point 29 in Fig.10) is covered by represented maximum-minimum values.

10	Moskvitch-2140	1.78	20	Moskvitch-2141 series 1	1.89	30	UAZ-3160	3.03

Better correlation factor to TsAGI (38) in comparison to automotive wind tunnel (37) is explained by testing the same vehicle specimens that have been tested on the road. A large share of vehicle specimens tested in automotive wind tunnels is of the same make names and numbers, but has different body numbers than tested on the road. Besides that, the data were obtained in the different wind tunnels. Despite the fact that Buchheim's et al system of comparison [28][29] is indirectly applied for the data obtained in different wind tunnels, the value of correlation factor of the data field expressed by relationship (37) was affected by the difference of the tunnels themselves.

The reasons of higher c_x values for the same vehicle in the road condition in comparison with automotive wind tunnels have been discussed for a long time including wind tunnel blockage, stationary vehicle wheel, etc. By opinion of different authors, this phenomenon is mainly affected by the presence of the boundary layer on the stationary floor of the working section of the automotive wind tunnels that is notified by [1][3][5][25], and in the other works. This conclusion has been also confirmed by the author of the present paper in [18]. Apparently, the explanation of equality (38) can be found in the favourable conditions for blowing off the boundary layer from the road simulating disc in the aircraft wind tunnel. Besides that, the further application of the method along with wind tunnel testing has revealed that by reducing the flow speed in wind tunnel to 25-10 m/s, i.e. to the values comparable with initial and average speed values of the road tests, the coefficients c_x and c_w are converging (Table 5). More extended further studies should clear an effect of tunnel operational speed on c_w reduction like an effect of flow around sphere including crisis region.

Table 5: Aerodynamic drag coefficient as a function of full-scale wind tunnel operational speed (Test object: Jeep 4x4, F=3.028 m^2, c_x=0.5317)

V (m/s)	10.6	15.4	20.2	25.1
c_w	0.5222	0.5079	0.4991	0.4922
c_z	0.2337	0.2323	0.2169	0.2157
c_w/c_x	0.98	0.96	0.94	0.93
V (m/s)	30.1	35.0	40.0	45.6
c_w	0.4854	0.4778	0.4742	0.4751
c_z	0.2250	0.2259	0.2327	0.2247
c_w/c_x	0.91	0.90	0.89	0.89

It is noteworthy that for the case of additional vehicle configuration changes in order to reduce aerodynamic drag the road-tunnel data correlation degree decreases. This is illustrated by results for the 5050 mm length passenger car shown in Table 6. From these results it can be seen that maximum of discrepancy occurs when estimating an influence of drag reduction devices installed in the vehicle understructure (see, e.g., lines 2,3 of Table 6). Reduction of c_w in wind tunnels is lower than that of on-road c_x, as it had been recently shown by Le Good et al [25].

On the next stage of the method application the different full-size cars, trucks, buses, and articulated vehicles were tested. During the testing a correlation between c_x in road conditions and c_D of the scale models of these objects including bulky vehicles was examined (Fig.11).

Table 6 : Comparison of aerodynamic drag variations for road tests (Δc_x), aircraft wind tunnel TsAGI ($\Delta \bar{c}_w$), and automotive full-scale wind tunnel (Δc_w)

Changes of configuration and outfit	Explanation	Aerodynamic drag changes (%) *		
		Δc_x	$\Delta \bar{c}_w$	Δc_w
$c_x = 0.3534$	Sealing of headlight periphery 1 and of joint between front fenders and bumper 2	-9.9	-2.8	-1.0
$c_x = 0.3165$	Mounting of fog lights flush with spoiler 1. Installation of fairings 2 and 3 on spare wheel and rear suspension	-9.4	-4.5	-3.4
$c_x = 0.3095$	Windshield wipers put away behind hood deflector 1; deflector 2 radius enlargement	-1.8	-1.0	-1.0
$c_x = 0.2956$	Mounting of flat wheel caps, enhanced negative body pitching	-3.5	-3.6	2.3
$c_x = 0.2806$	Enhanced negative body pitching (second level)	3.8	-1.0	0.5
$c_x = 0.2738$	Removal of right-hand mirror	-1.7	-3.4	-1.5

Note: * Difference between $c_x (c_w)$ of each configuration and those of preceding configuration, divided on basic values: $c_x = 0.3925$ and $c_w = 0.3840$ of original outfit is assumed to by 100 %.

full-scale models has been utilized. As a result, on the base of the tests of 26 scale models in wind tunnel and of their full-scale analogs in road conditions the following correlation relationship for the forecast of c_x by c_D was obtained:

$$c_x = 0.9 \cdot \sqrt[8]{c_d^5} \pm 0.11 \qquad (39)$$

From the graphic data of Fig.11 and generalizing formula (30) related to the models without simulating air streams in the underbonnet space and in the ventilation systems, it suggests that for the full-scale models the error of c_x prediction can reach 15-35% (lower value for larger c_D).

ROLLING RESISTANCE - An effect of speed and tire inflation pressure on vehicle rolling resistance is shown in Figs. 12, 13, and 14.

These data demonstrate the method sensitivity to small variations of rolling resistance as affected by various factors. The experiments had confirmed the f_0 decreasing with the rising of inflation pressure. However, the same factors do not cause obligatory falling down of coefficient k_f that characterizes rolling resistance dependence upon speed (Fig.13). For a number of tire models this coefficient rises with p_t increasing, sometimes passing through the peak. For several tire models it passes through the valley which coincides with pressure value recommended by manufacturer for the correspondent load. This effect may be caused by the interaction of two opposite factors accompanied by raising of p_t, i.e. reduction of unsprung mass

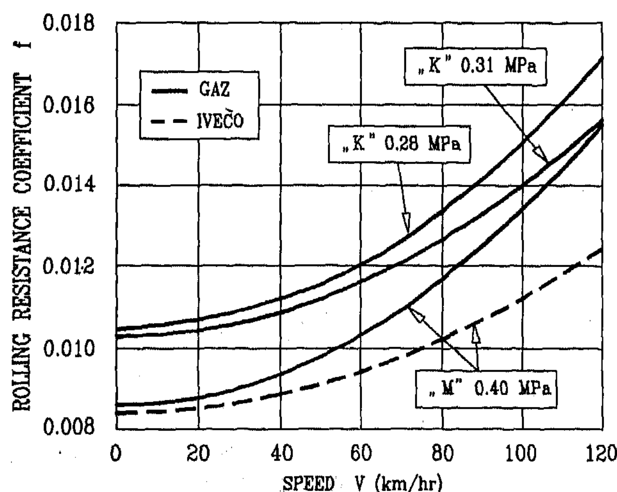

Figure 12: Typical rolling resistance coefficient versus speed for 4x2 1.5 t trucks GAZ-33022 and Iveco-Turbo-Daily 35.10-320 with tires 175/75R16 (at manufacturers "K" and "M" recommended pressure)

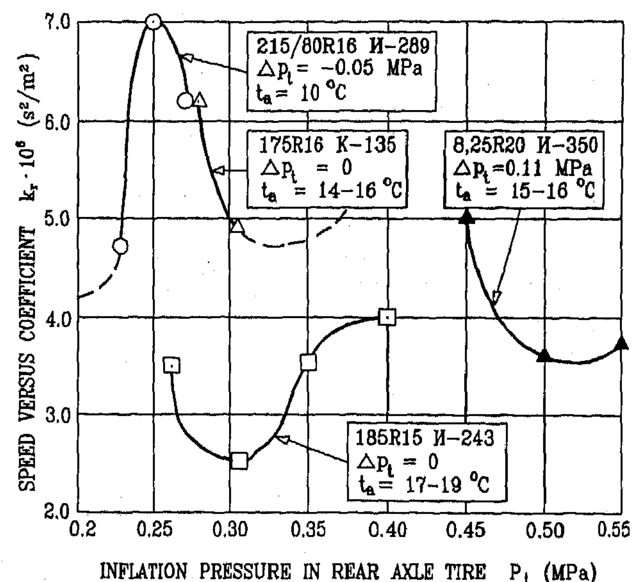

Figure 13: Typical k_f coefficient versus rear axle tire inflation pressure for several tire models of 2-axle truck (Δp_t - difference between inflation pressure of front and rear axle tires)

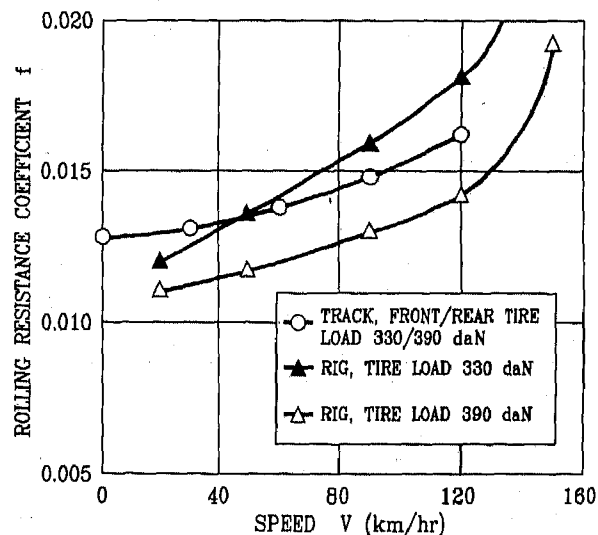

Figure 14: Rolling resistance coefficient of tire 165/180R13 versus speed on road and rig (wheel suspension system is the same for both cases)

oscillation amplitude and tire losses giving as a consequence a rise of sprung mass amplitudes as well as energy dissipation in shock absorbers. So, as opposed to the tire test data on the drum rig (with no vehicle suspension), energy dissipation for the tire rolling as a part of the tire-suspension-road system is expressed by coefficient k_f. It is of

importance in order to optimize parameters of the system. The tire of the given model may not be best among others being tested on the rig, but interacting with a suspension it can provide a significant reduction of rolling resistance in real road conditions in comparison with other models. Conducting the tire tests by the rig equipped with wheel suspension enhances the agreement between the bench and road results (see Fig.14).

DRIVELINE POWER LOSSES - The values that are reduced to the drive wheel circumference for direct summarizing with rolling resistance force are given in Table 7.

Table 7 : Driveline losses

LiAZ 5256**		6.7	67.0

Note : * For trucks;
** Gearbox with torque converter and disc clutch.

Considering these forces to be approximated by the linear dependence upon speed, two values at V=0 and V=90 or 80 km/hr are sufficient for its estimation.

The method allows altogether wide possibilities for studying relatively small resistance of this kind and also its dependence on oil temperature and running-in level of sealings and other driveline frictional pairs. In particular, in Figs. 15, 16 an estimation of the final drive temperature influence on the above mentioned losses is shown.

ROUTINE STUDY OF VEHICLE DRAG SHARES - The most typical opportunities and data obtained by the method developed during the studies of trucks and buses resistance parameters are given in Table 8.

Configurations 1,2 demonstrate 10% increase of passenger car c_x owing to 150 mm less overall length, unless tire profile width reduced.

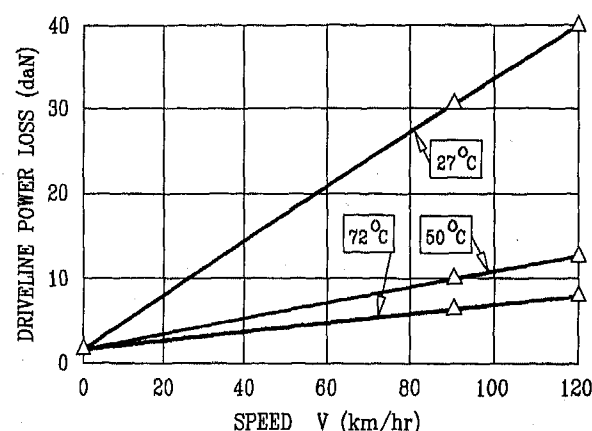

Figure 15: Driveline power loss versus speed (Volvo-760)

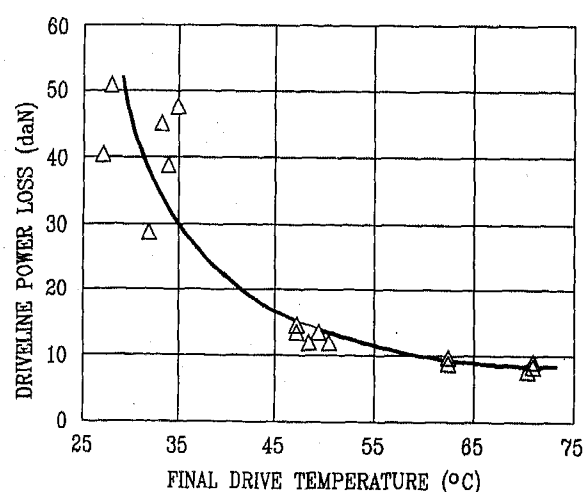

Figure 16: Driveline power loss versus oil temperature (Volvo-760 at speed tend to zero)

In configurations 3,4 an inadequate fairing design combined with pickup upper trunk results in 2% c_x rise.

Table 8 (Continued)

Note : * The values in parentheses represents half of significant error at 0.95 confidence level.
** Shields around radiator of engine are installed; frontal area of air intake of radiator is decreased by 20 %.

In configurations 5,6 coefficient c_x is reduced through the tent mounting over the cargo-carrying platform of the 1.5 t truck as compared to the open unloaded platform, unless c_xF of the latter is of lesser value.

In configurations 7,8,9 coefficient c_x of the closed truck is successively reduced by fitting, firstly, the shield fairing on the cabin roof (see configuration 8) and then the three-dimensional ellipsoidal one.

In configuration 10 of a police bus a light-sound signal device width as broad as 0.85 bus overall width is installed on the bus roof, that results in 10% c_x rise as compared to configuration 11.

In configuration 12 the same bus as in configuration 10, but with the higher roof has 24% c_x and 7% c_xF fall, unless the larger frontal area. This fact allows to come to a very important conclusion that an increase of vehicle height usually brings to considerable c_x reduction. Due to the lack of space for the detailed analysis of this effect, a distant but clear analogy of the vertical wing near the road having less drag than the horizontal one may be used. Likewise this effect may be noticed while comparing configurations 13, 14 of the van-type trucks with high and low roofs, despite of worse aerodynamic outline of Iveco-Turbo-Daily cabin. The similar effect is demonstrated by comparison of two unificated buses (configurations 20, 21). Configuration 21 is a tourist version of configuration 20, being 7% higher (but only 1% longer) and, consequently, has 14% lesser c_x.

As a whole, these results may be considered as unpremeditated embodiment of the old Rumpler's concept [30] at the modern vehicle design stage. The vehicle he had built was relatively high, and its horizontal plan was of wing profile form. As Hugo reports [30], in 1979 Buchheim had obtained c_W=0.28 on the museum specimen of Rumpler's vehicle in a large wind tunnel.

From configurations 17, 18 of the comfortable 18-seater bus an effect caused by displacement of saloon ventilation system air intake from the area of the windshield upper edge (configuration 15) to the rear roof part can be estimated. During the tests the chokes of the air intakes were fully opened. In configuration 16 ventilation system efficiency increased for more than 2.5 times resulting in 8% c_x rise. As far as f_0=0.0146 concerned account must be taken that the tests of the bus with improved ventilation system were performed on the tires not fully rolled.

Recurring to unificated city and tourist buses (configuration 20, 21), c_x reduction owing to the reduced area of engine front radiator intake of the first model for 8% and of the second one for 2% is observed.

A variety of the method employment illustrations is continued in the Table 9 including the articulated trailer trains.

Trailer train with six-wheel traction truck Mercedes-Benz 2238 of configuration 1 indicates 28% difference of vehicle aerodynamic drag with and without aerodynamic fairing. In configuration 2 of the similar trailer train, but with traction truck Scania R142 H, this difference being somewhat lower is caused by the enlarged distance from cabin to container, despite of the three-part fairing set on the cabin. The semitrailers of both trailer trains were equipped with twin wheels. A significance of semitrailer single wheel effect on the frontal aerodynamic drag reduction is shown by the test results of the trailer train (see configuration 3-MAZ-64227), despite a simplified fairing on the cabin. It can be explained by a strong influence of turbulent wake behind the truck on the twin wheel axle having a larger frontal area. For single wheels a high turbulence stream flows into the space between semitrailer wheels with the less aerodynamic energy loss.

Finally, comparison of c_x values of a concept truck (configuration 4) and of the trailer train on its base (configuration 5) indicates that c_x reducing due to significant test object lengthening is unexpectedly not so large as against to the negative influence of friction resistance, as well as resistance of enhanced number of protruding parts, particularly in the underbody space, and also to the influence of trailer train sections on each other.

In Table 9 a significant rolling resistance reduction of large cross section single tires on the 22.5" rim (items 4, 5) as compared to the twin wheels (items 1-3) is shown.

COAST DOWN TESTS WITH RECORD INTERRUPTION - To assess the possibilities of the method application for trials on the straight-line measuring sections alternating with curved track segments (Fig.5a), or turns on the ends of the measuring sections where data record is interrupted, the tests were undertaken by employing the measurement schemes shown in Fig. 5b realized on one extended 1400 m length road segment. To provide the opportunity not only of calculating time T_c but also of its measuring the length of segment 4-4' was chosen successively equal to 0, 200 and 400 m (Table 10).

It is obvious from these results that straight test sections having length of 600-1000 m, or 2-2.5 times shorter than total coasting distance of the object examined may be used. Since distance and time of record break are enhanced, some deterioration of the data convergence may be expected. It is especially affected by significant

speed variation on the record break sections which may cause variation of tire temperature and, consequently, of rolling resistance.

The most promising comparative data for a number of vehicles are represented in Table 11.

So, the future progress of the coast down techniques presented is associated with the reliability of the instruments for tire temperature control during vehicle motion.

VEHICLE WHEEL ROLLING RADIUS - As referred above it can be measured by the time interval meter with two sensors hooked up (see Fig.9). One of them responds to the road marks of the measuring section start and finish, and the other senses wheel marks to count revolution number including its fractions on both ends of measuring section. An employment of such measuring scheme indicated the maximum 0.05% rolling radius variation for the tire inflation pressure of trucks and buses higher than 0.55 MPa, in the speed range from 0 to 120 km/hr and tire temperature range 20-60^{0}C.

The testing of the vehicle of configuration 7 (see Table 8) has shown that for such conditions a scheme with wheel revolution number counter can be employed for coast down tests similarly the driveline testing. Thus, for express evaluation of drag components for the vehicles with tire pressure higher than 0.5 MPa the track marking may be not in use.

SUMMARY AND CONCLUSIONS

1.The method of integrating the vehicle coast down equation eliminates the traditional need for measuring or calculating vehicle velocity or deceleration to determine vehicle drag and rolling resistance. In particular, the explicit form of the speed-time and distance-time functions are derived with resistance parameters and their combinations in coefficient form. The equations are based on constant coordinates of separate points of the distance-time curve.

2.By excluding speed recording the coast down test procedure was simplified, and an acceptable sensitivity to small changes of aerodynamic vehicle configuration, and also of tire and transmission parameters, was achieved.

3.It has been demonstrated that parameter measurements can be reduced to time recording only owing to replacement of distance measuring by precision track marking. The research equipment is simplified, and achievement of measurement accuracy, reliability, and replication presented is obtained under 6 coast-downs only.

4.Aerodynamic drag and rolling resistance separation by 2- or 3-level vehicle weight varying being combined to distance-time dependencies and widely verified by the tests had shown its effectiveness for examining motion resistance of these kinds.

5.By means of the method developed a considerable quantity of test results was accumulated that allowed to set the stable correlation between coefficient c_W of full-size passenger cars, and also of the scale models of trucks and buses in wind tunnels, on the one hand, and c_x of the correspondent full-scale vehicles in road conditions, on the other.

6.The method is widely used for investigation and comparative testing of different models of passenger cars, buses, trucks, and articulated vehicles as well as for their updating and operational development.

ACKNOWLEDGEMENT

The author wishes to thank Chief Designer Board of GAZ corporation and Board of Directors of the Central Automotive Proving Ground (Dmitrov, Russia) for their co-operation, and also Mr. N.Hur and Mr. I.Ahn - from Korea Institute of Science and Technology for their interest to the author's investigation, especially for Mr. Hur's initiative and idea [27] of application of the method developed to the task of coast down testing on the short tracks.

PAC-ITS: Towards AHS and 150 mph Highways

Jim Haugen, Sr.
Haugen Associates

ABSTRACT

A unique approach to intercity highway transportation entitled PAC-ITS: Packet Autopiloted Cruiseway - Intelligent Transportation System, has been detailed in a recently completed contract for the National Automated Highway System Consortium (NAHSC). The PAC-ITS concept focuses on: (1) improving the productivity of intercity travel (2) facilitating increased highway speeds in a safe and environmentally permissible manner; and (3) minimizing automation complexities. Key concept features include:

- Use of PAC-ITS convoys which are composed of a mix of 15 or 20 vehicles - personal cars, buses and freight units - electronically and mechanically linked together.
- Interconnection of all vehicle power trains and brakes enabling unified convoy acceleration and braking.
- Individual active lateral guidance for each convoy vehicle
- Professional "pilot" control of each convoy from a specially equipped lead vehicle.

This paper outlines the functional features of PAC-ITS; describes the rationale behind the concept; and structures a three phase evolutionary development and deployment scenario leading to 150 mph operations.

This paper draws upon the author's years of involvement in strategic planning and R&D of advanced transportation systems at U.S auto companies, as well as his more recent consulting work in Intelligent Transportation Systems.

INTRODUCTION

- Must U.S. highway and vehicle progress permanently plateau within the constraints of the 70 or 75 mph Interstate Highway System?
- Shouldn't R&D progress continue to upgrade or supplant the Interstate?

The PAC-ITS concept provides a basis for initiating a dialogue on these issues; especially important as we mark the beginning of the second 100 years of the U.S. auto industry.

Construction of the Interstate highway network was a major milestone in highway transportation. Its many benefits are best summarized in two words - improved productivity. PAC-ITS seeks to continue to extend highway productivity through the use of emerging technology capabilities. Furthermore, the introduction of such a system is expected ignite a new era of transportation innovation and growth - in infrastructure construction; control and communications development; higher performance vehicle engineering; and business and organizational change.

CONCEPT DESCRIPTION

PAC-ITS concept basics are simple:

- Temporarily link a group of 15 or 20 vehicles together for highway trips, thereby saving energy through train type aerodynamics. Operate such convoys on a single dedicated lane at constant speed to simplify operations and minimize construction costs.
- Establish standards for performance and physical design constraints for all convoy vehicles - cars, trucks and buses.
- Use advanced electronic controls to link all the power trains; guide all the vehicles in the same path; convey individual vehicle status through diagnostics; and keep an eye on all the convoys on the highway.
- Place a single trained pilot up front in a special vehicle to lead the convoy; maximize his productivity and salary through the number and value of trailing vehicles; and provide him with adequate sensing and monitoring devices.
- Design this advanced system so it can be initially operated on the Interstate freeways and also evolve into a future nation-wide high-speed (possibly 150 mph) network.

PAC-ITS can be viewed as equivalent to a train, but with rubber tire advantages: the system is dual-mode, so all PAC-ITS vehicles can also be conventionally driven on all existing roadways; flexible convoys of 20 or so highway vehicles can

be assembled on a demand basis; departures and convoy spacing can be at intervals of less than a minute.

The PAC-ITS concept is illustrated in Figures 1 through 3.

- Figure 1 shows a close-up of three of the PAC-ITS vehicles in a convoy, illustrating:
  - -- The unique Pilot vehicle which, in this case, is also carrying passengers. The pilot sits up high for best visibility and is assisted by (1) a laser based Adaptive Cruise Control system; and (2) a laser beam or machine vision system controlling lateral position with respect to roadway markers.
  - -- A four wheel drive vehicle and a sports sedan linked up behind the pilot vehicle, illustrating the versatility of the concept to allowing mixing of vehicle types.

- Figure 2 is similar to Figure 1, only projected forward some 15 years. PAC-ITS convoys are now operating on an exclusive lane at speeds in excess of 100 mph. Features shown are:
  - -- Translucent flexible adapter pieces unfolded between each pair of vehicles for improved high speed aerodynamics.
  - -- The use of traffic barriers separating the dedicated lane from any manually driven traffic.

- Figure 3 illustrates three different convoy arrangements as compared to a double bottom semi configuration: (1) a Phase I convoy where all the freight vehicles have driver positions; (2) Phase II freight vehicles with no driver positions, assuming remote control of these vehicles at the freight center; and (3) a string of minivan size passenger vehicles behind the larger lead vehicle.

PAC-ITS OPERATIONS

Figure 4 illustrates a three step roadway entry process for PAC-ITS vehicles. In step 1, vehicles enter a queuing area from an arterial roadway, selecting the appropriate queuing lane for a designated convoy destination. In step 2, vehicles from one of these lanes move forward to link up with a lead vehicle to form a convoy. Finally, in step 3, the convoy receives a go ahead signal, accelerates and merges into an open slot on the dedicated freeway lane. The acceleration and merge operations are expected to take place under the manual control of the convoy pilot, except for the steering which is automatic. Once on the dedicated lane the pilot's role becomes supervisory only, monitoring convoy headway, automatic lane keeping, potential roadway obstacles, weather conditions and individual vehicle diagnostics.

PAC-ITS R&D NEEDS

Certainly any new system such as PAC-ITS requires extensive R&D and design efforts. Examples of some of the important areas include:

<u>VEHICLE TECHNOLOGY</u>

- Lateral guidance system - Electronic sensing based, such as lasers or machine vision; or mechanical based, such as the use of fold-out guidance arms to provide positive vehicle roadway containment.
- Vehicle linking - Development of low speed automatic coupling; coupling tie-in to the vehicle structure; throttle and brake interconnection and minimum accel/decel performance standardization.
- Vehicle design changes - Intake and exhaust re-routing; electronic steering and braking; remote diagnostics.

<u>ROADWAY TECHNOLOGY</u>

- Cooperative vehicle guidance - Addition of guidance system targets or guidance arm rails.
- Road construction - Smooth concrete construction for 150 mph operation, or use of plastic "smoothing" track inserts (since all vehicles follow the same path).
- Barrier design - Use of barriers to exclude manual vehicles and animals; to reduce side wind gusts; permit entry of emergency service vehicles.

<u>CONTROLS AND COMMUNICATIONS</u>

- Vehicle controls - Automatic steering; vehicle and convoy adaptive cruise control; remote maneuvering and automatic parking (especially for freight vehicles); automatic user "fare" payment.
- Convoy controls - Slot reservation techniques for ease of merging; convoy tracking and management; entry/exit management.

AHS RELATIONSHIP

The general concept of the automated highway system is often referred to as 'hands-off", "feet-off" driving on exclusive guideway lanes, with emphasis on solving urban area congestion. However, this concept has important weaknesses:

- Physical constraints, high infrastructure costs and marginal benefits make its deployment in urban areas doubtful
- A driver's desired "eyes-off" or :brain-off" function is doubtful because of emergency intervention concerns with very short headway operations
- Driver trust in total electronic roadway and traffic monitoring and control is yet to be proven
- The need for increasing headway gaps as speeds are raised preclude good aerodynamics and fuel consumption at high-speeds.

PAC-ITS CONCEPT RATIONALE

The PAC-ITS concept focuses on improving the productivity of interstate highway travel through high speed operations with mixed vehicle convoys. The rationale behind this approach is as follows:

- SYSTEM DESIGN SIMPLICITY - The PAC-ITS convoy approach simplifies many facets of advanced highway system design:
  - -- Minimizes complexity - single lane operations; no lane change maneuvers; all vehicles at a constant speed with no passing
  - -- Vehicle linking provides inherent system redundancy - if, for example, one vehicle's engine fails, the convoy tows the failed vehicle to the next exit
  - -- Linking the power trains of 20 vehicles can have large traction benefits, allowing safe operations in deteriorated weather conditions

- PROFESSIONAL PILOT VEHICLE CONTROL - Each freeway train will have a trained professional pilot in the lead vehicle, with many advantages:
  - -- History has shown that is impossible to design a perfect automatic system; human supervision and intervention, in systems ranging from subways to airplanes to spacecraft, is always needed for unforeseen problems.
  - -- Use of a human pilot minimizes the cost and complexity of sensor and system electronics additions to individual vehicles
  - -- People already have confidence in the use of trained pilots from airline experience
  - -- The trained pilot can monitor the diagnostics of all convoy vehicles for failures and apply human judgment to take appropriate action

- USER FRIENDLINESS AND CONFIDENCE - The PAC-ITS concept emphasizes a user orientation, supplemented by technology:
  - -- PAC-ITS use is intended to be simple - personal cars do not have to be turned into the equivalent of jet aircraft cockpits; no user special training required
  - -- Hands-off, feet-off, and eyes-off trip convenience
  - -- Executive jet equivalency in comfort and safety is expected as new personal vehicle designs emerge
  - -- The use of a human pilot achieves "go to sleep" confidence; frees drivers for on-road productive activities
  - -- A relative public feeling of safety is natural, given cultural familiarity with mechanically linked trains

- COMMERCIAL VEHICLE IMPROVEMENTS - The use of PAC-ITS "freeway trains" has special advantages for commercial vehicle users:
  - -- "Slipstreaming" will reduce overall drag by a significant amount, lowering operating costs
  - -- Productivity will be improve greatly since one driver can handle a payload as much as 10 times as large or valuable, with even better on-time delivery
  - -- As safety benefits are demonstrated, speeds can be increased, further increasing productivity
  - -- The public image of "killer trucks" can be radically improved by a combination of lower profile, aerodynamic trailers; precise lateral guidance eliminating trailer sway
  - -- Reduces commercial vehicle turnover problems and provides new higher paying jobs - PAC-ITS pilots instead of truck drivers

- POTENTIAL FOR HIGH SPEED OPERATIONS - PAC-ITS makes future highway travel at higher speeds a practical possibility:
  - -- PAC-ITS trains inherently minimize vehicle drag - drag is highway vehicles' biggest enemy; expensive in fuel consumption and emissions; a major factor in preventing the move to higher freeway speeds
  - -- The mechanically fixed vehicle spacing allows transition shrouds between vehicles, further enhancing high speed aerodynamics
  - -- Increasing speed significantly, as long as safety also improves, reaps major highway travel benefits:
    1) Car and bus competition with air travel
    2) Increased rural travel range
    3) More life style options
    4) Much higher freight hauling productivity

EVOLUTION PHASES

PAC-ITS Intercity deployment might occur over three phases, as postulated in the Deployment Schedule of Figure 5.

- Phase I - Deployment of limited size PAC-ITS packet convoys on Interstate freeways in mixed traffic.
  - -- As shown in the figure, first operations in mixed traffic, on a limited scale, are assumed to begin within 11 years - in January, 2008.
  - -- Mixed traffic operations would then be extended to other regions over the following decades as interest grows.

- Phase II - Interstate deployment expands; adding exclusive PAC-ITS lanes in some locations; adding low speed off-guideway maneuvering:
  - -- Automated Convoy Formation - This feature allows drivers to switch to automatic control upon entering the convoy formation area. The driver's vehicle is then automatically routed to the correct lane and automatically docked to other vehicles in the convoy.
  - -- Automated Parking and Yard Operations - This feature allows PAC-ITS equipped vehicles to be automatically routed and parked without a driver on board. It allows automatic storage of vehicles in parking areas or decks; remotely controlled movement of freight vehicles within a freight terminal.

- Phase III - PAC-ITS deployment on separate right-of-way with staged evolution to higher speeds.
  - -- Research and Development on increasing PAC-ITS speeds continues through a span of several decades, as shown.
  - -- Approval and funding - public and/or private - for construction of a national PAC-ITS type AHS network is shown occurring in the year 2014. This timing assumes expected positive reactions to initial Interstate based operations, combined with demonstrations of high speed operations feasibility. Within four years of approval, the first link begins 100 mph operations.
  - -- PAC-ITS operating speeds are shown being increased at a programmed rate of 10 mph every three years, based on meeting safety, energy consumption and emissions targets. This planned evolution of operating speed yields a top speed of 150 mph by the year 2033, some 25 years after the initiation of the first PAC-ITS operations. It also gives vehicle manufacturers known time frames in which to schedule corresponding higher performance vehicle introductions.

CONCLUSIONS

The National Automated Highway System program has, thus far, focused on the possibility of alleviating urban congestion using a total electronic automation approach. The PAC-ITS concept offers a different direction - a focus on improving intercity transportation productivity and the use of an Autopiloted approach which greatly simplifies system design and provides users with the confidence of a pilot in charge.

Electronics plays an assist and support role, similar to its proven role in airline operations.

The PAC-ITS concept raises important issues which should provide the basis for a national dialogue regarding continuing Interstate system development. Important questions in this dialogue are:

- Should the U.S. have an Interstate II design, development and deployment program over the next 40 or 50 years?
- Will AHS with a total automation approach ever be feasible and capable of achieving user confidence?
- What relative priorities should be placed on urban congestion alleviation vs intercity productivity improvement?
- What are the relative costs, benefits, feasibility and risks?
- Should we endeavor to push the speed envelope of cars and trucks, achieving requisite service gains, by taking advantage of advancing technology to do so, while maintaining environmental sensitivity?

Analytical Methodology for Design and Performance Assessment of Run-Off-Road Collision Avoidance Systems

ABSTRACT

Research in Intelligent Transportation Systems (ITS) has been increasingly focussed on the development of Collision Avoidance Systems (CAS). A CAS would reduce the incidence of collisions by providing warnings to the driver to take evasive action. Because single vehicle roadway departures, also known as Run-off-Road (ROR) events, are a cause of a significant portion of vehicle accidents and fatalities, an effective CAS for ROR can potentially improve highway safety dramatically.

The development of performance specifications for CAS for ROR events is a part of an ongoing three-phase program for NHTSA (National Highway Traffic Safety Administration). This paper focusses on the development and application of a powerful simulation tool, RORSIM, for CAS assessments over a wide range of environmental, roadway, driver, vehicle and CAS operating conditions. The results of CAS effectiveness studies are presented. These results indicate that such systems can improve highway safety significantly by providing consistent and timely warnings to the driver.

INTRODUCTION

There are existing prototypes of ROR CAS such as the RALPH system, developed by Carnegie Mellon University, [Pomerleau, 1995], and the CAPC [Ervin, 1995] system developed by University of Michigan Transportation Research Institute, which use a time-to-line crossing (TLC) algorithm to warn drivers of incipient ROR events. A dynamic simulation capability is a powerful supplement to on road and test track evaluation with such systems, which can be time-consuming, costly, and limited in the range of conditions that can be assessed.

The goal of the ROR program is to develop a simulation tool to establish normal driving scenarios and study the effectiveness of a ROR CAS when brief periods of driver inaction are imposed during the normal driving. In the first phase of study of CAS for ROR events [Pape et. al., 1996], an analytical approach was developed specifically for evaluating CAS effectiveness in preventing ROR incidents. To meet the need for the ability to evaluate large numbers of driving scenarios and the influence of variations in several vehicle, driver and CAS parameters, the analytical approach was expanded. Distributions were defined for a wide range of input parameters. Effectiveness criteria were defined for the CAS and, in order to allow the user to study CAS performance over a wide range of scenarios, a "Monte Carlo" like technique was introduced. Results of simulation studies involving tens of thousands of cases are presented in this paper.

ANALYTICAL METHOD

This simulation tool was implemented in the software package RORSIM. RORSIM is a menu-driven time-domain simulation program that predicts driver/vehicle/CAS dynamic interaction. It is an enhancement to VDANL (Vehicle Dynamic Analysis, Non-Linear), which is a general-purpose rubber-tired vehicle simulation program developed for NHTSA by Systems Technology, Inc. in Hawthorne, California [Allen et. al. 1992]. VDANL provides the basic vehicle dynamics model for the simulation as well as the closed-loop driver model. VDANL includes a 17-degree-of-freedom model of a general vehicle.

In addition to representation of the dynamics of vehicle motion, the model also captures the realistic dynamic interactions of vehicle-road, driver-vehicle, and CAS-driver interfaces. An explicit driver model takes into account the delays associated with the different response modes of a human driver such as driver reaction times to braking and steering commands. Nominal driver lane-keeping behavior, aggressiveness of response to warnings issued by a CAS, and brief periods of driver inaction also have been modeled.

The CAS includes a sensor system that acquires the data required by the decision module of the system. The decision module then uses these data with available vehicle state information to determine whether the driver requires a warning. Several CAS methodologies have been proposed for studying ROR events. A detailed description of these methods and their benefits was included in [Pape et. al., 1995]. In the present study only the lateral, downward-looking system (TLC) was used. However, the methodology developed could be applied directly to evaluate other CAS methodologies.

The RORSIM package can simulate a complete driving scenario: a situation develops, it is sensed by the CAS, the driver responds to the warning and regains safe control of the vehicle. When applied in this manner, RORSIM is useful for demonstrating that a CAS can successfully prevent a ROR accident for a given driving situation.

MONTE CARLO SIMULATION TECHNIQUE - The scope of the RORSIM simulation studies was to conduct extensive parameter studies using a Monte Carlo like approach. This provided a more comprehensive characterization of the effectiveness of CAS schemes in incipient ROR events.

A statistical approach was used in which all the key parameters were varied simultaneously according to a scheme that ensured good coverage of the range and distribution of each parameter value. A scheme known as the "Latin hypercube" approach [Stein, 1987 and McKay et.al. 1979], essentially similar to but more efficient than a pure Monte Carlo approach, was used to generate the input variables for the simulation runs. The distributions for defining the various input parameters have been outlined in this section.

Latin hypercube sampling is a simulation procedure which is an appealing alternative to conventional Monte Carlo methods because it generally produces estimates with a lower variance than simple random sampling of input vectors. Latin hypercube sampling stratifies each marginal distribution of the input vector as much as possible but otherwise picks the vectors randomly. Approximately six hundred random input vectors, (i.e., values for vehicle speed, lane keeping performance amplitude, driver reaction time etc.), were generated using a series of Latin hypercube samples.

PARAMETER DISTRIBUTIONS - Table 1 lists the input parameters that were varied randomly by the Latin hypercube method. The range of values considered and corresponding distributions selected for each parameter have also been included. The distributions were selected based on reviews of existing literature, and standard highway design handbooks. A brief discussion on the selection of distributions for some of the key input parameters is presented below.

Table 1. Distributions of parameters for the Latin hypercube simulation studies

Parameter	Range of Values	Distribution
Roadway Curvature	250 ft, 500 ft, 1000 ft, 2000 ft, straight	Uniform
Lane Width	12 ft	Fixed
Road Friction	0-1	Beta
Shoulder Friction	0-1	Beta
Shoulder Rolling Resistance	0.015-0.9	Log normal with an offset
Vehicle Speed	(30-110) feet/second	Normal
Driver Lane-Keeping Performance	0.1-0.35	Uniform
Driver Reaction Time	0.01-2.0 seconds	Log Normal
Driver Aggresiveness of Response	0.4-2.5	Uniform
Initial Time of DriverInattentiveness	2-17 seconds	Uniform
Duration of Driver Inattentiveness	2.2 - 13.2 seconds	Uniform
TLC Threshold	-0.6, 0.0, 0.6, 1.2, 1.8 seconds	Fixed for each run
CAS Accuracy	0.0, +/-0.25, +/-0.5, +/-1.0	Uniform

<u>Roadway Design and Vehicle Speed</u> - Nine different roadways were adopted for these studies. These included a straight road and roads with left-hand and right-hand curvatures of 250 ft, 500 ft, 1,000 ft and

2,000 ft. The curved road consisted of a straight section followed by a curved section with entry and exit spirals. Vehicle speeds for each road design were normally distributed with a standard distribution of 3 fps. The mean speed on the tighter curves (250 and 500 ft radius) was 10 percent above the rated speed, determined using AASHTO guidelines, [AASHTO, 1994]. The mean speeds on the remaining curves were selected to provide reasonably uniform coverage over the entire range of speeds.

Driver Lane Keeping Performance - This feature was modeled by applying a randomly-varying lateral wind force. The vehicle path approximates the paths followed by drivers in real vehicles. Higher amplitudes were used to model drivers who, for one reason or other, do not follow as straight a path as others.

Driver Aggressiveness of Response to Alarm - This driver is characteristic was modeled by changing the gain in the steering feedback loop after the alarm. A high multiplicative factor corresponds to a driver who panics when an alarm is issued and over corrects. A lower factor represents a driver who responds more sluggishly to an alarm. This effect was applied in addition to the steering reaction time which is a delay between the alarm and the driver's beginning of response.

For each curved roadway, assuming a constant speed of travel, the time of onset of driver inattentiveness and the duration of inattentiveness were selected to ensure that a ROR event can occur in any portion of the roadway with uniform probability. This allowed for the possibility of a ROR event on entry and exit spirals as well as curved sections of roadways.

EFFECTIVENESS MEASURES

The primary function of RORSIM for these studies was to estimate CAS effectiveness for a wide range of driving scenarios. To serve this function a suite of normal driving cases was selected. In each case driver inattention was imposed to generate potential run-off-the-road events. The effectiveness of the CAS was evaluated by studying the same scenarios with and without CAS protection.

RUN-OFF-ROAD CRITERIA - A key issue in the development of an effective ROR countermeasure system that is not overly restrictive or annoying is the establishment of limits of acceptable vehicle excursions. Perhaps the least ambiguous but most restrictive ROR criterion is any situation in which at least one tire crosses over the lane edge. This criterion, which for the purposes of this study is defined as the "1-Tire ROR Criterion" implies that it is unsafe for the vehicle to use any part of the shoulder or adjoining lane during normal driving or for maneuvering to avoid a potential accident. This criterion is particularly relevant to situations where no shoulder exists (e.g., under bridges or through construction zones).

A more forgiving ROR criterion is one that allows excursions of the vehicle onto the shoulder (e.g., "lane-cutting" during curving). This "2-Tire ROR Criterion" defines a ROR as an event in which both front tires are outside the original lane of travel and permits more vehicle lateral excursion before the result is considered to be an ROR event.

PERFORMANCE CRITERIA - A CAS must be extremely reliable and at the same time must not be a nuisance to the driver. The performance criteria for the CAS address these issues. Post processing of the data obtained from the Latin hypercube simulation runs reveals a wealth of information. This information can be tested against the performance criteria defined in this section to evaluate the overall effectiveness of the system.

Each pair of simulations (one situation with and without CAS assistance) was categorized as one of six outcomes to determine the effectiveness of the CAS system:

Safe Correct Detection (SCD) - The system issued a warning of an incipient ROR situation. In response to the warning, the driver maneuvered the vehicle, avoiding a ROR situation.

Late Correct Detection (LCD) - The system issued a warning of an incipient ROR situation. In response to the warning, the driver maneuvered the vehicle, resulting in a ROR situation.

Missed Detection (MD) - The system failed to issue a warning of an incipient ROR situation.

Correct Non Detection (CND) - The system did not issue a warning and none was required.

Safe False Alarm (SFA) - The system issued a warning, when there was no incipient ROR situation. The driver maneuvered the vehicle, and no ROR occurred.

Unsafe False Alarm (UFA) - The system issued a warning when there was no incipient ROR situation. The driver, overreacting to the alarm, drove the vehicle off the road, causing an ROR event.

The simulation cases were designed so that the driver could react to a warning only during an inattentive period. Thus, LCDs and UFAs were possible only during the inattentive period. Further, MDs were possible only (1) if the CAS was not perfectly accurate or (2) if the TLC threshold was set to a negative value (corresponds to a case where an alarm is issued only after the vehicle is paretically off the road).

RESULTS

Each of the 591 ROR test cases was run with an operating CAS, and the characteristics of the CAS were varied to evaluate the influence on its effectiveness. Five thresholds of the system were tested, each with seven levels of error in the sensor, (including a 0 CAS error case). Note that the negative 0.6 TLC case corresponds to 0.6m distance beyond the lane edge. The results have been plotted a number of ways to study different trends, but the basic question underscoring the analysis is whether the vehicle in a particular simulation left the 12-ft lane, and if so, by how much. In all the figures, the performance of the TLC-based CAS is compared to that for the Sonic Nap Alert Pattern (SNAP), a "rumble strip" feature that has been implemented by the Pennsylvania Turnpike Commission. The SNAP feature is installed just inside the roadway shoulder and in the plots corresponds to a TLC of -.25m.

INFLUENCE OF TLC THRESHOLD - Cumulative Frequency Distributions (CFDs) of maximum lateral excursion are shown in Figure 1 for inattentive driver cases without a CAS and with a CAS with TLC thresholds set at several levels. As shown in this figure, the presence of the CAS generally reduces the population of large vehicle lateral excursions. For example, about seventy five percent of the maximum lateral excursions for the cases without a CAS were above 10 feet. In contrast, only about 10 percent of the cases were above 10 feet using a CAS with a TLC threshold of 1.8 seconds, and the percentage of these cases increased with decreasing TLC threshold. These results provide a good first indication of the potential of a CAS in reducing ROR events by limiting vehicle lateral excursions.

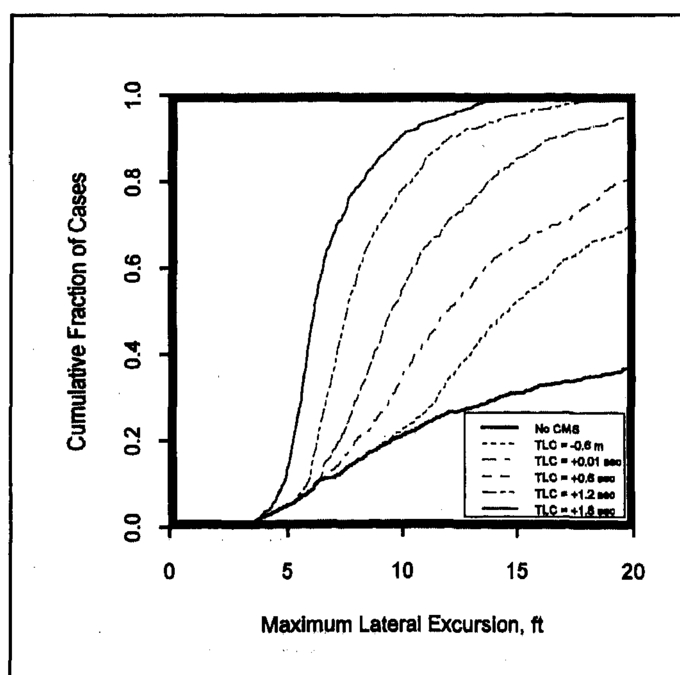

Figure 1. CFDs of maximum lateral tire excursion for inattentive driving with a CAS set at several TLC threshold levels

Lateral position of the front tire is plotted against the different TLC thresholds in Figure 2 at the 50th percentile levels, along with 90% confidence limits. The tight confidence intervals indicate that using sets of 591 simulation cases in this study was sufficient to provide good esttimates of the lateral excursoins. The percentile curves are compared with the no CAS assisted cases in Figure 2, indicating the substantial decrease in maximum lateral excursion levels caused by using the CAS. Also indicated in the figure are the lateral deviations that correspond to the case when 1 tire or both tires are on the shoulder. It is clear that sufficiently high TLC thresholds are required to ensure that not even 1 tire will stray onto the shoulder.

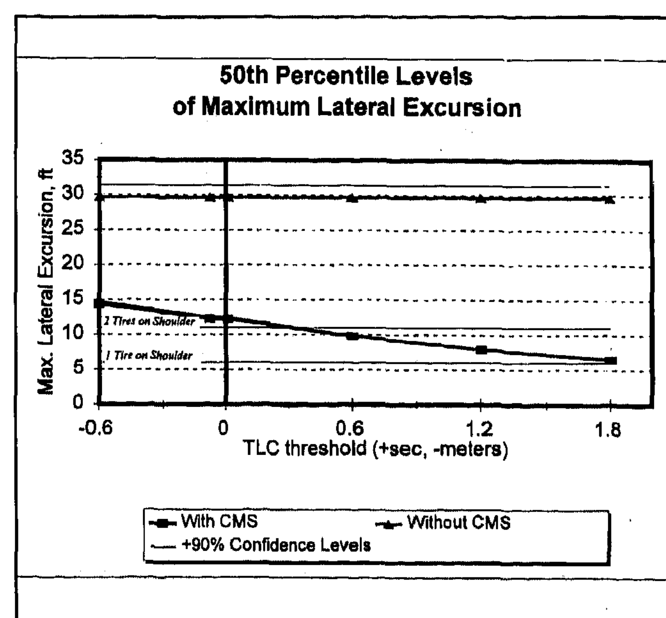

Figure 2. Influence of TLC threshold on 50th percentile values of maximum lateral excursion with 90 percent confidence levels (The very high excursions are only for comparison. The vehicle is well beyond the shoulder when the excursion is more than about 20 ft.)

INFLUENCE OF ROR CRITERION - Both the "1-Tire" and "2-Tire" ROR Criteria were applied to evaluate CAS effectiveness. The results of this exercise are summarized in Figure 3.

In Figure 3, the fraction of cases with maximum lateral excursions exceeding 6 ft (1-Tire ROR Criterion) and 11 ft (2-Tire ROR Criterion) are plotted versus TLC threshold. For comparison, the fraction of cases that exceeded these levels for inattentive drivers without a CAS are shown. The results imply that the perceived effectiveness of a CAS depends strongly on how a ROR event is defined.

Figure 4 highlights the influence of shoulder widths on CAS performance. The percentage of ROR events prevented at different TLC thresholds have been shown for 3 different shoulder widths. The 13 ft shoulder is the nominal shoulder width adopted by the

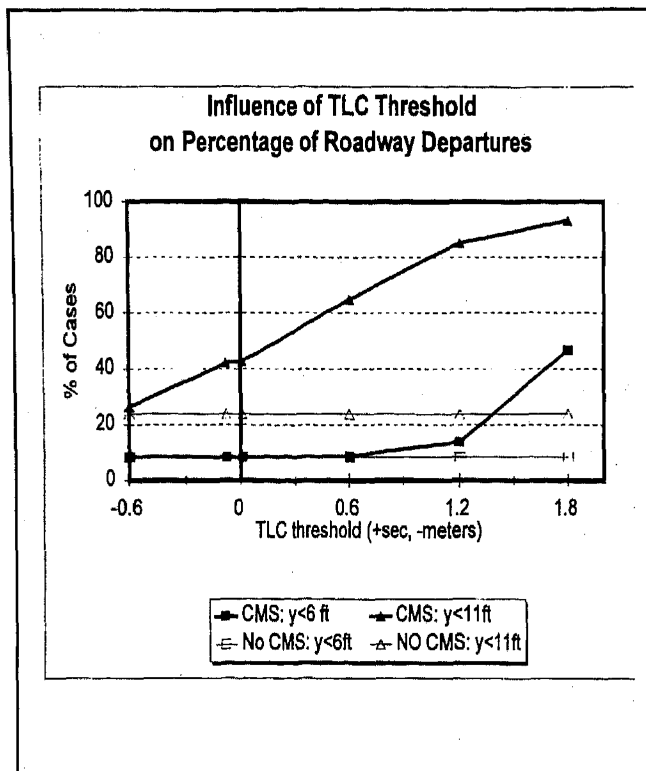

Figure 3. Influence of TLC threshold on CAS performance - comparison of roadway departures based on 1-tire and 2-Tire ROR criteria

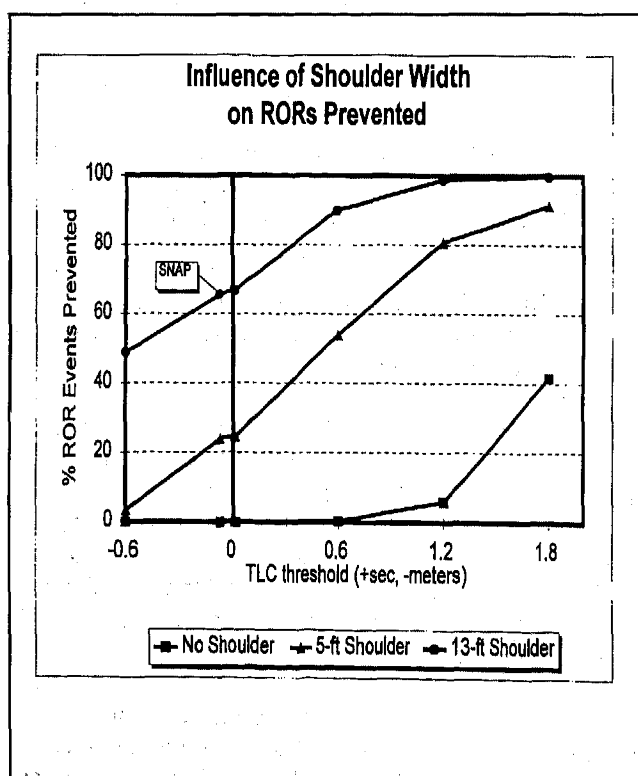

Figure 4. Influence of shoulder width on ROR events prevented at different TLC threshold levels

Pennsylvania Turnpike Commission. As expected the number of ROR events prevented shows a marked with the increase in width of the shoulder. If the driver is allowed to use the shoulder to maneuver the vehicle to avoid a ROR event, then the CAS can be credited with many more ROR preventions compared to a policy of defining any instance of a tire on the shoulder as a ROR event.

Additional results based on application of the 2-Tire ROR Criterion are shown in Figures 5 and 6. In Figure 5, the percentage of ROR cases involving Safe Correct Detects, Late Correct Detects and Missed Detects are plotted as a function of TLC threshold. In Figure 6, the percentage of non-ROR cases involving Safe False Alarms, Unsafe False Alarms and Correct Nondetects are plotted as a function of TLC threshold. As indicated in these figures, the percentage of Safe Correct Detects increases monotonically with increasing TLC threshold, while the percentages of Late Correct Detects and Missed Detects decrease. However, this beneficial trend of increasing Correct Detects is offset by an increase in the percentage of False Alarms (and corresponding decrease in Correct Nondetects). These results stress the need for careful optimization of a CAS to provide the best combination of high correct detections, tolerable false alarm rates and minimal missed detections.

The effect of road curvatures on CAS effectiveness can be seen in Figure 7 which shows the percentage of ROR events prevented for curved, straight and all roads(selected for the study). The percentage of ROR events prevented is higher in the straight than curved roads for higher TLC thresholds. This study

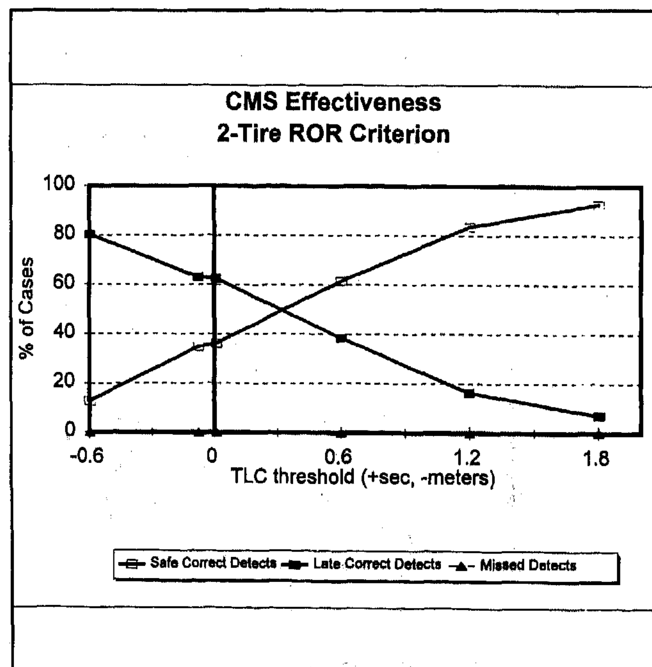

Figure 5. Influence of TLC threshold on CAS performance - comparison of safe and late correct detections and missed detections based on the 2-Tire criterion

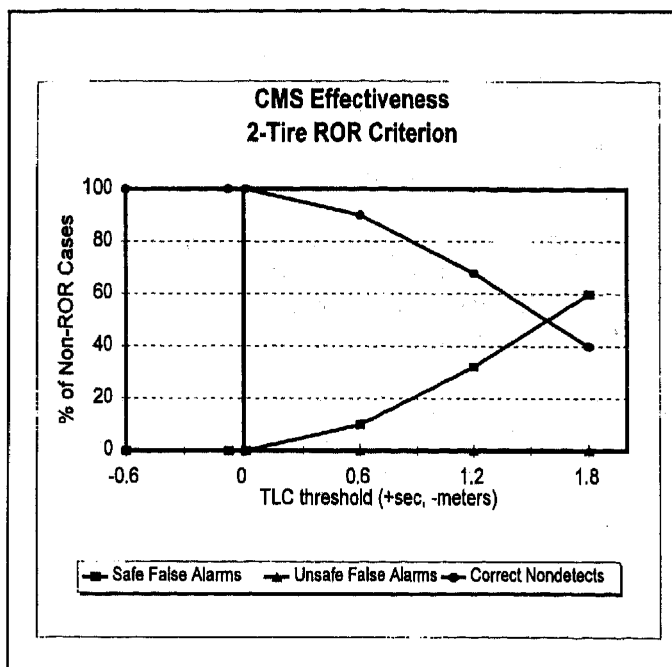

Figure 6. Influence of TLC threshold on CAS performance - comparison of false alarms, detections and non-detections based on the 2-Tire criterion

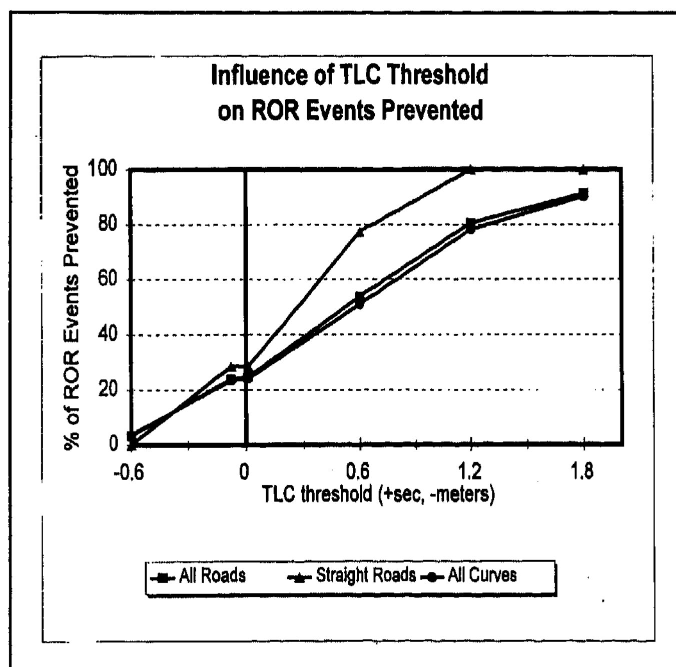

Figure 7. Comparison of CAS performance for different TLC thresholds for straight and curved roads

involves steering control of the vehicles in response to a ROR warning. Future studies reflecting a combination of steering and throttle control should mitigate the speed-curvature effects on CAS effectiveness.

Several thousand simulations were also run to evaluate the influence of CAS accuracy on CAS effectiveness. The studies revealed that lane postion sensors with errors under 6 inches caused no appreciable change.

The TLC based electronic CAS shows consistently better effectiveness than the SNAP system for thresholds greater than 0. This indicates that a CAS with a properly selected TLC threshold could potentially prevent more ROR accidents than such a rumble strip feature, primarily because a CAS provides an earlier warning of incipient danger.

Conclusion

The following conclusions have been drawn from the results of the foregoing simulation studies:

1. The CAS configuration evaluated in the studies showed considerable potential for effectively reducing a vehicle's probability of a ROR accident compared to a vehicle not equipped with a CAS.

2. The TLC method for warning of incipient ROR conditions is effective and is relatively insensitive to errors in lane position measurement (bias) error. A TLC threshold level in the range 1-1.4 seconds may have the most overall effectiveness.

3. The effectiveness of a CAS depends strongly on the amount of clear shoulder available for maneuvering. Therefore, the reported effectiveness depends on the criterion used to define a ROR event. The results of this study indicate that the CAS is much more successful (on the basis of accidents prevented) if instances of the vehicle riding partly on the shoulder are not considered as a ROR event. That is, if the driver is allowed to use some of the shoulder to maneuver the vehicle back into the lane, the success of the CAS is quite good. This strongly suggests the need for information on available shoulder widths, the presence of culverts and overpasses, etc., in order to ensure that proper ROR warnings are issued to the driver on a site-specific basis. In cases where obstacles are unusually close to the lane edge, an occasional early warning would be appropriate.

ABSTRACT

This document presents preliminary guidelines for a forward looking collision warning system. The intent of a forward looking collision warning system is to eliminate or mitigate vehicular rear-end collisions through driver notification or warning. All aspects of performance are addressed including general system requirements, driver / vehicle interface methodology, collision dynamics, standardized testing and estimation of associated benefits.

This guideline is intended to be used by manufacturers and developers of vehicular based forward looking collision warning systems as a tool to 1) standardize system requirements; 2) standardize driver interface and control among systems developed by different manufacturers; 3) standardize testing to be used in verifying proper operation of the forward-looking collision warning systems and; 4) measure the system benefits prior to widespread deployment of such systems.

PREFACE

The document that follows presents preliminary performance guidelines for forward-looking collision warning systems to improve vehicular safety by eliminating or mitigating rear-end collisions through driver notification or warning. Numerous variations exist within this category such as adaptive cruise control, automatic collision avoidance, and driver warning system types. This document is specific to those devices designed to detect potential rear-end collisions and provide a warning to the driver to avoid the collision. Automatic collision avoidance is excluded from the scope of this document, although some braking of the vehicle is allowed to provide a warning to the driver. Automatic collision avoidance and adaptive cruise control are covered in separate guidelines being developed as part of the research on this contract.

This document represents the second generation of performance specifications associated with this forward-looking collision avoidance research. It represents a significant change in philosophy from the previous version that provided detailed parametric specifications for a forward-looking collision warning system. This change in philosophy is a result of a peer review workshop that was held in December 1995 to receive feedback from industry participants. The consensus was to provide guidelines associated with system performance rather than specifications. This and subsequent versions of the performance guidelines will focus on "what" the forward-looking collision warning system is supposed to do, but not "how" to do it.

The parameters specified within this document should be considered guidelines for acceptable performance. Since forward-looking collision warning systems are extremely complex, especially the man-machine interface, numerous tradeoffs exist that allow the system designer to balance performance over variations in system parameters. System performance that deviates from these guidelines may degrade system effectiveness.

Numerous technical details, beyond the scope of this research must be resolved before a cost effective forward-looking collision warning system can be deployed. The technology required for a forward-looking collision warning system has relatively recent origins in expensive military hardware but must be made very low cost and reliable for entry into the vehicular market.

The major key to success of a forward-looking collision warning system is the man-machine interface. User acceptance is critical to gaining the publics trust of these systems. Technical problems can eventually be overcome but it is impossible, and not very cost effective, to determine all associated driver responses to a properly designed system. A great deal of time and effort has been expended to research the basis of the driver warning methodology presented within this guideline. The results are intended to be broad enough to allow vehicle manufacturers latitude in creating warnings / displays that are acceptable to both vehicle manufacturer and buyer. However, they must be restricted enough to make forward-looking collision warnings salient and unique and at the same time prevent them from interfering with warnings from other systems. Coupling a forward-looking collision warning system with an adaptive cruise control system may be one way to boost public acceptance of this technology.

One result discovered in developing these guidelines was the need for additional research as well as limited deployment of these types of systems to gain real world data. Very little empirical data is currently available to assess wide spread user acceptance of such devices. This should be the focus of future effort: gathering long term data and assessing user acceptance as well as aiding near term deployment.

In developing these guidelines, extensive mathematical modeling and simulation was performed specifically for rear-end collision avoidance. These mathematical models and simulations form the basis for much of the information presented, especially in the area of benefit estimation. Additional research under this contract will verify and refine the models with on-road testing using a test bed system. The simulations will then be re-run and this document updated. Once completed,

additional peer review workshops will be held to discuss the results with industry participants and receive feedback as to the utility of the guidelines.

The guidelines presented herein, allow for both cooperative and autonomous systems as long as the required information can be received, processed and the driver warned in a timely manner. Current industry focus is primarily on autonomous systems.

INTRODUCTION

This document establishes the performance guidelines for a forward-looking collision warning system for improving vehicular safety. A forward-looking collision warning system assists the driver in avoiding or mitigating rear-end collisions. A rear-end collision is defined as a two or more vehicle collision in which vehicles are moving in the same direction prior to the collision or one in which the struck vehicle is stationary.

PURPOSE

The purpose of this document is to present preliminary guidelines for a forward-looking collision warning system for improving vehicular safety.

OBJECTIVE

The objective of a collision warning system following these guidelines is to reduce deaths, injuries and economic losses resulting from rear-end collisions. This is accomplished by aiding in development of forward-looking collision warning systems. This document establishes the necessary system parameters as an aid to system designers and manufacturers of forward-looking collision avoidance systems. This document is intended to provide a standard for driver interface and control aspects of the forward-looking collision warning system and a set of test scenarios to be used to judge the ability of a particular system to meet the guidelines contained herein. A methodology to estimate overall effectiveness and associated benefits of a forward-looking collision avoidance system is also included.

SCOPE

This document presents preliminary performance guidelines for forward-looking collision warning devices to improve vehicular safety by eliminating or mitigating rear-end collisions through driver notification or warning. Numerous variations exist within this category such as adaptive cruise control, automatic collision avoidance, and driver warning system types. This document is specific to those devices that detect potential rear-end collision circumstances and provide a warning to the driver to avoid the collision. Automatic collision avoidance is excluded from the scope of this document, although some braking of the vehicle is allowed to provide warnings to the driver.

BACKGROUND

According to data from the General Estimates System (GES) and Fatal Accident Reporting System (FARS) databases, rear-end collisions are the second largest single category of collisions. They represent 23% of all collisions, 1.45 million per year out of 6.26 million police reported crashes per year. In greater than ninety percent of rear-end collisions, driver inattention/distraction and/or following too closely were contributing factors. This information leads to the conclusion that a forward-looking collision avoidance system should be beneficial in reducing the total number of vehicular crashes and that a system that aids the driver's capabilities, by giving a warning of an impending collision situation or maintaining a safe headway for example, could provide this service.

LIMITATIONS

To the greatest extent possible, the guidelines presented herein are based on empirical research data, detailed modeling and simulation, and discussions with industry experts and/or system developers. Because the basis for this type of research is relatively new and this is the first publicly funded program of this type, the basis for many guidelines is simply sound engineering and/or human factors judgment. Additionally, since this research is a bridge from concept to prototype realization, little data is available to verify the wide spread deployment issues associated with these types of systems.

GUIDELINES

This section presents the guidelines for a forward-looking collision warning system. The guidelines are operating performance parameters that should be included as part of the system. The need for a forward-looking collision warning system is based primarily on driver inattention. However, following too closely is a secondary causal factor. Therefore, the guidelines presented herein contain an inattentive driver warning system that warns the driver of potential crash situations **and** a following-too-closely warning system that provides situational awareness to the driver for following too closely situations and attempts to modify driver behavior to provide a safer driving environment.

A block diagram of a representative forward-looking collision warning system is shown in Figure 1. The forward looking collision warning system uses a forward looking sensor to detect vehicles or objects in the forward path. A collision warning algorithm processes the raw sensor input and determines if a collision threat exists, and if so, warns the driver.

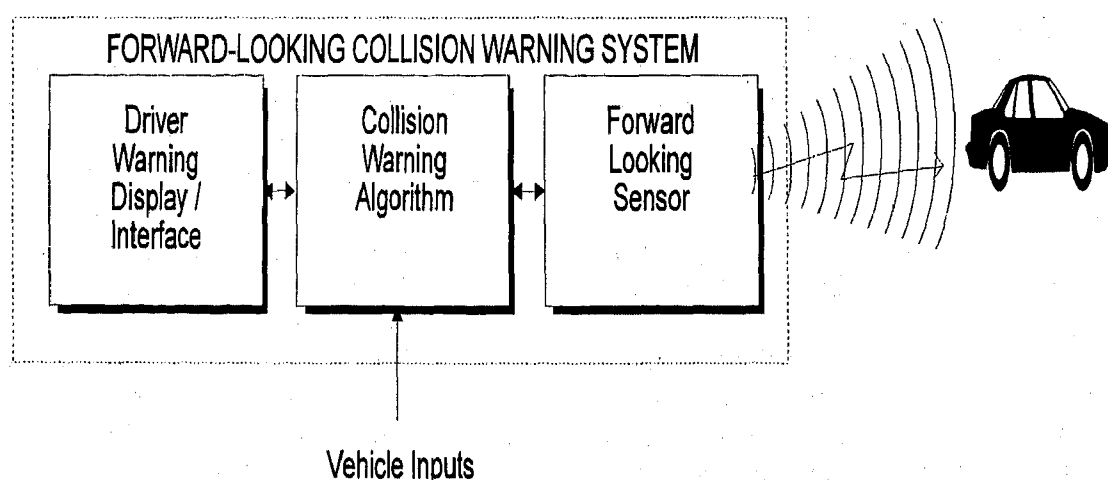

Figure 1 Driver Warning System Block Diagram

SYSTEM GUIDELINES

The system guidelines are those guidelines that are key to bounding the overall system operating environment but do not include issues of driver interface or driver control.

Moving versus Stationary Targets -- A forward-looking collision warning system must detect and warn the driver for all kinematics and dynamics of the host and

lead vehicles especially, stopped vehicles in the forward path. Most rear-end collisions (approximately 70%) occur with the vehicle in the forward path stopped while the remainder occur with the vehicle in the forward path moving (decelerating, constant slower speed, etc.). The ability to detect and warn the driver for stopped vehicle scenarios is the main parameter that distinguishes a forward-looking collision warning system from other types of systems. Other systems such as Adaptive Cruise Control are able to sense stopped vehicles, but ignore these stopped vehicles in order to provide smoother longitudinal control of the host vehicle.

Vehicle Types -- The forward-looking collision warning system shall detect all licensable vehicles. Because of the statistical nature of the forward-looking collision warning system, it is unrealistic to require the system to detect all licensable vehicles at maximum range. This is due to the potentially small "effective" cross-sectional area of some vehicles, such as motorcycles and sports cars. However, the forward-looking collision warning system must detect and react to low cross-section targets to the greatest extent possible. The system must be constructed to allow detection of all licensable vehicles at some (unspecified) range.

It is unrealistic to require each system be tested against every vehicle type for system verification and qualification. Therefore, for qualification testing, representative vehicles shall be used as standard targets.

Acquisition Range -- The forward-looking sensor acquisition range should be ≥ 130 meters. The minimum range at which the forward-looking sensor acquires targets should be 2 meters. The acquisition range is defined as the point at which a vehicle in the forward path has been detected reliably enough to permit tracking. An acquisition range of ≥130 meters is recommended because a system effectiveness of 98% is sufficient to eliminate or mitigate most collisions as shown in the section on benefits estimation. No statistical data exists for minimum acquisition ranges, although a large number of rear-end collisions are known to occur at low velocities and short ranges. As a guideline, the minimum acquisition range should be no greater than two meters. Care must be taken to ensure that the acquisition range is not degraded due to mud, dirt, snow, etc., on the sensor aperture.

Limitations in acquisition range will allow drivers to "drive beyond the sensor limit" of the forward-looking collision warning system. The worst scenario for this problem is the lead vehicle stopped scenario. For example, with a 0.9 second warning time and the host vehicle traveling at 96 kph (60 mph) the required warning distance is 131 meters. The ability to drive beyond the sensor limit may warrant a warning to the driver.

Horizontal Field-of-Regard --The collision warning sensor should have a minimum of ± 8° horizontal field of regard. This is necessary to prevent crashes due to roadway curvature and horizontal field of view limitations. To minimize nuisance alarms from vehicles in adjacent traffic lanes, parked vehicles, roadway signs, etc., the horizontal resolution needs to be fine enough to discriminate vehicles in adjacent lanes out to the acquisition range of the system. For the forward-looking collision warning system to function effectively, it must be capable of reacting properly to vehicles in

the forward path on curves. By providing this capability, the number of nuisance alarms received by the driver should be reduced in relation to curved roadways. Also, a number of rear-end collisions (approximately 9%) occur on curves and a system that ignores road curvature will have a resulting decrease in system benefit. Due to the statistical nature of forward-looking collision warning systems, it will not be possible to respond properly to all curved road scenarios. The guideline of at least ±8° should provide for 97% sensitivity in system effectiveness to horizontal field of view limitations and road curvature, see Figure 6. Scenarios on curves greater than the horizontal field of regard will manifest themselves as late alarms to the driver. This still provides an opportunity for collision mitigation, but will lower system effectiveness.

Vertical Field of Regard -- The driver warning sensor should have a nominal ±2.5° to ±3.5° vertical field of regard. The vertical field of regard was selected to provide 97% sensitivity in system effectiveness to changes in roadway grade and vehicle pitch, see Figure 7. A vertical field of regard of ±3.5° may not be feasible due to the problem of detecting overhead objects as threats. This problem may be eliminated with the system having some vertical *resolution*, but this may not practical with certain sensor technologies. Current knowledge indicates that the forward-looking collision warning system must have some vertical field of regard to respond to changes in roadway grade and vehicle pitch. A minimum vertical field of regard should be ±1° to ±1.5°.

Collision Warning Methodology -- The forward-looking collision warning system must provide a suitable warning to the driver. At a minimum, an inattentive driver warning must be included. A following-too-closely warning would also be beneficial (refer to the Section on driver warning). Rear-end collisions occur for various reasons. The primary reason is due to the driver being inattentive to the driving task (approximately 77% to 84%). The secondary reason is due to the driver following too closely (approximately 7% to 18%). Other rear-end collisions (approximately 4%) are due to vehicle failure, seizure, etc., and are considered unavoidable. A forward-looking collision warning system must provide a suitable warning for the inattentive driver. If the forward-looking collision warning system only contains an inattentive driver warning then the corresponding system effectiveness is reduced (by 7% to 18%). By including a following-too-closely warning the system effectiveness can be improved. Therefore, these guidelines are structured to provide two types of warnings to the driver. First and most important is the inattentive driver warning (see the Section on driver warning). Second, a following-too-closely warning that provides situational awareness feedback to the driver is an attempt to modify driving behavior by creating safer following distances.

Driver Warning Time -- Refer to the Section on driver warning for a discussion of the driver warning time. The warning should be based on range, relative speed and host vehicle absolute speed. It is difficult to provide more than basic guidance to driver warning time at this point in the research. Human factors testing in conjunction with forward-looking collision warning systems must still answer a number of questions prior to providing a sound basis for driver warning time. Testing performed to date in conjunction with this

guideline has shown significant increase in benefit based on **when** the driver is warned prior to collision. The more conservative the warning, the more drivers will find the warning to be a nuisance, and thus lower overall user acceptance and system effectiveness. Additionally, drivers react differently to different types of scenarios which may require different warning times for lead vehicle decelerating, lead vehicle stopped, etc.

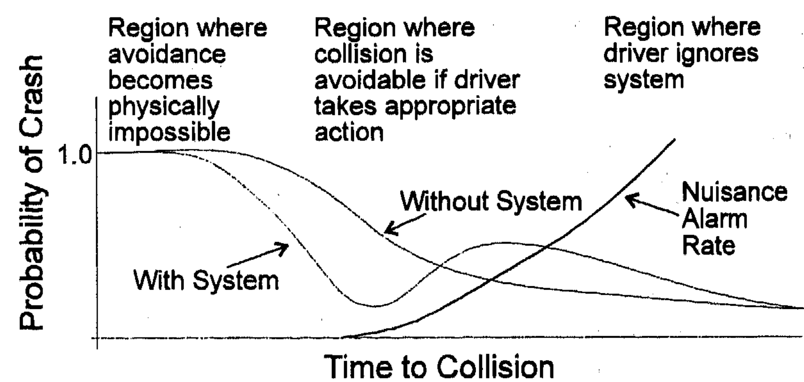

Figure 2 Diminishing Likelihood Curve

The diminishing likelihood curve shown in Figure 2 represents the probability of crash in comparison with the time to collision. In any circumstance there is a region where the collision is physically impossible. In this region, the probability of a crash approaches 1.0. Backing away (in time) from the collision there exists a region where the crash is avoidable if the driver takes appropriate action. The idea of the forward-looking collision warning system is to reduce the probability of a collision through driver notification as shown in the figure. However, if the warning to the driver occurs too far from the potential collision the driver will consider the warning a nuisance and the driver's overall reliance on the system will diminish and/or the probability of a crash will increase with the system. On-going research is attempting to quantify this curve for various collision scenarios.

System Delay Time -- The recommended system delay time is 300 milliseconds or less. System delay time is defined as the time required for the system to determine an object is present in the forward path (acquisition) and warn the driver by changing the status of the warning indicator. The system delay time contains the processing delay time (acquisition and track initiation, state estimation, warning algorithm) and the time required to change the status of the warning indicator. For scenarios where the lead vehicle is acquired at long range (either straight line or curves) longer system delay times can be compensated by longer acquisition ranges or wider horizontal fields of regard (for curves). The area where the system delay impacts overall effectiveness is in lane change and merging situations where lead vehicles are in relative close proximity and warning the driver of collision threats must occur quickly. System delay times that are greater than 300 milliseconds may cause a reduction in overall system effectiveness.

Atmospheric Conditions -- The driver warning system should function properly during varying environments such as rain, road spray, snow, fog, etc. As drivers begin to rely on the system, it is necessary that the system (either directly or through secondary systems) be able to detect when its sensing capability has degraded and inform the driver that the system is not operating properly.

Atmospheric Conditions are highly correlated to roadway conditions. It is anticipated that as roadway conditions degrade that the overall system effectiveness will degrade due to the associated longer stopping distances, independent of the forward-looking collision warning system performance degradation. Unless the system has the ability to detect and compensate for the roadway condition, system effectiveness will likely degrade.

Electromagnetic Compatibility / Electromagnetic Interference -- Other unrelated, non-safety, systems must not emit electromagnetic interference that would interfere with the operation of the forward-looking collision avoidance system. The forward-looking collision warning system must be compatible with other forward-looking collision warning systems developed by different manufacturers (FCC part 15 rules). Other specifications may apply. The system shall comply with DHHS Rules 21 CFR Subchapter J. Other specifications may apply such as SAE J1113. Due to the safety nature of these systems, it may be necessary to require that other emitting devices, that are not safety related, not be allowed to produce harmful interference that would interfere with a forward-looking collision warning system. Not much emphasis is placed on EMI / EMC for the prototype systems being developed by various manufacturers. However, once these systems have been developed it is possible that EMI issues could prevent deployment. This may be especially true of optical systems that are not restricted to a particular bandwidth for the collision avoidance task.

Safety -- The system must pose no threat to human safety and must meet or exceed all regulations for the provided technology.

IEEE *Standard for Safety Levels with Respect to Human Exposure to Radio Frequency Electromagnetic Fields, 3 KHz to 300 GHz*, IEEE, C95.1-1991

DRIVER WARNING

Standard driver displays are desirable to prevent confusion by the driver when using systems from different manufacturers. The methodology used to communicate with the driver is of paramount importance. The quicker the system can direct the driver's attention, and the faster the system can get the driver to respond the better the overall system effectiveness. All of the benefits of implementing a forward-looking collision warning system could be lost on a poorly designed driver interface.

It is important to understand that rear-end collision have two primary types of causal factors: inattention and following too closely. Primary focus is on the inattentive driver since they constitute a larger overall problem (approximately 77% to 84%), but ignoring the following too closely

(tailgating) driver also ignores a portion of the rear-end problem (approximately 7% to 18%). Therefore, the system described and recommended within this guideline consists of two separate warning systems, one for the inattentive driver and one for the following-too-closely driver.

Inattentive Driver Warning -- The recommended inattentive driver warning is haptic (tactile or proprioceptive). This imminent warning should utilize braking initiation with a high jerk rate limit and a moderate deceleration level. An imminent collision warning is defined as requiring an immediate vehicle control response or modification of a planned response in order to avoid a collision. Because of the inattentive nature of the driver that is typical at the point of the warning, it is necessary to design the warning to grab the driver's attention quickly. Haptic or auditory alerts are the only sensory inputs capable of communicating with an inattentive driver. The haptic alert is recommended because it can grab the driver's attention and begin to slow the longitudinal progress of the vehicle with a single warning. Any alert modality will cause a delay in driver response due to driver perception and reaction. By using braking initiation, some of this delay can be overcome with the deceleration component of the warning. Auditory alerts are not recommended. However, if the warning is auditory it should emanate from the front of the vehicle to draw the drivers' attention toward the hazard. It should also be unique and salient and separate from all other displays especially other collision warning displays. An auditory display shall override the background noise level and be uniquely identifiable from other sound sources. User acceptance for auditory warnings is considered low, and may not be uniquely identifiable when other collision warning systems are present on the vehicle. A visual display can provide no warning benefit to the inattentive driver. A visual display can be used to provide feedback to the driver that the warning is not a malfunction of the system or vehicle. Jerk rate limit equates to a delay in actuation and therefore a high value is specified. Work is progressing on quantifying driver response to jerk rate limit and deceleration value. For this preliminary research, the following limits are defined:

Deceleration Level	Deceleration Value (g's)	Jerk Rate Limit (m/s³)
Low	$\alpha \leq 0.15$	$\beta \leq 35$
Moderate	$0.15 < \alpha \leq 0.3$	$35 < \beta \leq 75$
High	$\alpha > 0.3$	$\beta > 75$

A cautionary collision warning is defined as requiring immediate attention from the driver and which may require a vehicle maneuver, but which does not meet the definition of an imminent collision avoidance situation. A "following-too-closely" warning can be considered a cautionary warning for the inattentive driver. If a following-too-closely warning is not available then the system should have a cautionary warning. For this cautionary warning display it is recommended that a push-back accelerator pedal be utilized. A "push-back" accelerator pedal resists the

force placed by the driver on the accelerator pedal. This force informs the driver that he/she is driving too close to the vehicle in front, but does not prevent the driver from overriding.

Future vehicles may include a number of collision warning systems such as: rear-end, backing, side-looking, etc. It will be necessary for the driver to be able to automatically distinguish the rear-end crash warning from another warning type. For this reason, it is desirable for the haptic queues to be restricted to longitudinal haptic queues. The imminent warning using braking initiation is desirable since it tends to increase overall response to the collision by initiating vehicle braking. Braking initiation not only draws the driver's attention, but provides the driver with guidance to a desirable response. The braking initiation should be restricted to approximately moderate values (justification currently being researched). Higher values of braking initiation are possible but this begins to get into the realm of collision avoidance. The intent of the braking initiation for these guidelines is to provide the driver a warning and a suggested course of action. Haptic warning queues are recommended over auditory warning queues based on studies of user acceptance because haptic warning queues do not alert passengers in the vehicle to errors in judgment by the driver. The "push-back" accelerator pedal provides good system feedback to the driver with the ability for the driver to ignore and override the warning. Auditory displays must be easily separable from background noise for the driver. It may be difficult for the auditory warning to be distinguished over background noise without startling the driver.

If the collision warning system employs active deceleration (braking initiation) as a haptic warning to the driver, then the system should illuminate the brake light when the deceleration system is active.

Inattentive Driver Warning Time Model - The driver of the system should be warned when an imminent collision threat exists. The warning time should be based on range to vehicles (objects) in the forward path, relative speed (range rate) and host vehicle absolute speed. The driver should be warned in response to the vehicle that presents the highest threat of collision. Refer to the Section on driver warning for a discussion of the driver warning time. Without a warning, a driver is in jeopardy of becoming inattentive and having a collision. Studies have shown that any warning will tend to increase the driver's perception time. A warning must be processed by the driver before the driver can react. This adds a finite amount of delay to the driver's reaction. A properly timed warning can actually decrease driver reaction even with the resulting increase in driver perception time.

Following-too-Closely Display -- A Following-too-Closely display should provide the driver situational awareness for tailgating scenarios. It is not the intent of this warning to provide the driver with an optimum following distance but rather make the driver aware of unsafe following (tailgating) situations. It is expected that the following-too-closely warning will be relatively conservative in comparison to the inattentive driver warning. This may lead to an increase in nuisance alarms to the driver and may justify allowing the driver to turn off the following-too-closely warning. However, there is a corresponding reduction in system effectiveness if this feature is

allowed. This includes the ability to "dim" the display (assuming a visual display) along with the vehicle dash lights. These guidelines do not restrict the following-too-closely display from being adjustable by the driver. Again, this adjustability may cause lower overall system effectiveness.

The following-too-closely display can be visual, auditory or haptic. If the following-too-closely display is visual, then the following color codes should be utilized: Green shall be used for safe following distances, Orange, Amber, or Yellow for cautionary following distances and Red for unsafe following distances. The display may flash or vary in intensity when a collision becomes imminent. The visual display should be mounted to protrude above the dashboard slightly above the speedometer and be positioned within 15° of the driver's line of sight (this provides about 12-20 inches of margin for placement of the display in the dashboard). The visual display should be separate from all other displays and must be large enough with sufficient contrast and intensity for the driver to perceive the display in his or her peripheral vision. An example visual display is shown in Figure 3. If the following-too-closely display is haptic then it is recommended that a "push-back" accelerator pedal be used.

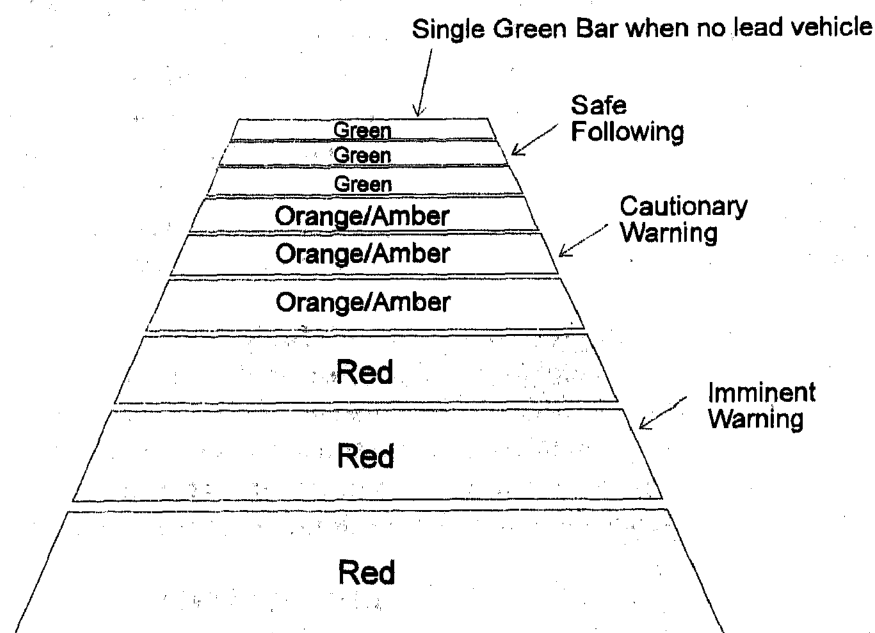

Figure 3 Example Following-to-Closely Visual Display

Following-too-Closely Warning Time Model -- The driver of the system should be made aware of following-too-closely situations. The warning time should be based on range and host vehicle absolute speed. Refer to the Section on driver warning for a discussion of the driver warning time. This warning should provide situation awareness to the driver and should be visual in nature.

Nuisance Alarms -- Nuisance alarms must be controlled to the greatest extent possible. Additional research, in relation to this contract, is being performed to quantify this requirement. Nuisance alarms are defined by efficacy rate. Efficacy rate is the number of times the system provides a true positive to the number of times that a signal is required according to the following table. Efficacy rate is also known as the hit rate and the complement is known as the "miss" rate.

System Response	Situations requiring a signal	Situations in which a signal is not required
Signal	True Positive (hit)	False Positive (false alarm)
No Signal	False Negative (miss)	True Negative

Nuisance Alarms are defined as false positive indications that occur when the system functions as designed but when the situation does not constitute a true crash threat for the driver in question. Conversely, false alarms are defined as false positive indications that occur when the system does not function as designed. From the driver's perspective, nuisance alarms and false alarms may appear to be the same but the causes and remedies are different.

Minimizing nuisance alarms is the key to user acceptance for forward-looking collision warning systems. It is not expected that nuisance alarms will ever be completely quantified because by definition, nuisance alarms are based on an individual drivers' driving behavior.

Additional Display(s) -- The forward-looking collision warning system may contain additional displays. If only haptic warnings are used, it is recommended that a visual status display be used to provide the driver feedback that the system is functioning properly. Additional displays may contain fault and/or status information as long as this information is separated from the warning display. It may be beneficial to warn the driver when driving beyond the sensor limit of the system by using a status display.

Icon -- Vehicles equipped with a forward-looking collision warning systems should display a unique and standardized symbol to inform the driver that the vehicle is so equipped. This icon should be different from ACC icons that may be present on the vehicle, or other types of collision warning system icons.

Fault Indication -- A fault indication must be presented to the driver when the system fails a self test, operational diagnostics test, or the sensor is unable to reliably detect vehicles in the forward path making the system inoperable.

DRIVER CONTROL

Standard driver controls should be used to avoid confusing the driver when using systems from different manufacturers.

Power-On Activation -- The driver warning system should power-on with application of ignition power. All other settings should be automatic. Under no circumstances should the driver have the ability to turn-off or disengage the imminent inattentive driver warning system. Drivers cannot be relied on to turn

on their collision warning devices each time they turn on the vehicle ignition. Therefore, the system should turn on automatically each time the vehicle is started. To prevent rear-end collisions, the inattentive driver warning must always be active. It is possible to allow the cautionary warning or the following-too-closely warning to be disabled, but again the result will be a lower overall effectiveness. The driver may forget that the system has been turned off and have a false sense of security about his or her driving behavior.

Warning Time Adjustment -- No adjustment of the inattentive warning time should be included with the system. By allowing the driver to adjust the warning time, it places the driver in the role of expert in knowing when the warning should occur. Current human factors testing of forward-looking collision warning systems shows that the inattentive driver warning should be based on an aggressive algorithm to improve driver response and reduce nuisance alarms. A warning time adjustment feature may be included as part of the cautionary warning or the following-too-closely warning. Under no circumstances should the driver have the ability to adjust the warning time below the minimum imminent warning time. If the driver was allowed to adjust the imminent warning time, below the minimum, the overall system effectiveness may be significantly reduced. Also,

DYNAMIC SITUATIONS

Dynamic situations describe the kinematics associated with longitudinal encounters with vehicles. Dynamic situations also provide a introduction and basis for the qualification testing. Two types of dynamic situations exist, one based primarily on the kinematics involved and the interaction of the two vehicles. Table 1 shows a matrix of lead and following vehicle dynamic situations. The fifteen dynamic situations consist of all combinations of five lead vehicle and three following vehicle kinematic situations. The system must meet the requirements of these guidelines under all kinematics of the host and target vehicle(s). The percentages shown are the actual occurrence of rear-end collisions as taken from an analysis of the 1992 National Accident Sampling System (NASS) Crashworthiness Data System (CDS).

Table 1 Percent of Rear-End Collisions versus Dynamic Situations

Lead Vehicle	Following Vehicle			Total
	Accelerating	Constant Velocity	Decelerating	
Stopped	1%	18%	1%	20%
Constant Velocity	2%	7%	0%	9%
Decelerating	0%	14%	3%	17%
Accelerating	0%	2%	0%	2%
Decelerating & Stopped	1%	50%	1%	52%
Total	4%	91%	5%	100%

The other type of dynamic situation is based on typical scenarios that lead to rear-end collisions. With each situation, an explanation of the system response is included.

No vehicles in the forward path -- The forward-looking collision warning system continually monitors the forward path of the host vehicle. No warnings are issued to the driver. The driver may be warned if he or she is driving beyond the sensor limit of the system, that is the absolute speed causes the warning distance to be beyond the acquisition range. Minimization of nuisance alarms in this situation is critical especially in relation to close proximity roadway objects and curves.

Vehicle in forward path, stopped -- If the range, relative speed and host vehicle absolute speed meet the warning criteria, then the driver is warned. This is a driver warning situation with a high relative speed between vehicles. Therefore, the warning system must warn the driver, the following-too-closely display may or may not be activated in this circumstance.

Vehicle in forward path, moving at the same speed -- The relative speed is assumed to be near zero and the following range short (tailgating). No driver warning is issued unless the relative speed causes an imminent collision warning. The cautionary collision warning may be used to provide the driver a warning for this circumstance. The following-too-closely display should be illuminated to inform the driver of the tailgating situation.

Vehicle in forward path, decelerating or decelerating to a stop -- If the range, relative speed and host vehicle absolute speed meet the warning criteria, then the driver is warned. This is a driver warning situation with a high deceleration rate possible between vehicles. Therefore, the warning system must warn the driver, the following-too-closely display should be activated if the driver was following too closely.

Changing Lanes -- If the lead vehicle speed is greater than the host vehicle's absolute speed, no warning is issued. If the range, relative speed and host vehicle absolute speed meets the warning criteria then the driver is warned. The following-too-closely display is illuminated if the criteria is met. In this scenario the driver's view may be blocked and the sensor's view may be blocked to the threat vehicle. This scenario may not allow sufficient time for an attentive driver to react and stop, or allow the system to warn the driver to avoid the collision. Certain kinematic situations exist with this scenario that may make the collision unavoidable, see the section on driver warning.

Vehicle merging into forward path -- If the lead vehicle speed is greater than the host vehicle's absolute speed, no warning is issued. If the range, relative speed and host vehicle absolute speed meets the warning criteria then the driver is warned. The following-too-closely display is illuminated if the criteria is met. This scenario may not allow sufficient time for an attentive driver to react and stop, or allow the system to warn the driver to avoid the collision. The sensor beam must be formed so as to allow for the earliest warning possible for this type of scenario. Certain kinematic situations exist with this scenario that may make the collision unavoidable.

QUALIFICATION TESTS

The following tests have been outlined to verify driver warning system operation in relation to the guidelines presented herein. A "black box" approach has been used to develop the qualification tests. This is to allow testing of "off-the-shelf" units instead of requiring the manufacturer to deliver a special unit for testing. Details of the qualification tests will be left to a separate document. Tests may be executed a number of times to judge system repeatability. Other requirements for testing are that the tests be relatively easy to perform and easily repeatable.

INTERFERENCE

The driver warning system shall comply with applicable standards for Electromagnetic Compatibility (EMC) and Electromagnetic Interference (EMI).

SAFETY

The system shall pose no threat to human safety and must meet or exceed all regulations for the provided technology. The directed energy from the sensor shall be measured and compared with the applicable standard(s).

STANDARD TARGETS

The guidelines are intended to be as technology independent as possible. As a result, test vehicles will be used as standard targets for the system under test. The following types of vehicular targets may be included: cars, light trucks, buses, heavy trucks, towed trailers, and motorcycles. These vehicle types will be detected and tracked without the requirement for special vehicle reflectors or an unreasonably high minimum cross sectional area. Additionally, the system may detect other objects in the forward path.

LONGITUDINAL PERFORMANCE

To execute the longitudinal performance tests, a measure of the absolute velocity of both vehicles as well as an independent measure of the range and relative velocity between vehicles will be required.

Inattentive Driver Warning -- The inattentive driver warning will be measured using a straight line approach to both stopped and moving lead vehicles. The host vehicle with the forward-looking collision warning system will proceed toward a lead vehicle traveling on a straight section of roadway. A measure of the range (distance in meters) at which the system warns the driver (both cautionary and imminent) will be obtained along with measures of absolute and relative speed for the two vehicles.

Following-too-Closely Warning -- The following-too-closely warning will be measured using a moving lead vehicle in a tailgating scenario. The host vehicle with the collision warning system will tailgate the lead vehicle traveling at a constant velocity. A measure of the range (distance in meters) at which the following-too-closely warning system warns the driver (both cautionary and imminent) will be obtained along with measures of absolute and relative speed for the two vehicles.

Range Resolution -- The ability of the forward-looking collision warning system to warn the driver on a smaller vehicle positioned behind a larger vehicle will be measured. This test will be performed in a manner similar to the inattentive driver warning test using a large lead vehicle (heavy truck trailer) stopped with a small vehicle (motorcycle) positioned behind the large lead vehicle. The tests will be executed without the small vehicle and then with the

small vehicle and the warning difference measured.

Angular Resolution -- The ability of the forward-looking collision warning system to not warn the driver while passing other vehicles will be measured. Using a straight section of three lane roadway, with the host vehicle occupying the center lane. Stopped and moving lead vehicles will be positioned one lane width to the right and one lane width to the left. The host vehicle will pass the lead vehicles and warning indications from the system will be measured.

CURVE PERFORMANCE

Horizontal Field-of-Regard Testing -- The performance of the forward-looking collision warning system will be measured on curves. Using a lead vehicle stopped, and a curve of known radius the inattentive driver warning will be measured.

Vertical Field-of-Regard Testing -- The performance of the forward-looking collision warning system will be measured on grades. Using a lead vehicle stopped, and a known change in grade the inattentive driver warning will be measured.

MERGE PERFORMANCE

The performance of the forward-looking collision warning system will be measured for merging scenarios.

System Delay -- The system delay of the forward-looking collision warning system will be measured. Using a blocking vehicle, a merging scenario will be scripted to allow the lead vehicle to "pop-up" in the warning range. The delay in warning from this scenario to the straight line scenario will be measured.

OTHER PERFORMANCE

Atmospheric Testing -- The performance of the forward-looking collision warning system will be assessed over varying atmospheric conditions. It is not possible or cost effective to measure system performance over varying atmospheric conditions. Therefore, no direct atmospheric testing will be performed. The manufacturer must provide evidence that the system performs well in varying atmospheric conditions.

Driver Interface -- The driver interface and the driver display to the system will be compared to this guideline for compliance. The intent is to keep a record of the system interface functions to determine what features may cause a detriment or benefit to overall safety. It is overly restrictive for this guideline to specify the exact nature of the driver interface. Many variations exist that should provide acceptable performance. The intent of this testing is to keep a record of interface characteristics to note any potential trends in safety benefit or dis-benefit.

BENEFITS ESTIMATES

This section presents system effectiveness versus system design parameters and a cumulative estimate of benefits. Prior to widespread deployment of forward-looking collision avoidance systems, an estimate of potential system benefit is desirable. This estimate will help quantify the need for such systems and allows top-level parameters to be optimized. In order to perform this, extensive mathematical modeling and simulation of a forward-looking collision warning system has been performed. The mathematical model is based on a 6-Degree-of-Freedom model with various random variables and constant quantities. The simulation is a Monte Carlo simulation

using a set of 159 accident cases that is representative of the population of rear-end collisions.

As previously stated, Rear-End Crashes represent 23% of all collisions, 1.45 million per year out of 6.26 million police reported crashes per year. This represents the scope of rear-end collisions over which the following statistics apply.

Research into rear-end causal factor analysis has identified the primary causes of rear-end collisions to be driver inattention and/or following-too-closely. Additionally, the causal factor analysis did identify four percent of the rear-end collisions that were unavoidable due to brake failure, seizure, etc.

The mathematical model is based on a modified warning distance algorithm that takes lead and host vehicle absolute speed and calculates a warning distance (range, relative speed and absolute speed). This warning distance is compared with the range to the vehicle in the forward path and if exceeded, the driver is warned.

$$WD = \frac{V_f^{\,2}}{2*\alpha_f} - \frac{V_l^{\,2}}{2*\alpha_l} + V_f * T_d + R$$

where,

V_f	following (host) vehicle speed
α_f	following (host) vehicle acceleration 0.75 g's
V_l	lead vehicle speed
α_l	lead vehicle acceleration 0.85 g's
T_d	warning time 2.4 seconds
R	confidence interval 2 meters, this is provides a stopping gap between the vehicles

Additionally,

D_{RT}	driver reaction time log-normal distributed between 0.9 and 2.4 seconds with a 0.3 second standard deviation and a mean that is a linear function of headway time.
T_{PROC}	processing delay time 0.300 seconds, is the delay between request for the warning and the actual warning initiation
R_a	acquisition range $\geq$ 130 meters

Noise is added to range and range rate measurements as in a real-world system. A optimized Kalman filter is used to perform range and range rate estimation.

Warning times are not solely a function of the warning time (T_d) as specified in the mathematical model. It is a result of a combination of parameters including the assumed deceleration, acquisition range, processing delay, etc.

System effectiveness is defined as the number of crashes prevented divided by the total number of runs. The mitigation rate is meant to give a broader measure of benefit than system effectiveness. The mitigation rate takes into account crash severity, while the effectiveness counts a 1 kph crash the same as a 55 kph crash, it is assumed that damage is proportional to kinetic energy which is proportional to velocity squared. The total damage is then the sum of the squares of the damages from all of the runs. It is then normalized by dividing by the total maximum damage which could result if no action were taken. So the mitigation is defined as:

$$Mitigation = 1 - \frac{\sum_{i=1}^{N} (\text{Final Lead vehicle velocity}(i) - \text{Final Following vehicle velocity}(i))^2}{\sum_{i=1}^{N} (\text{Initial Following vehicle velocity}(i))^2}$$

Where the velocity in the denominator is the initial following vehicle velocity and the velocities in the numerator are velocities measured at the time of impact. Mitigation is always the upper curve on the plots.

Warning Times -- Sensitivity of system effectiveness versus driver warning time is shown in Figure 4.

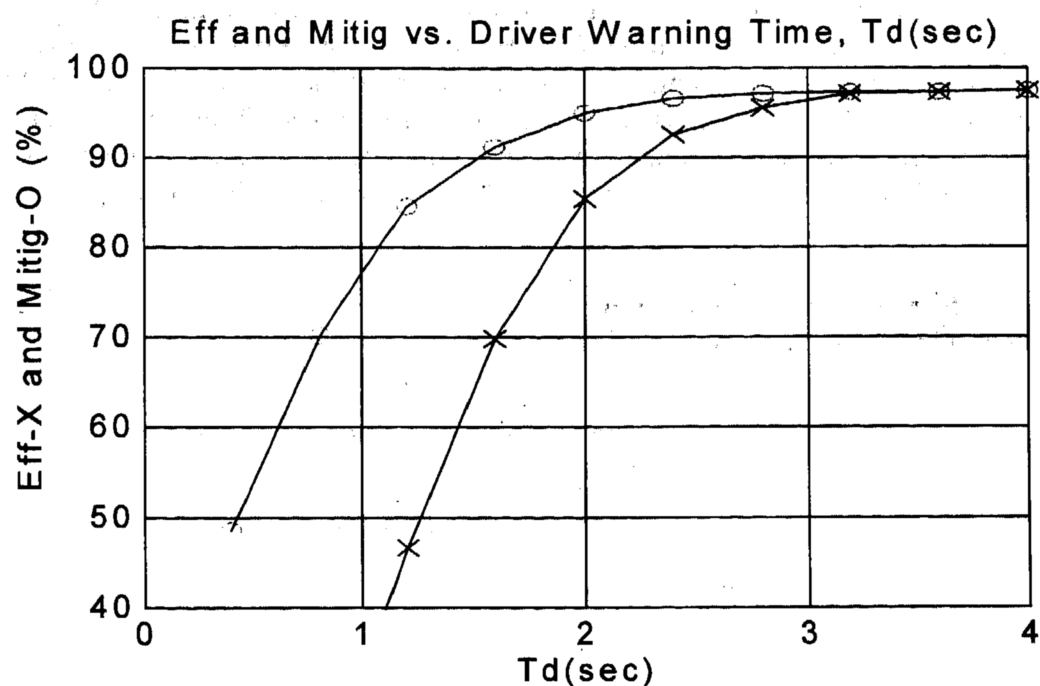

Figure 4 Effectiveness and Mitigation to Warning Time

Acquisition Range -- Sensitivity of system effectiveness versus acquisition range is shown in Figure 5.

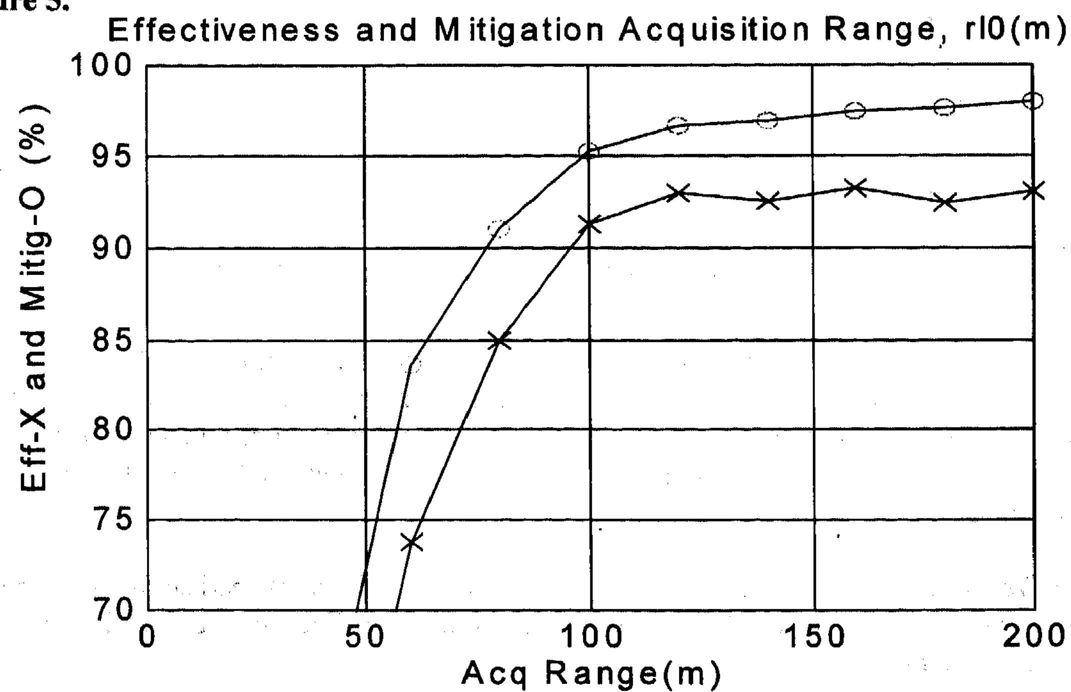

Figure 5 Effectiveness and Mitigation to Acquisition Range

The acquisition range plot includes both stationary and moving vehicles. For the purpose of these guidelines an acquisition range of ≥ 130 meters was selected. Because of the statistical nature of these systems, it was felt that a sensitivity of 93% is sufficient to eliminate or mitigate most collisions. A minimum acquisition range of 2 meters is a guideline. It should be noted that even at an acquisition range of ≥ 130 meters that the effectiveness drops off rapidly for high closure rate scenarios, such as lead vehicle stopped. At 65 mph the effectiveness drops to 64% for a lead vehicle stopped scenario and to 15% at 75 mph. This is a problem with any acquisition range chosen.

Horizontal Field-of-Regard -- Sensitivity of system effectiveness to horizontal field of regard is shown in Figure 6.

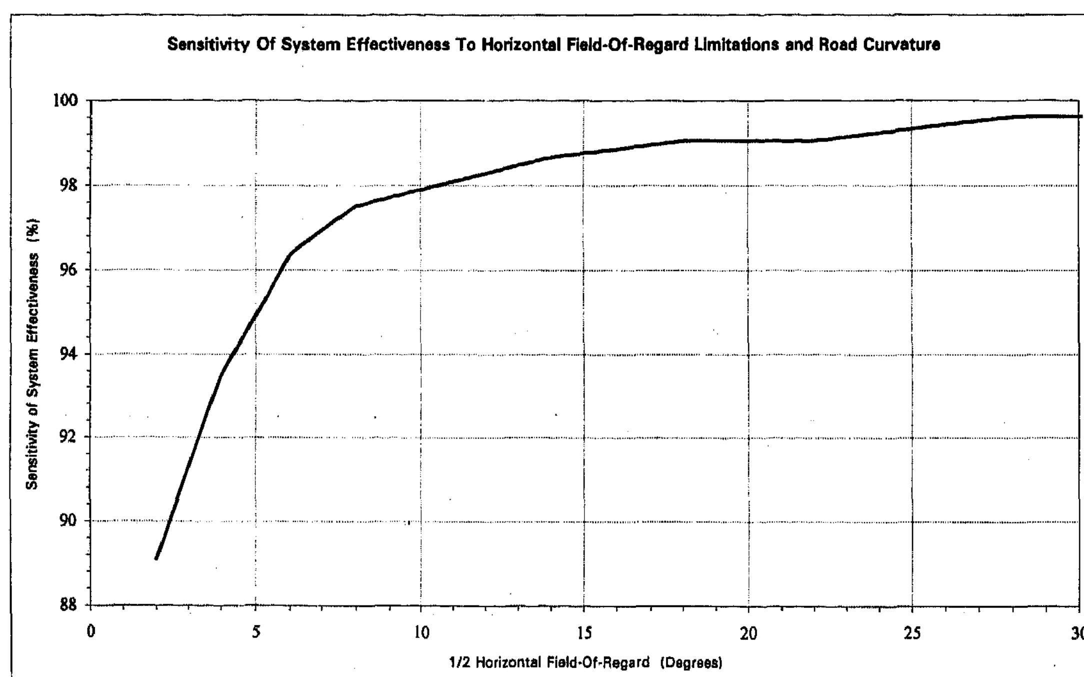

Figure 6 Effectiveness to Horizontal Field-of-Regard

The horizontal field of regard refers to the angle of view in the horizontal direction referenced to the longitudinal axis of the host vehicle. Because of the statistical nature of these systems, it was felt that a sensitivity to system effectiveness of 97% is sufficient to eliminate or mitigate most collisions. The sensitivity approaches 100% but never reaches 100% due to limitation of acquisition range.

To minimize nuisance alarms from vehicles in adjacent traffic lanes, parked vehicles, roadway signs, etc., the horizontal resolution must be fine enough to discriminate vehicles in adjacent lanes out to the acquisition range of the system.

Vertical Field-of-Regard -- Sensitivity of system effectiveness to vertical field of regard is shown in Figure 7.

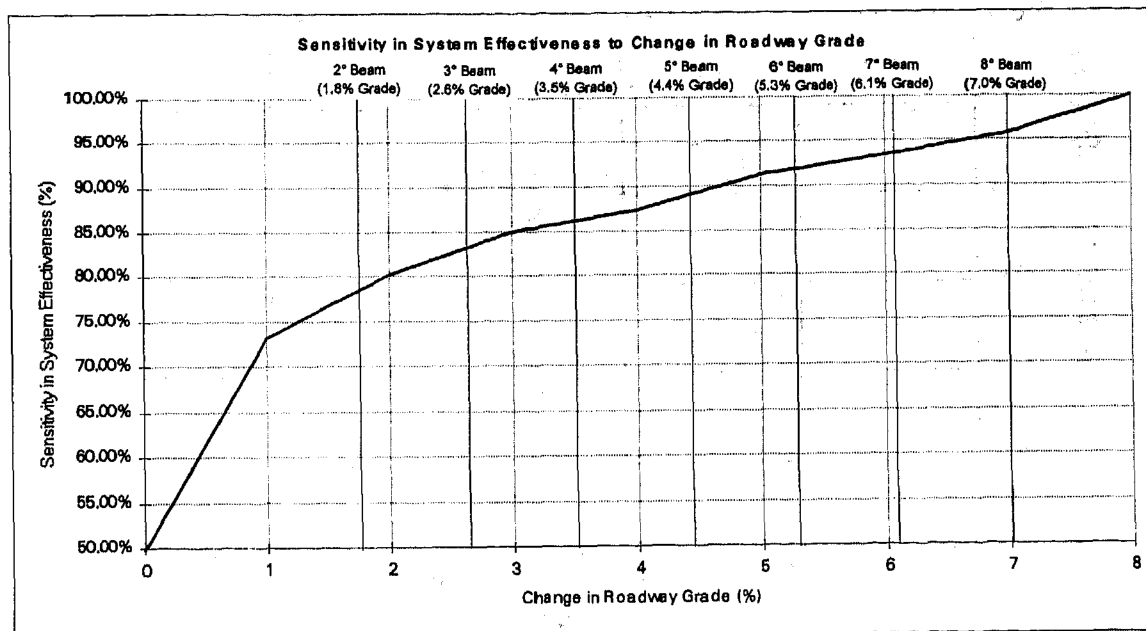

Figure 7 Effectiveness to Vertical Field-of-Regard

The vertical field of regard refers to the angle of view in the vertical direction referenced to the longitudinal axis of the host vehicle. Vertical field of regard relates system performance to roadway changes in grade and host vehicle pitch. The main issue for a forward looking system is the change in grade from the host to the target vehicle. This requirement affects the vertical field of regard required as well as the vertical angular resolution. The vertical field of regard should be large enough to overcome problems with the host and lead vehicle being on different roadway grades but not so large that overhead roadway objects present nuisance alarms.

System Delay -- Sensitivity of system effectiveness to system delay is shown in Figure 8.

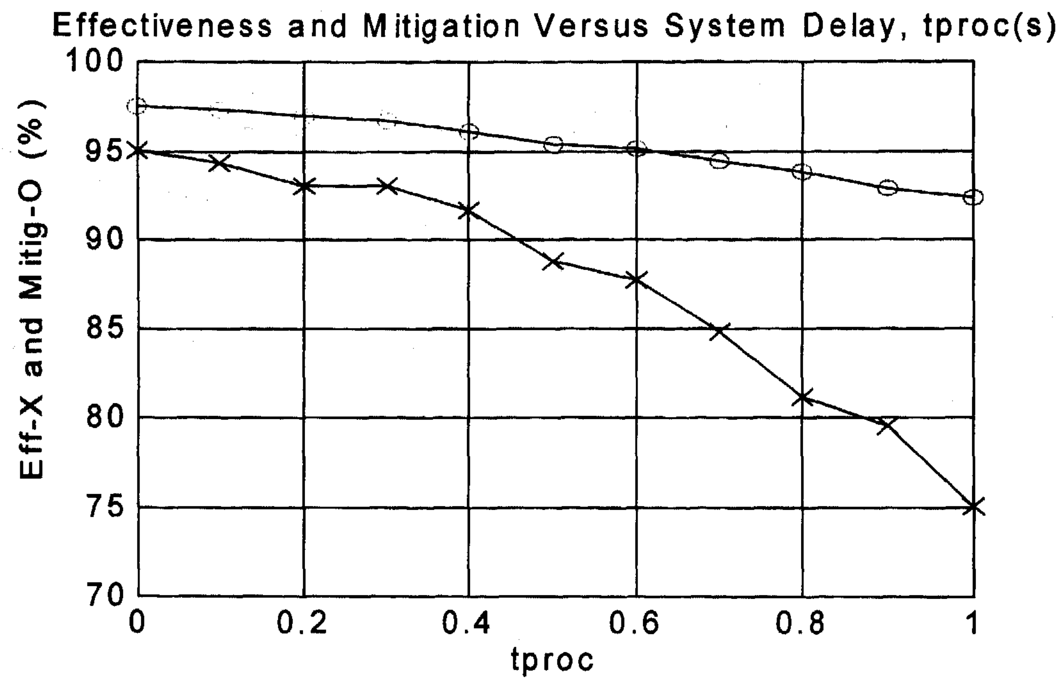

Figure 8 Effectiveness and Mitigation to System Time Delay

System delay is defined as the time required for the system to determine an object is present in the forward path and warn the driver by changing the status of the display. The system delay time contains the target acquisition delay time, the time to process through the warning algorithm and the time required to change the status of the display. A value of ≤ 300 milliseconds was selected. Because of the statistical nature of these systems, it was felt that a sensitivity to system effectiveness of 94% is sufficient to eliminate or mitigate most collisions.

Atmospheric Conditions -- Sensitivity of system effectiveness to atmospheric condition is shown in Figure 9.

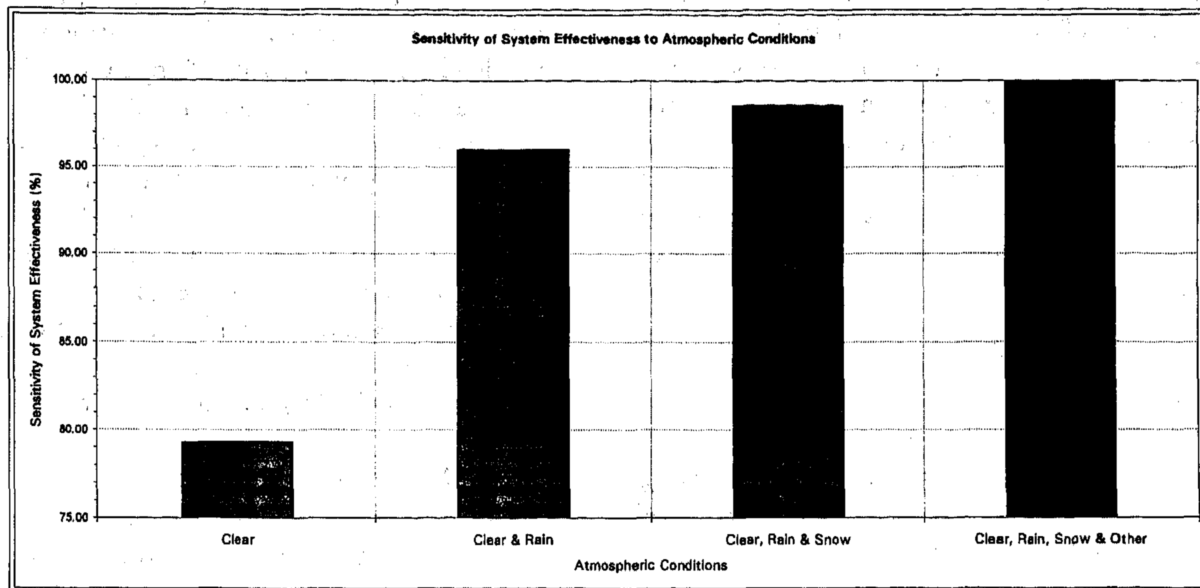

Figure 9 Atmospheric Condition vs. System Effectiveness

Atmospheric conditions relate to the system performance during various conditions: rain, snow, fog, dust, etc. If the system operates in clear and rainy conditions then the system effectiveness is approximately 96% instead of 79% for a system that only operates in clear atmospheric conditions. No quantitative measure of the amount or density of the atmospheric condition is available, but for a forward-looking collision warning system to be effective, it must operate correctly under degraded atmospheric conditions, or notify the driver that it is non-functional.

Table 2 Forward-Looking Collision Warning System Recommendations

Effectiveness	Description	Recommendation
96%	Driver Display Type	Collision Warning Display, Following-Too-Closely Display. Warning display only 77%.
96%	Moving and Stationary Threats	Both
93%	Warning Time	2.4 seconds
93%	Acquisition Range	≥130 meters
96%	Horizontal Field of Regard	± 8 degrees
92%	Roadway Profile, Vertical Field of Regard	5.3% Grade, 6 degrees
98%	Atmospheric Condition	Clear, Rain, Snow
94%	System Delay Time	≤ 300 milliseconds

ESTIMATION OF BENEFITS

Table 2 shows recommendations and their associated system effectiveness estimates. Overall effectiveness is calculated by the product of individual components (with assumed independence and equal weight). With these assumptions, the overall effectiveness is 65%. True effectiveness is expected to be considerably higher since some of the factors will have a greater weight.

LIMITATIONS

This section presents those items known at this time that may be beyond the capability of a forward looking collision warning system. System users need to be aware of these system limitations.

Head-On -- The forward-looking collision warning system is not required to respond to Head-On collision scenarios. This information may be eliminated from processing in order to reduce nuisance alarms.

Crossing-Path -- The forward-looking collision warning system is not required to respond to crossing path collision scenarios.

Operation beyond sensor limit -- The forward-looking collision warning system is not required to respond when the absolute speed of the host vehicle causes the warning distance to be beyond the sensor range. This problem is compounded on curved roadways and may necessitate a cautionary warning to the driver when the system is operated beyond the sensor limit.

Curves -- The forward-looking collision warning system is not required to respond on very short radius curves (corners), or the warning may be late dependent on the amount of roadway curvature.

Obscured Vehicle -- The forward-looking collision warning system is not required to respond to obscured vehicle scenarios where the lead vehicle suddenly "appears" within the warning distance and inside the finite system delay time. Some obscured vehicle scenarios may not allow the driver enough time to avoid a collision, let alone the system enough time to warn the driver to avoid the collision. An example of an obscured vehicle scenario is when the system and driver's view of the lead (target) vehicle is blocked by another vehicle.

CONCLUSION

Presented are preliminary performance guidelines for a forward-looking collision warning system. On-going work will further define and demonstrate the guidelines through on-road and simulator testing. Current work allows for development of a test bed system to meet the performance guidelines as well as extensive on-road testing and human factors development.

Additionally, this work is examining systems that automatically take control of the vehicle from the driver to avoid an impending collision as well as systems that perform Adaptive (Intelligent) Cruise Control.

These preliminary performance guidelines have been augmented with qualification tests to verify system performance versus these guidelines.

For additional information, or for a complete copy of the preliminary performance guidelines contact Terry Wilson at Frontier Engineering Sciences.

ABSTRACT

This paper describes the evaluation methodology for the Intelligent Cruise Control (ICC) Field Operational Test (FOT). The primary purpose of the evaluation is to assess safety impacts of the ICC system. Other benefits, such as convenience and comfort, as well as impacts of the system, e.g., fuel consumption and emissions, are also being assessed.

The ICC system incorporates a forward looking sensor and a headway controller with a conventional cruise control system, to automatically maintain a headway (with accelerator and downshift control inputs) between the ICC-equipped vehicle and a vehicle that precedes the equipped vehicle. The FOT will collect daily usage experiences from up to 162 lay drivers, each of whom will drive one of 10 ICC equipped vehicles for periods of 2 or 5 weeks. Data collection is scheduled to last 12 months. Each of the 10 vehicles has a data collection system that will support the evaluation. The data collection system will collect video data and a variety of vehicle performance measures.

Six evaluation goals have been identified. These include the evaluation of system benefits to users, system performance, institutional and legal issues, user acceptance, system costs, and ICC impacts on the transportation system. This paper focuses on the safety evaluation process, describing the safety objectives, hypotheses to be tested, measures of effectiveness, measures of performance, data sources and analysis methods.

INTRODUCTION

PURPOSE - This paper presents the evaluation methodology for the Intelligent Cruise Control (ICC) Field Operational Test. The purpose of the evaluation is to assess, based on data collected from the field operational test, actual and potential safety impacts of the ICC system. Other impacts of the system will be evaluated if they affect safety impacts indirectly (e.g., comfort, convenience, willingness to purchase, and willingness to use the system), or if those impacts are easily assessed as corollaries to the safety findings (e.g., fuel consumption, emissions). The following safety questions will be addressed:

1. Do drivers drive more, or less, safely with the system than without it, in ways related to the system?
2. Do vehicles equipped with the system have fewer, or more, collisions than vehicles without the system?
3. If all vehicles were equipped with the system, would there be a decrease, or increase, in the total number of collisions and collision-related injuries?

BACKGROUND - Recently, NHTSA signed a cooperative agreement with the University of Michigan Transportation Research Institute (UMTRI) to conduct a field operational test of an ICC system.[1] Other parties contributing to the field operational test are Leica AG, the Michigan Department of Transportation, and Haugen Associates.

With ICC, a forward looking sensor and intelligent controller are incorporated with normal cruise control to automatically maintain a headway between the ICC equipped vehicle and a vehicle that precedes the equipped vehicle. When other traffic are encountered, ICC equipped drivers are provided some relief from engaging, disengaging, or manually resetting speed, as might more often be necessary with conventional cruise

control. When not in traffic, the ICC system functions like conventional cruise control.

ICC was not developed as a safety device, and its potential effects on safety are being studied now. Plausible safety benefits include reduced driver fatigue and a reduction in rear-end collisions that may result from both (a) better maintenance of safe following distances, and (b) the alerting function that ICC's automatic response to closing headway may provide. However, by automating headway maintenance, ICC may also change demands on the driver in ways that adversely affect safety. Plausible adverse effects include: (a) delayed driver response to traffic because of over-reliance on the ICC system, and (b) driver disorientation due to sudden accelerations or decelerations as a result of the system losing lock on a preceding vehicle, or incorrectly locking on to a vehicle not in the user's lane of travel.

ICC FIELD OPERATIONAL TEST[2]

For the ICC Operational Field Test, ten 1996 Chrysler Concordes have been equipped with identical ICC systems by UMTRI. The ICC system consists of the standard Chrysler cruise control, Leica sensors, intelligent (adaptive) controller, and a data acquisition system. The data acquisition system will collect video data and a variety of system performance measures. Among the system performance measures that will be sampled 10 times per second (10 Hz) are:

- Range to the preceding vehicle
- Rate of change in range to preceding vehicle
- Vehicle velocity
- The headway time selected by the driver
- Curve radius
- Throttle setting

The video data will capture a 60 degree field of view scene in front of the vehicle. Video episodes of 2 to 30 seconds will be stored when predetermined criteria are met for certain driving events such as braking and near encounters. The stored video episodes will include a portion of time before the triggering event. The video data will later be used to assist in evaluating the effects of the ICC system on driving performance and safety.

Up to one hundred sixty-two volunteers will be recruited to drive the ICC equipped Chrysler Concordes each for 2 or 5 week durations in a naturalistic setting. No experimenters will be on board. One hundred eight drivers will receive vehicles for 2 weeks and the remaining 54 drivers will receive vehicles for 5 weeks.

Both groups of drivers will experience one week of driving the Concorde in a standard configuration (no ICC) before ICC functions are made available. The one week without ICC is intended to provide baseline data for driving performance without ICC.

One and four week exposures to ICC are included in the research design to enable assessment of longer term changes in behavior as a function of experience with ICC usage. Other subject variables in the research design are:

- Driver age
- Previous cruise control usage

Drivers in three age groups will be recruited: 20 to 30; 40 to 50 ; and 60 to 70 years of age.

Among the 108 drivers who participate for 2 weeks, half will be from among drivers who say that they regularly use conventional cruise control. The other half of this group will be from among drivers who say they do not use cruise control. All 54 drivers who participate for 5 weeks will be selected from among those who say that they regularly use conventional cruise control.

ICC EVALUATION

The ICC evaluation is being conducted by US DOT's Volpe National Transportation Systems Center (Volpe Center) with support from Science Applications International Corporation (SAIC).

ICC EVALUATION GOALS - In accordance with DOT FOT evaluation guidelines[3], six ICC evaluation goals have been identified:

1. Evaluate System Benefits to Users
2. Evaluate System Performance
3. Evaluate Institutional and Legal Issues
4. Evaluate User Acceptance
5. Evaluate System Costs
6. Evaluate ICC Impacts on the Transportation System.

ICC EVALUATION APPROACH - Separate evaluation studies will be conducted to address each of the goals.

Benefits Study - The *Benefits Study* will evaluate three classes of benefits that may derive from the use of the ICC system:

- Changes in driving performance that are potentially safety-related
- Changes in accident probability, accident severity, and in the frequency and severity of "near accidents"
- Non-safety related changes in driving performance.

The study will utilize digital vehicle data; video data; data from questionnaires, focus groups, and debriefings; and ICC accident investigation data if there are any crashes.

System Performance Study - In addition to providing a complete documentation of the ICC system design, the *System Performance Study* will evaluate the ICC system from three perspectives:

- IR sensor characterization
- Driver interface
- Overall integrated ICC system characterization.

Institutional and Legal Issues Study - The objective of this study is to identify the non-technical impediments, commonly called institutional and legal issues, that are likely to arise during the ICC field operational test. Identification of non-technical impediments during the field operational test may serve to minimize the ramifications of these issues on the commercial deployment of ICC and on the implementation of other ITS operational tests.

The *Institutional and Legal Issues Study* will attempt to answer four questions:

1. What institutional and legal impediments were encountered in establishing partnerships, deploying ITS services and products during the operational test, and developing and deploying ICC technologies?
2. Where in the life cycle of the operational test did these impediments occur?
3. What were the causes of these impediments and how were they overcome?
4. What lessons can be learned in dealing with these impediments that can be applied to the full deployment of ICC and to other operational tests?

Interviews and questionnaires will be the data sources for the study. Subjects of the interviews and questionnaires will include partners, evaluators, and other parties from government and industry who are involved in the operational test, as well as parties who are not partners in the field operational test, but may be key players in the deployment of ICC systems.

User Acceptance Study - The *User Acceptance Study* will evaluate the volunteer drivers' acceptance of the ICC system from three perspectives:

1. Actual Usage — how much, when, and where the drivers use the system
2. Stated Preference — what the drivers say they like and dislike about the system
3. Value — what the drivers think the system is worth.

Questionnaire, focus group, and debriefing data from ICC driver participants will serve as the data sources for addressing these questions.

Cost Study - The purpose of this study is to identify the projected costs to deploy the ICC systems. The cost estimate will include the initial costs to procure, install and calibrate a typical system (non-recurring costs) as well as the annual operations and maintenance (O&M) costs (recurring costs).

System Impacts Study - The purpose of the *System Impacts Study* is to assess the potential impacts of ICC at various levels of market penetration. The study will assess impacts on:

- Safety
- Traffic flow and/or capacity
- Fuel consumption
- Emissions.

The Impacts Study will use the following data sources:

- In-vehicle data logs
- User acceptance study data
- System performance study data
- Other ICC vehicle performance measures
- Traffic data logs
- Loop-detector data
- National Accident Statistics
- EPA/MOBILE5A.

Data analysis will include a number of modeling techniques and include the use of the INTEGRATION traffic model.

SAFETY EVALUATION - The remainder of this paper will focus on the safety evaluation process for the ICC system.

Table 1 summarizes the technical approach to the evaluation of the safety benefit objectives of 1) determining whether drivers drive more or less safely with the ICC system than without it in ways related to the system, and 2) assessing driver perceptions of safety and performance.

Several hypotheses will be tested under these objectives as indicated in the table. To the extent that data are available, each of the hypotheses will be examined for specific driving scenarios. The driving scenarios that are being considered for the ICC FOT are shown in the appendix.

Use of ICC reduces driver response time relative to driving without ICC - The hypothesis that driver response times will be reduced with ICC compared to response times driving without ICC (i.e., both without cruise control and with conventional cruise control) will be tested for events that cause drivers to brake rapidly or to make evasive lateral maneuvers. Because the ICC will cause noticeable deceleration when there is a high rate of closure between preceding and host vehicles, the ICC system has the potential to alert drivers to the need to brake earlier than they might detect this requirement on their own.

For rapid braking and lateral maneuvers, when captured on video, the evaluator will examine the video record for the event that precipitated the response. It is hypothesized that the response to the event will occur earlier with ICC than with conventional cruise control or without cruise control. Several assumptions underlie this hypothesis. One assumption is that for any type of event, rapid reactions sufficient to trigger video capture will occur regardless of the lag between event start and driver response. Where rapid response is required because the driver responded late, this assumption could be wrong. If there is evidence for a large and disproportionate number of late responses in conjunction with a cruise control mode (i.e., ICC, conventional cruise control, or no cruise) then the reaction time data used to test this hypothesis should be viewed with caution. Nonetheless, a disproportionate number of late responses in a particular mode will in itself be an important finding.

Because of limitations in the data recording, driver reaction time differences between cruise control conditions that differ by less than ¼ sec will be difficult, if not impossible, to identify. The difficulty in detecting small differences results because the video may be captured at a rate of 10 frames per second. Thus for any video frame, times can not be resolved below 100 milliseconds. Other temporal ambiguities, such as vertical and horizontal video sweep, and computer interrupt priority, compound the resulting imprecision. Therefore, this test is for relatively large response time differences, not for subtle differences. Because range data, when the sensor is tracking a lead vehicle, will be recorded at a rate of 10 hertz, it may be possible to resolve reaction times to about 100 milliseconds. Even 100 milliseconds is a relatively large difference relative to operator response capabilities.

Headway varies as a function of cruise control mode, road class, traffic density, and road geometry - It is hypothesized that, because use of automated headway control is convenient, drivers will use ICC and, as a result, have longer average headways than they otherwise would maintain. In addition to road characteristics, driver age is included as a factor. Although the direct relationship between any given headway time and safety is not well understood, there is an implicit assumption that within the normal range of headways, longer headways are safer.

ICC decreases driver use of brake pedal relative to driving without ICC - Because the ICC automatically controls speed with accelerator and downshift control inputs, ICC users should be able to moderate headway with less brake use. With conventional cruise control, the driver must either disengage the system with the brake, or may manually decrease the selected speed. Manual decreases in selected speed makes inputs to the accelerator but not the transmission and therefore could be expected to require brake intervention more frequently than would the ICC which, in addition to not requiring manual speed setting adjustments, can request downshifts for greater deceleration authority.

Brake pedal usage will be correlated with driver perceptions of effects on performance and with close call frequency and severity.

ICC decreases braking force required - Like conventional cruise control, the ICC system requires the driver to intervene by braking when headway closure rates are greater than the driver will tolerate. Unlike conventional cruise control, the ICC system automatically attempts to compensate for decreasing headway by coasting or downshifting. Therefore the rate of closure should, on average, be less when the driver intervenes. Given that the discrepancy between desired headway and actual headway should be less on average with ICC, driver interventions with the brake should require less force and less duration. Driver age will be a factor in the analysis.

Table 1. Approach to Evaluation Safety Benefits to Individual Users.

Objective	Hypothesis	Measure of Effectiveness	Measure of Performance	Data Source	Method of Analysis
Determine if drivers drive more or less safely with the ICC system than without it, in ways related to the system	Use of ICC reduces driver response time relative to driving without ICC	Reaction time to driving events to which drivers respond by braking	Latency to initiate braking	• Forward video record • Range Rate • Range • Brake Pedal • CONCERN button • Accelerometer	For all braking events when deceleration is high, determine latency of brake pedal change following beginning of rapid change in range rate
		Reaction time to driving events to which drivers respond with lateral avoidance maneuvers	Latency to initiate avoidance maneuver	• Forward video record • YawRate • CONCERN button	For all high YawRates that are the result of an avoidance maneuver, determine latency from initial stimulus to driver avoidance response
	Headway varies as a function of cruise control mode (ICC, CCC, no cruise control), road class, traffic density, and road geometry.	• Headway	• Range/velocity	• Range • Velocity • Tracking target	• Analysis of variance.
	ICC decreases driver use of brake pedal relative to driving without ICC	Frequency of Brake Use	Brake pedal depressions per kilometer by road class	• Road class • Time of day • Brake Pedal	Brake pedal usage analyzed as a function of road class and traffic density. Loglinear analysis.
	ICC decreases braking force required and this varies as a function of road class and traffic density	Brake pedal force	RMS G force while brake applied	• Road class • Time of day • Velocity • Accelerometer	Analysis of Variance
	Driver workload is reduced when ICC is used relative to driving without ICC	Subjective workload	Subjective workload rating	• Questionnaire • Observer probes	Descriptive statistics and analysis of variance
	ICC users show fewer indications of inattention to the roadway	• Yaw rate variability[1]	• Frequency of large yaw rate variance	• Yaw rate sensor	• Analysis of variance • Log-linear analysis
Assess driver perceptions of performance	Users perceive driving performance and safety to be enhanced by ICC	• Perception of driving performance • Perception of driving safety	Perception of: • Speed maintenance. • Awareness of other vehicles • Safety	• Questionnaire • Focus groups • Debriefing • Real-time observations	• Descriptive statistics • Analysis of variance

[1] It would be desirable to filter out lane changes and turns.

Driver workload is reduced when ICC is used relative to driving without ICC - Mental workload is a hypothetical construct in which it is posited that drivers have limited mental resources, and that drivers can perceive when the amount of resources required approach or exceed available resources. Perceived mental workload will be assessed from user questionnaires and focus group responses.

ICC users show fewer indications of inattention to the roadway than drivers not using ICC - Whenever a manual, or perceptual-motor task is automated, it is prudent to examine whether the system operator will continue to maintain a level of awareness of system operation so that operator intervention occurs in a timely and appropriate fashion. Therefore, the ICC evaluation will assess whether driving behaviors consistent with inadequate operator supervision are evident. With the ICC system, very late or inappropriate responses to roadway events would indicate the possibility that the driver was not adequately attentive to the driving task. The evaluator will examine the video data for signs of behavior consistent with inattention: hard braking that follows the initiating event after an excessive delay, or evasive maneuvers that follow an initiating event after an excessive delay. This analysis requires that the event that precipitated the driver response be identifiable in the video record.

Users perceive driving behavior to be enhanced by ICC - At the conclusion of their ICC experience, drivers will be debriefed and given a questionnaire. Later, the same drivers will return to participate in focus group sessions that address their ICC experience. Data from all three sources will be used to address whether the drivers perceived enhancements or detriments to safety that they attribute to use of the ICC system. In addition to perceptions of safety effects per se, users will be asked if they perceived their driving behaviors to change in other ways. Some behavior changes that the drivers may not perceive to be related to safety may have important safety implications. Although drivers may not think of road class and speed selection choices in terms of safety, these factors may have implications for accident exposure and severity of potential injuries.

Table 2 presents the approach to determining whether any accidents involving ICC vehicles are related to ICC use. The evaluation will also examine the frequency of close calls recorded in the video data. Three hypotheses will be tested:

Table 2. Approach to the Evaluation of Reduction in Accident Occurrence and Accident Severity Attributable to the User of ICC.

Objective	Hypothesis	Measure of Effectiveness	Measure of Performance	Data Source	Method of Analysis
Determine if any accidents of ICC vehicles are related to the use of the ICC system	• Accidents (if any) involving ICC equipped vehicles are not related to ICC use • ICC use results in fewer close calls • Close calls encountered when using ICC are qualitatively different from close calls encountered without ICC	• Cause of accident • Frequency of close calls	• Factors contributing to accident • Close call frequency • Close call severity	• Accident investigation • Video analysis • Observer recordings	• Accident analysis • Chi-square tests. • Close calls categorized and analyzed as a function of type of close call • Qualitative analysis of severity, and situational factors • Frequency of close calls related to overall exposure

Accidents (if any) involving ICC equipped vehicles are not related to ICC use - Because there will be only 10 ICC vehicles, and because across all participants in this study it is unlikely that more than a million miles will be logged, it is highly unlikely that a sufficient number of accidents will occur to support statistical analysis, either for testing whether accidents are more or less likely with ICC than without it, or whether ICC is associated with more or less severe accidents. However, the *Benefits Study* detailed study plan will provide a procedure for documenting accidents. The documentation will specifically address whether ICC was being used at the time of the accident, and whether ICC could have been a contributing factor. Procedures will be detailed for rating the severity of accidents, with special attention to the severity of rear end collisions.

ICC use results in fewer close calls. Close calls encountered when using ICC are qualitatively different from close calls encountered without ICC - The evaluator will examine the video data associated with extreme braking, extreme lateral accelerations, and CONCERN button pressings to document occurrences of close calls, or near accidents. Procedures used for the TravTek Camera Car Study and documented in the test plan for the Safety Evaluation of the ADVANCE Project will be used to quantify close calls.[4,5] Because the video analysis will only be done for close calls that resulted in extreme driver reactions or pressings of a CONCERN button that is provided in the vehicle for this purpose, several kinds of close calls may be missed entirely, or be underrepresented in the sample. Missed or underrepresented close calls may include: close calls that do not require extreme responses; close calls which the driver detects but then fails to press the CONCERN button; and close calls that the driver does not detect. Whereas the close call analysis may be suggestive of increased or decreased accident risk with ICC, given the dependence of the analysis on triggers for video data collection, this analysis, by itself, will not be definitive. However, close call findings, when considered with the body of evidence from tests of other safety hypotheses, are expected to provide a robust body of evidence regarding the safety effects of the ICC system.

DATA SOURCES AND DATA FLOWS - Much of the evaluation data will be collected onboard the ten ICC vehicles. These and other sources of data are indicated in Figure 1. Traffic data will be determined from vehicle-based video records and digital records derived from this video. In addition, a separate video will be captured by placing a camera on overpasses overlooking various freeway locations in the Michigan test area. GIS software will be used to identify roadways and road classes from GPS coordinates recorded in the time history and event log files. The data referred to as "digital" includes only the GPS, time history, and event files from the vehicles. This digital data will be used to characterize driving performance as a function of road class, road geometry, previous cruise control use, and ICC experience. The subjective data refers to the data generated from recruiting, questionnaire, debriefing and focus group activities. Comparable systems data will be obtained to project the costs to deploy a typical ICC system. Interviews of the partners will provide the information for the Institutional Issues Studies.

SUMMARY

This paper introduces the concepts involved in the safety evaluation process for the ICC Field Operational Test. The ICC system is first briefly described. Then the evaluation goals are delineated. Specific objectives, hypotheses, measures of effectiveness, measures of performance, data sources and methods of analyses are described to evaluate safety benefits to individual users and to evaluate reduction in accident occurrence and accident severity attributable to the user. The safety evaluation tasks will be carried out as an integral part of the overall ICC evaluation. The ICC Field Operational Test will cover approximately a period of one year with completion targeted for August, 1997.

Facial, Periorbital and Ocular Injuries Related to Steering-Wheel Airbag Deployments

Donald F. Huelke, Lawrence W. Schneider, Matthew P. Reed, and Ryan J. Gilbert
University of Michigan Transportation Research Institute

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

To determine the frequency of facial injuries from steering-wheel airbag deployments, 540 consecutive steering-wheel airbag deployments, investigated by the University of Michigan Transportation Research Institute (UMTRI) personnel, were reviewed. About 1 in 3 drivers sustain an injury to the face. Injuries to the area surrounding the eye (periorbital) or to the eyeball (ocular) rarely occur. The frequencies of facial or ocular injuries are the same for belted and unbelted drivers. Drivers of short stature had a higher frequency of facial injury. Females sustained ocular injuries more frequently than males. Untethered airbags were not overly involved in drivers with an ocular injury. No specific make or model car were overly represented in the ocular injury cases.

INTRODUCTION

The effectiveness of steering-wheel airbags has been well documented in the medical and engineering literature.[1-8] When properly used as a supplemental restraint with the lap-shoulder belt, the steering-wheel airbag reduces driver fatalities by about 23% in frontal and front angular crashes.[6] However, the airbag has also been implicated as the cause of certain injuries. For the most part, these injuries are minor, including abrasions, contusions, and lacerations of the upper extremity, face, and torso areas. More serious airbag-induced injuries have also been observed, including hand, finger, and forearm fractures or dislocations have been reported along with injuries to the torso.[9-16] Numerous articles have documented airbag-induced ocular injuries such as corneal abrasions, hyphema, angle recession, lens subluxation, traumatic iritis, viteous hemorrhage, retinal tears, commotio retinae, macular hole, chorodial rupture and alkali keratitis.[16-40]

The steering-wheel airbag module consists of the pyrotechnic inflator, the airbag, the outer module covering, and the module door or flap. When the airbag sensor system detects a crash for which the airbag should deploy, an electrical signal triggers the airbag pyrotechnic inflator. The pyrotechnic inflator produces gas which begins to inflate the folded airbag. As the gas pressure rapidly increases, the airbag punches through the module door. This occurs about 5 to 10 ms after the airbag is triggered. In order for the airbag to be fully deployed before any significant forward excursion of the driver's body occurs, airbags must be fully inflated in 40-50 ms. These high inflation rates can result in airbag initial fabric velocities of 320 km/h or more.[41,42] Vents on the back side of the airbag allow the gasses to flow out, so that the airbag deflates completely in about 2 seconds (The pressure inside the airbag returns to atmospheric within about 0.2 seconds).

During deployment, the trajectory of the airbag fabric is determined by the type of fold pattern and the presence or absence of tethering. In an untethered airbag, the filled airbag volume is about 60 liters and has a full and rounded convex surface (Fig. 1). The tethered airbag usually has a smaller filled airbag volume of about 50 liters and has several strips of material sewn to the center portion of the airbag surface (Fig 2). These tethers restrict the excursion of the airbag fabric during deployment and control the shape of the airbag during filling. When the airbag is completely filled, the tethered region of the airbag results in a depressed and

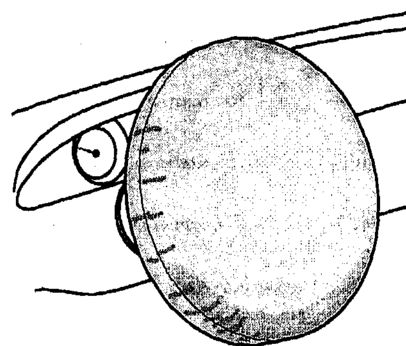

Figure 1. Steering wheel untethered airbag

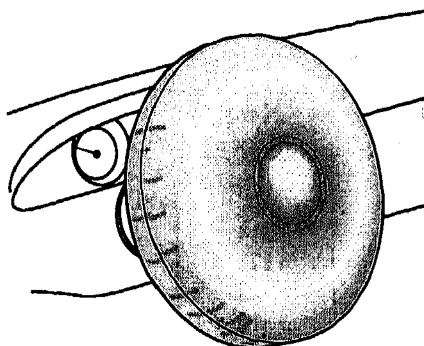

Figure 2. Steering wheel tethered airbag

flattened area about 6 inches in diameter in the center of the airbag surface facing the driver. Additionally, the type of bag folding pattern influences the airbag deployment kinematics and may aid in reduction of some injuries to the face or torso.[43] Both tethered and untethered airbags are used in various makes and models of vehicles.

This paper presents results from analysis of crashes involving steering-wheel airbag deployments with regard to the frequency of steering-wheel induced injuries to the face, periorbital area, and eyes. In the analysis that is presented, ocular (eye) injuries are a subset of periorbital injuries, which are a subset of facial injuries.

MATERIALS AND METHODS

Accident investigations are routinely conducted by the University of Michigan Transportation Research Institute (UMTRI) with the general goal of determining the causes of injuries and deaths in motor vehicle accidents. In all of the UMTRI investigations, the crush damage of the vehicle is measured and photographed, occupant contacts within the vehicle interior are noted and documented, and other vehicle and driver characteristics are obtained and recorded. Injury data are obtained for case-vehicle occupants from medical records of cooperating hospitals. A telephone interview is usually conduced with the driver to obtain additional crash or injury details. Since cases selected for investigation generally involve a tow-away crash with an injured occupant, the resulting data sets tend to be biased toward the injury-producing crash.

As more vehicles have been equipped with steering-wheel airbags, crashes involving steering-wheel airbag deployments have occurred with increasing frequency. A case database comprised of 540 UMTRI-investigated crashes involving steering-wheel airbag-deployments was available for analysis in this study. Each case was individually reviewed to determine if the facial injuries to the driver were caused by the airbag deployment. The data were analyzed and tabulated to establish the frequencies of facial, periorbital, and ocular injuries for different conditions of airbag tethering, belt restraint use, driver gender and stature, and vehicle make and model. The presence of an airbag tether was determined by reviewing the photographs of the steering-wheel or from inquiries to the vehicle manufacturers. In tabulating the data, each driver with an airbag induced facial injury was counted only once, even if there were multiple facial areas involved. Of the drivers with an airbag-induced facial injury, the periorbital injury cases were extracted as a subset, and ocular trauma cases were identified and separately reviewed as a subset of the periorbital injuries. The periorbital area includes the eyelids, eyebrow, adjacent nose, medial and lateral canthal areas and infraorbital cheek. "Ocular" refers to the eyeball only.

RESULTS

A. FREQUENCY OF INJURY--Table 1 displays the frequencies of driver injuries related to steering-wheel airbag deployments in the UMTRI database. An airbag injury to any body region was found in 63% of the drivers. Most of these injuries are at the AIS-1 level and include abrasions, contusions, small lacerations or errythemia. Approximately half of the drivers who were injured by the airbag sustained an airbag-induced facial injury, but only 27 of all drivers (5%) sustained a periorbital or ocular injury caused by contact with the airbag. Eleven drivers sustained an injury directly to the eyeball, and only two of these sustained an ocular injury without periorbital involvement.

B. INFLUENCE OF DRIVER STATURE ON THE FREQUENCY OF FACIAL INJURIES--Table 2 shows the frequency of facial, periorbital, and ocular injuries by driver stature. As indicated above, 32% of all drivers sustained a facial injury from the airbag. The percentage of drivers receiving facial injuries in each stature range, decreases with increasing stature (Table 2). For the short drivers (150-159 cm), approximately half sustained facial injuries. In contrast, for the tall drivers, only about 9% sustained facial injuries. Most of the facial injuries were sustained by drivers who were less than 189 cm in stature and drivers with ocular injuries, with or without periorbital injuries, were all less than 179 cm tall. However, seven of the 11 drivers with ocular injuries were of average stature (170 -179 cm).

C. INJURY FREQUENCY WITH SEAT BELT USE--Table 3 shows a breakdown of facial injuries by belt restraint use. While the number of restrained drivers sustaining facial injuries is significantly higher than the number of unrestrained drivers, the percentages of facial injuries are very similar for the two groups. This is also true for ocular injuries. Nine restrained drivers receiving ocular injuries and two others were unrestrained, but both represent only 2% of their respective group. Although few in occurrence, the frequency of periorbital injury, with or without an ocular injury, for the unrestrained drivers, was twice that of the restrained drivers (8% vs. 4%) even though restrained drivers outnumbered the unrestrained by 6 to 1.

Table 1

D. FREQUENCY OF INJURY BY GENDER--As expected from the results for stature, the incidence of facial, periorbital, and ocular injury is different for male and female drivers (Table 4). Of the 292 male drivers involved in airbag deployments, 24% sustained a facial injury from the airbag versus 42% of the 247 female drivers . Females also sustained a disproportionate number of injuries to the periorbital and ocular areas. Periorbital and/or ocular injury occurred to 7% of female drivers compared to 3% of the males, while ocular injury alone occurred to 3% of the female drivers compared to 1% of the male drivers.

E. EFFECT OF AIRBAG TETHERING AND VEHICLE MODEL ON OCULAR INJURY--Table 5 shows the frequencies of facial, periorbital, and ocular injuries by airbag tethering. As indicated, most of the cases involved tethered airbags, but it is also clear that the occurrence of facial and ocular injuries differs for the two airbag conditions. Airbag-induced injury to any facial area, occurred to 27% of the drivers with tethered airbags and to 44% of the drivers exposed to untethered airbags. Of the drivers with ocular injuries, there is an equal number for untethered and tethered airbags, but the frequency of occurrence of the ocular injuries is lower with tethered steering-wheel airbags. The frequencies of periorbital injuries for the two types of airbags are similar (3% vs. 2%).

Table 6 indicates the presence of an airbag tether, and the make, model, and year of the vehicle for the cases with ocular injuries. The occurrence of these injuries is distributed over a wide range of vehicle and airbag types.

Table 6

Ocular Trauma Cases - Airbag Type and Vehicle Information

Tethering	Year	Make	Model

Untethered	1996	Chevrolet	Cavalier

DISCUSSION

Almost all of the drivers in this study were involved in frontal-type crashes. This is expected, because the airbag crash sensors are designed to respond to longitudinal deceleration of the vehicle. Based on detailed crash investigations, all of the airbag-induced facial injuries appear to have resulted from the airbag and not from the airbag module cover.

In previous studies of frontal crashes of cars without airbags, a large percentage of facial injuries involve fracture of the facial bones, with or without overlying soft tissue damage, and/or brain injury, due to contact with the steering-wheel. Approximately one-third of all steering-wheel airbag deployments in the current study resulted in facial injury, but almost all of these injuries are minor-- including erythemia, abrasions and contusions. These injuries usually occur to the cheeks, chin, or tip of nose. Forehead involvement is infrequent. Occasionally small, deep abrasions are incorrectly reported as lacerations. Facial fractures due to the airbag are extremely rare in the UMTRI database and appear to be due to the hand or forearm being flung into the face by the airbag, resulting in an undisplaced nasal bone fracture. Periorbital and ocular injuries are less frequent than overall facial injuries. The frequency of airbag-induced periorbital injuries is low (5%) with only 2% of the drivers sustaining an ocular injury.

Facial injuries are just as likely to occur to belt-restrained drivers as to unrestrained drivers. This is probably due to the fact that the deploying airbag contacts the driver's face before the lap-shoulder belt has its full effect in limiting the driver's forward movement. Also many drivers, particularly those of short stature, are in the airbag deployment envelope before the crash.

In a previous study on cranial-cervical dislocations from driver interaction with the steering-wheel airbag, all injured drivers were 165 cm or shorter.[46] In the current study, there is a decrease in the frequency of airbag-induced facial, periorbital, and ocular injuries, with increasing driver stature, although these injuries occur throughout most of the range of stature. The UMTRI database also indicates that females are more likely to sustain both facial and ocular airbag-induced injuries, probably because of their shorter stature and closer proximity to the airbag module. Also, even though 74% of the 540 steering-wheel airbag deployments involved tethered airbags, the frequency of facial injuries was higher in the untethered airbag population.

Crash related ocular injuries are not new. Numerous ocular injuries in car crashes have been reported for unrestrained occupants in older model vehicles without airbags. In these cases, interior contacts producing ocular injuries include the windshield and pillars, sunvisors, side door glass, steering-wheel and instrument panel.[44] In England and Europe, Australia and Asia, unrestrained front-seat occupants of older vehicles with tempered-glass windshields often sustained ocular perforations and, during the 1970s and 1980s, approximately 1800 British occupants received serious eye injuries each year.[45]

Airbag-induced ocular injuries have been previously reported from direct airbag contact with the eye, with eyeglasses, and with a tobacco pipe stem, as well as from the driver's hand being flung into the driver's face causing fracture to the nasal bones and infraorbital rim. Of the eleven drivers in the UMTRI study with ocular injuries, all were less than 179 cm in stature, nine were restrained by a lap-shoulder belt, seven were females, and five were injured by tethered airbags.

From the literature and the UMTRI database, 60 cases of airbag-induced ocular injury have now been reported.[16-40] Of these drivers 27 are known to have sustained an ocular injury from a tethered airbag compared to 21 injured by an untethered airbag. The number of tethered airbags is probably higher in the total population and thus more ocular injuries are related to the tethered airbag.

ABSTRACT

Automobile insurance claims of two popular midsize cars with different air bag deployment frequencies -- the Dodge/Plymouth Neon and Honda Civic -- were examined to determine performance in higher severity crashes (the upper 30 percent of crashes ranked by adjusted repair cost). Previously, it was found that drivers sustained more, mainly minor, injuries in the Neon which had a higher deployment frequency in low speed crashes. This study examined, for these two cars, whether there was any trade-off associated with a higher deployment threshold. It was found that even at higher speeds, the Neon had a greater frequency of air bag deployments, which in turn resulted in a greater likelihood of driver injury. Once again upper extremity injuries were most prevalent for Neon drivers and were highest for female drivers. At the same time, there was little evidence that driver protection was compromised in the Civic in the more important high speed crashes. The limited evidence from this study suggests that efforts should be made to reduce the number of air bag deployments in low speed crashes.

INTRODUCTION

Air bags can be designed to deploy at various speeds, but the assumption is that deployments should not occur below the injury threshold. However, there is growing concern about the large numbers of air bag deployments in crashes where speeds are slow enough that air bags are not needed to provide protection, particularly for belted occupants (1, 2, 3). This is particularly troubling because air bags can cause injury even in very low severity crashes. Air bag-related injuries are mostly minor, but in rare instances they involve serious and fatal injury to the head and chest to people who are close to them when they deploy (2).

Air bags are designed to deploy in frontal crashes at barrier equivalent speeds of about 10-12 mph. However, many of them are occurring at speeds lower than this nominal threshold depending on sensor type and location as well as crash type. Analyses of data from the National Highway Traffic Safety Administration (NHTSA) National Accident Sampling System (NASS 1990-1994) reveals that about a third of all deployments occur in frontal crashes at longitudinal delta Vs of less than 10 mph (2). Forty-two percent occur between 10 and 15 mph. There is also evidence of tremendous variation in deployment frequencies and deployment thresholds among different makes and models (3,4). Moreover, a recent study found, in a comparison of low severity crashes in two popular midsize cars, that drivers in the vehicle with more low speed deployments were injured more often than drivers in the vehicle with fewer deployments; albeit these were mostly minor injuries (3).

It has been suggested that the solution to the high number of low speed deployments is to raise the deployment threshold. A recent petition to NHTSA (5) recommended that Federal Motor Vehicle Safety Standard 208 be amended to set a 12 mph threshold below which the air bag cannot deploy. There are, however, some concerns that need to be addressed. If deployment thresholds are higher there is the possibility that injury rates will increase for unbelted occupants who no longer will be protected by an air bag in some crashes. There is also the concern that higher deployment thresholds may result in later deployments. This could have the effect of increasing injuries because occupants have the potential to be closer to the air bag at the time of deployment.

The previous study using insurance claims data for the 1995 Dodge/Plymouth Neon and the 1992-1995 Honda Civic found higher injury rates for the vehicle with higher deployment frequencies in low speed crashes (3). However, these comparisons provided no information on the overall performance of these two vehicles. That is, there was no analysis of the protection offered at higher speeds. This paper provides a comparison of injury likelihood in the same make/model vehicles, but in crashes of higher severity -- the crashes that were not included in the previous paper.

METHOD

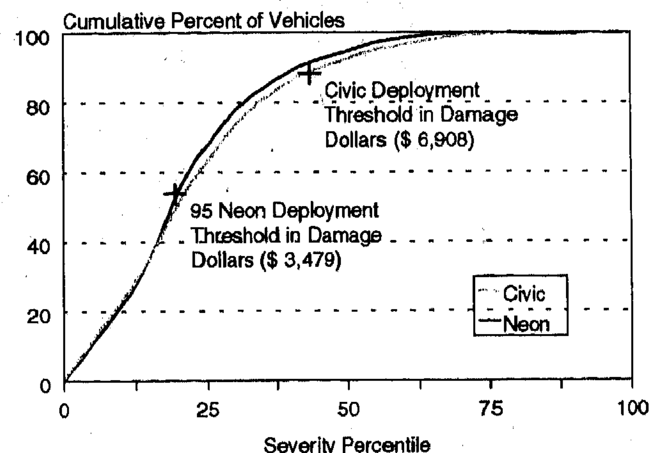
The following sources of information form the basis for the analysis and discussion in this paper:

1. State Farm Mutual Automobile Insurance Company's electronically prepared damage repair estimates for towed vehicles.

2. State Farm survey of claims involving frontal crashes for the 1995 Dodge/Plymouth Neon and the 1992-1995 Honda Civic.

3. The leading edge speed and excursion profile of driver air bag fabric in the 1995 Dodge/Plymouth Neon, the 1996 Neon, and the 1993 Honda Civic.

DEPLOYMENT FREQUENCY - A 1996 study escribed the use of State Farm damage repair estimates) identify towed vehicles with frontal damage (3). Deployment status was determined by analyzing the amage estimate for driver air bag module replacement. The Plymouth/Dodge Neon and the Honda Civic have imilar repair cost severity distributions, but a large ifference in their air bag deployment frequencies - the Honda Civic with an estimated deployment frequency of 0 per 100 frontal crashes, and the Plymouth/Dodge Neon rith an estimated 50 deployments per 100 frontal rashes.



CLAIM SURVEY - Because insurance claim ıvestigators do not require crash severity or delta V to be etermined as part of the claim settlement process, the delta V" distribution of the vehicle crashes represented by ısurance data was approximated by fitting the rank rdered cumulative distribution of dollar damages for ıese two cars to the cumulative delta V distribution etermined from a analysis of midsized cars in the lational Accident Sampling System (NASS 1989-1994,). The repair costs were adjusted to remove air bag ystem related expenses. Claim files representing the pper 30 percent of the cumulative distribution of crashes, ank ordered by adjusted repair cost, were selected for ıis study.

In the absence of crush measurements for insurance ata, the correlation between the rank ordered repair cost istribution and the NASS delta V distribution is not exact; owever, a review of the photographs of vehicle damage nd a review of the damage estimates show a systematic ıcrease in the extent of unibody structural damage. The uthors are confident that the claim files selected for this tudy are representative of the moderate to serious rashes seen in NASS.

Claim files were surveyed to provide information egarding policyholder involved crashes. Information abulated included a crash description, age and gender of ıe insured driver, driver injury descriptions, and erification of air bag deployment status. The Abbreviated njury Scale (AIS) and Occupant Injury Classification OIC) coding were used to document the injuries to insured drivers that sought treatment resulting in claim payments.

RESULTS

REPAIR COST DISTRIBUTION - Figure 1 depicts the cumulative percentage of 1995 Neons and 1992-1995 Civics repaired by damage severity percentile for frontal crashes. Severity percentile was determined by dividing each car's repair cost range into eight equal repair dollar intervals. A Kolmogorov-Smirnov test was used to compare the equivalency of the two cumulative repair cost distributions. The test results support the assumption that the repair cost distributions are equal for 1995 Neons and 1992-1995 Civics (KSA [1020] = 0.697, $p = 0.716$).

Note: 100th severity percentile represents $16,198 for the Neon and $15,893 for the Civic.

Figure 1. Cumulative Neon and Civic collision claim severity distributions for frontal impacts with towing.

Cases included in these analyses were those in the upper 30 percent of the cumulative distribution of crashes rank ordered by adjusted repair costs. This portion of the distribution includes crashes judged to be of moderate to high severity. For 1995 Neons, these crashes represent damages in excess of $4,264 in adjusted repair costs. For Civics, crashes with more than $4,461 in damages were included.

$$\log(p/(1-p)) = b_0 + b_1x \quad (1)$$

$$x(p=.5) = -b_0/b_1 \quad (2)$$

A logistic regression model (Equation 1) was used to determine the damage severity at which the probability of an air bag deployment reached 50 percent. P is the probability of deployment and x is the damage severity (in dollars). For p = 0.5, the damage severity is given by Equation 2. The derived value is defined for this study as the air bag deployment threshold, that is, the dollar point in the distribution where the probability of deployment is 50 percent. The adjusted repair cost,

where the probability of deployment is 50 percent is $3,479 for Neons (95 percent CI = $3,223 to $3,757). Civics have a 50 percent probability of air bag deployment at a $6,908 adjusted repair cost (95 percent CI = $6,452 to $7,484).

DEPLOYMENT FREQUENCIES - Figure 2 shows air bag deployments per 100 frontal crashes by damage severity, for the comparison vehicles. The Civic has an estimated deployment frequency of 48 per 100 moderate to serious, frontal crashes, and the Neon has an estimated 89 deployments per 100 moderate to serious, frontal crashes.

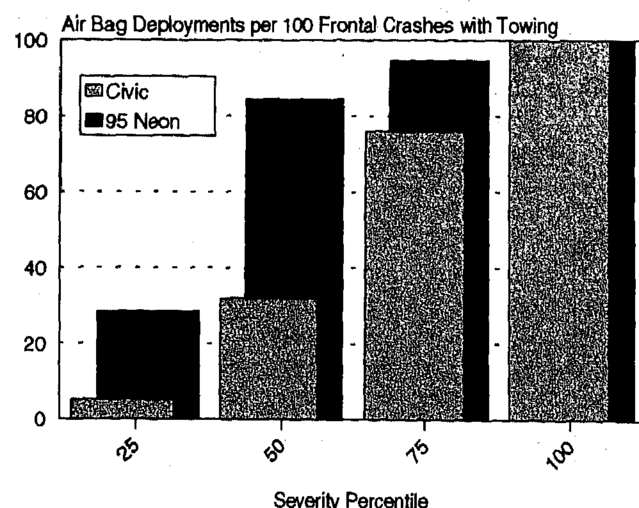


Figure 2. Air bag deployment rate by severity, frontal crashes with towing.

An analysis of the odds of deployment for moderate to serious crashes shows that there are significantly more deployments per 100 frontal crashes for Neons than for Civics (OR = 9.17; 95 percent CI = 4.72 to 17.54).

INJURIES - The following analyses compare injury rates in the two cars for moderate to serious crashes (the upper 30 percent of crashes ranked by adjusted repair amount). As shown in Table 1, 50 percent of Neon drivers report an injury in these crashes compared to 35 percent of Civic drivers. The relative risk of injury for Neon drivers compared to Civic drivers is 1.83 (95 percent CI = 1.16 to 2.96).

Table 1
Driver Injury by Car Model
for Moderate to Serious Crashes

	Driver Injury No	Driver Injury Yes	Total Crashes
Neon	57 (50.0%)	57 (50.0%)	114 (100%)
Civic	126 (64.6%)	69 (35.4%)	195 (100%)

Table 2 shows the maximum injury severity (MAIS) for the Neon and Civic drivers. Overall, injury severity was low for these drivers. Of the 309 Neon and Civic drivers, 292 (94.5 percent) had either minor injury or no injuries (MAIS-1); 15 (4.9 percent) had moderate injuries (MAIS-2); and 2 (0.6 percent) had a MAIS-3 injury. Very few MAIS-2 or greater injuries were associated with crashes in this crash severity range.

Appendix A shows the MAIS-2 or greater injuries, with driver age, gender, reported seatbelt use, and deployment status, rank ordered by the cumulative distribution percentile of crash severity.

Compared to the overall female-to-male driver ratio (2:1), females represented a higher proportion of the MAIS 2+ injuries (3.5:1). The odds of MAIS-2+ injury for female drivers was higher than for MAIS-2+ injured male drivers (OR = 1.81; 95 percent CI = 0.58 to 5.68). However, this relative risk was not significant.

Table 2
Drivers Injured by Maximum AIS
for Moderate to Serious Crashes

MAIS	Neon Count	Neon Percent	Civic Count	Civic Percent	Total Count	Total Percent
0	57	50.0	126	64.6	183	59.2
1	51	44.7	58	29.7	109	35.3
2	6	5.3	9	4.7	15	4.9
3	0	0.0	2	1.0	2	0.6
> 3	0	0.0	0	0.0	0	0.0
Total	114	100.0	195	100.0	309	100.0

Injuries by Gender - The injury data were also analyzed by gender of driver (Table 3). The proportion of male to female drivers involved in these crashes did not differ significantly for the two vehicles ($\chi^2[1] = .032$, $p = .857$), so overall injury risk can be compared without having to control for gender differences. Comparing across vehicles, the relative risk of injury to female drivers for Neons compared to Civics was 1.62. However, this relative risk was not significant (95 percent CI = 0.87 to 3.01). For male drivers, the relative risk of injury was 1.54 for Neons compared to Civics, again not significant (95 percent CI = 0.64 to 3.72).

Table 3
Driver Injury Status by Gender
for Moderate to Serious Crashes

Driver Gender	Driver Injury No	Driver Injury Yes	Total Crashes
Neon			
Female	26 (38.2%)	42 (61.8%)	68 (100%)
Male	19 (54.3%)	16 (45.7%)	35 (100%)
Civic			
Female	53 (50.5%)	52 (49.5%)	105 (100%)
Male	33 (64.7%)	18 (35.3%)	51 (100%)

Within a given vehicle, a comparison of injury risk differences by gender, shows that Neon female drivers

had higher odds of injury when compared to Neon male drivers (OR = 1.92; 95 percent CI = 0.84 to 4.39). In Civics, female drivers had a relative risk of injury equal to 1.83 when compared to male drivers (95 percent CI = 0.92 to 3.66) with neither result being statistically significant.

Injuries by Air Bag Deployment Status - Table 4 shows injury rates by car make and deployment status. In air bag deployment crashes Neon drivers had 1.45 times higher odds of injury than Civic drivers. However, this difference was not significant (95 percent CI = 0.83 to 2.54). For crashes in which the air bag did not deploy, the relative risk of injury for drivers was 0.87 for Neons, again not significant (95 percent CI = 0.22 to 3.45).

Table 4
Driver Injury Status by Deploy Status for Moderate to Serious Crashes

Deploy Status	Driver Injury No	Driver Injury Yes	Total Crashes
Neon			
No	9 (75.0%)	3 (25.0%)	12 (100%)
Yes	47 (46.1%)	55 (53.9%)	102 (100%)
Civic			
No	73 (72.3%)	28 (27.7%)	101 (100%)
Yes	52 (55.3%)	42 (44.7%)	94 (100%)

The odds of injury for Neon drivers in air bag deployment crashes was higher than for Neon drivers in non-deployment crashes (OR = 3.51; 95 percent CI = .898 to 13.73). Likewise, Civic drivers had higher odds of injury for air bag deployment crashes compared to non-deployment crashes (OR = 2.11; 95 percent CI = 1.16 to 3.82). However, it should be noted that crashes in which an air bag deployment occurs, typically are of higher severity and more injuries could be expected.

Location of Driver Injuries - Table 5 shows driver injury rates for "High" severity crashes (the upper 30 percent of crashes ranked by adjusted repair amount) and "Low" severity crashes (the lower 70 percent of crashes ranked by adjusted repair amount) by body region and car model. The injury rate (injuries per 1,000 frontal crashes with towing) includes multiple injuries per injured driver.

As might be expected, drivers in high severity crashes had higher rates of injury to all body regions, with the exception of head injuries to Neon drivers. Neon drivers had higher rates of injury to the upper extremities, including the upper arms, wrists, and hands for both high and low severity crashes. The rate of predominately minor facial injuries to Civic drivers is substantially higher than the Neon facial injury rate for the high crash severity category (103 compared to 35). The rate of facial injuries to Neon drivers is marginally higher than the Civic facial injury rate for the low crash severity category (20 compared to 13). The rate of lower extremity injuries for high severity crashes has a five-to-six fold increase over the rate of lower extremity injuries for low severity crashes. Neon and Civic drivers have similar lower extremity injury rates.

Table 6 shows driver injury rates by gender and car model for different body regions. Female drivers had generally higher injury rates compared with male drivers. Female Neon drivers had the highest overall injury rate in this comparison, with substantially higher injury rates to upper extremities compared with all other car model and gender categories. However, the rate of head, facial, and chest injuries to Civic female drivers is higher than for Neon female drivers.

Table 5
Driver Injuries per 1,000 Frontal Crashes with Towing by Car Model

Body Region	Neon Crash Severity High	Neon Crash Severity Low	Civic Crash Severity High	Civic Crash Severity Low
Head	26	38	41	22
Face	35	20	103	13
Upper Extremity				
Elbow	9	4	15	--
Upper arms	149	46	31	6

Back/T. Spine	105	53	138	71
Total Neck/Back	359	167	348	171
Lower Extremity				
Knee	88	19	113	22
Lower Leg	44	8	15	6
Ankle-Foot	61	8	36	--
Pelvic-Hip	9	4	26	2
Total Lower Extremity	202	39	190	30
Other Body Areas	--	--	10	--
Unknown	44	8	10	4
Total	1,122	457	901	296

Multiple injuries per injured driver possible.

Table 7 shows driver injuries by air bag deployment status and car model. There were very few claims to review for the Neon non-deployment classification, because of the high deployment frequency for Neons in these moderate to serious crashes. Neon drivers involved in air bag deployment crashes had higher rates

of injury to the upper extremities compared with Civic drivers involved in air bag deployment crashes.

Table 6
Driver Injuries per 1,000 Frontal Crashes with Towing by Gender and Car Model
Moderate to Serious Crashes

Body Region	Neon Male	Neon Female	Civic Male	Civic Female
Head	57	15	38	58
Face	57	29	58	163
Upper Extremity				
Elbow	--	15	19	19
Upper Arms	29	234	--	58

Lower Leg	--	74	--	29
Ankle-Foot	29	88	--	67
Pelvic-Hip	29	--	58	19
Total Lower Extremity	144	265	135	288
Other Body Areas	--	--	--	19
Unknown	57	44	19	10
Total	1,093	1,353	809	1,288

Multiple injuries per injured driver possible.

The rate of facial and chest injuries to Civic drivers involved in air bag deployment crashes was higher than the Neon facial and chest injury rate for air bag deployment crashes. Civic air bag deployments occur at the upper range of the crash severity distribution and likely reflect a more serious crash, on average, compared with Neon air bag deployment crashes.

Driver Air Bag Fabric Leading Edge Speeds and Excursions - As noted in the previous paper (3) both the Neon and the Civic air bags are tethered and constructed of relatively lightweight materials. The maximum excursion of the air bag fabric leading edge is also quite similar for the two bags (see Table 8). However, the maximum leading edge speed of the 1995 Neon air bag is much higher than that of the Civic (see also Figures 3 and 4). There is an increased potential for abrasive type injuries for higher speed air bags, particularly if they reach speeds in excess of 230 km/h (6).

Table 7
Driver Injuries per 1,000 Frontal Crashes with Towing by Air Bag Deploy Status and Car Model
Moderate to Serious Crashes

Body Region	Neon Deploy Status Yes	Neon Deploy Status No	Civic Deploy Status Yes	Civic Deploy Status No
Head	29	--	21	58
Face	39	--	149	58
Upper Extremity				
Elbow	10	--	11	19
Upper Arms	167	--	43	19

Lower Extremity				
Knee	98	--	138	87
Lower Leg	49	--	32	--
Ankle-Foot	69	--	43	29
Pelvic-Hip	10	--	53	--
Total Lower Extremity	226	--	266	116
Other Body Areas	--	--	21	--
Unknown	49	--	21	--
Total	1,216	333	1,117	683

Multiple injuries per injured driver possible.

However, it should be noted that the Neon air bag underwent a design change for the 1996 model year and leading edge speeds in the 1996 Neon air bag now are lower than either the Honda Civic, or the 1995 Neon.

Table 8
Air Bag Maximum Leading Edge Speeds and Maximum Excursions

Model	Tethered	Maximum Excursions (mm)	Maximum Edge Speed (km/h)
Honda Civic	Yes	328	227
1995 Dodge Neon	Yes	334	325
1996 Dodge Neon	Yes	274	158

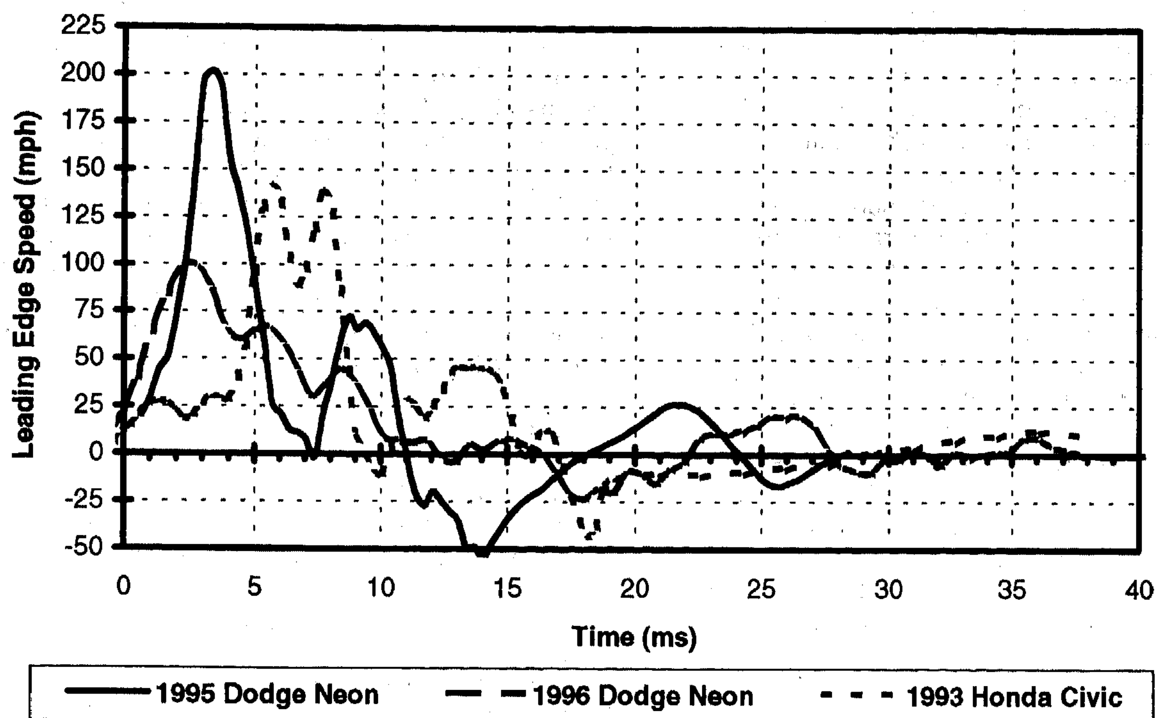

Figure 3. Air bag leading edge speeds by deployment time for the Neon and Civic air bags.

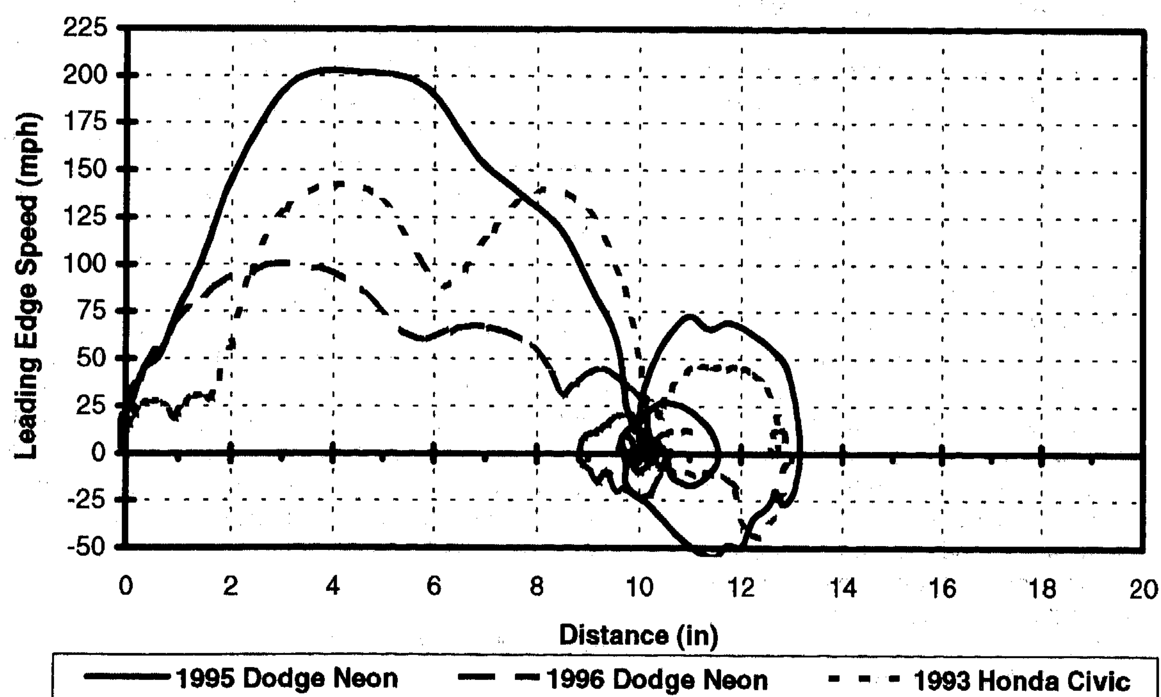

Figure 4. Air bag leading edge speeds by deployment distance for the Neon and Civic air bags.

DISCUSSION

The comparative performance of two similar mid-sized cars in moderate to serious crashes was considered in this paper to supplement results from a previous paper examining injury likelihood for the same two vehicles in low severity crashes. The previous study determined that drivers in the vehicle with more low speed deployments were injured more often than drivers in the vehicle with fewer deployments.

For the moderate to serious crashes surveyed in this study, one vehicle had substantially more deployments than the other vehicle. One might expect more moderate and serious injuries to drivers of the vehicle with fewer deployments in these moderate to serious crashes if air bags are failing to deploy when needed to prevent injury. This was not observed. There were very few moderate and greater injuries to the drivers of both vehicles and the proportion of these injuries was very similar; moreover, drivers in the vehicle with more deployments were injured more often overall than drivers in the vehicle with fewer deployments.

A comparison of the MAIS-2 and greater injury patterns, by body region, between vehicles, revealed no clear differences. Although drivers in both vehicles suffered head and chest injuries in crashes in which the air bag did not deploy, these injuries were predominantly minor. The absence of serious injuries to drivers of the vehicle with fewer deployments in moderate to serious crashes is encouraging. However, because of the limited number of cases available, and the absence of any very high speed crashes, further research is needed to confirm that in the Civic, and more generally, in other vehicles with fewer low speed deployments, that there is no injury trade-off when setting deployment thresholds higher.

The level of belt use is an important consideration for interpreting these results. Unbelted occupants are more vulnerable to injury. However, only self-reported belt use is available for drivers in this study and in the Civic and Neon, about 75 percent of the injured drivers reported that they used their belt. High belt use decreases the likelihood of observing serious injuries in non-deployment, moderate to serious crashes.

The results of this study indicate that the rate of upper extremity injury is higher, the higher the rate of deployment, regardless of crash severity. In addition, female drivers appear to be sustaining more injuries, particularly to the upper extremities, than males in these moderate to serious crashes. Proximity to the air bag at the time of deployment is clearly a risk factor. Less aggressive air bag designs and air bag systems currently under development that take into account occupant size, weight, and proximity to the air bag, may help alleviate this problem.

The authors' previous study outlined two factors that could be contributing to the higher rate of injury to Neon drivers compared with Civic drivers. Results of this study indicate that these same factors apply to the interpretation of the higher rate of Neon driver injury compared with Civic drivers in moderate to serious crashes. The 1995 Neon experiences many more air bag deployments in moderate to serious frontal crashes and the air bag fabric has a higher leading edge speed compared with the Civic. Both of these air bag performance characteristics appear to be changed for the 1996 Neon. The estimated deployment frequency for the 1996 Neon is 35 per 100 frontal crashes compared with 50 deployments per 100 frontal crashes for the 1995 Neon and 20 deployments per 100 frontal crashes for the Civic. Also, the leading edge speed in the 1996 Neon air bag is lower than either the Honda Civic, or the 1995 Neon. Results of this study and the previous related study suggest that these changes will result in lowering the injury rate to drivers of 1996 Neons involved in frontal crashes.

CONCLUSIONS

Auto manufacturers, the NHTSA, air bag system component suppliers, auto safety researchers, and auto safety advocates are currently challenged to find effective solutions to unintended injuries from air bag deployments. Smart air bag technology is expected to address the issues associated with the most serious of these unintended air bag induced injuries in the longer term. However, air bag system designs that optimize the air bag deployment threshold, using current and available technology, can partially address these concerns by reducing the number of unneeded deployments. For example, dual deployment thresholds that are set to deploy the air bag at different crash severities based on belt use could reduce unneeded deployments for belted occupants. Serious consideration should be given to raising the deployment threshold for unbelted occupants where the vehicle's air bag deployment threshold results in large numbers of low speed deployments. One concern in raising the unbelted threshold is that facial injuries, such as fractures to facial bones, could increase. This study, although limited in scope, found no evidence of such a trade-off.

The higher rate of mainly minor injuries for Neon drivers could be related both to the higher frequency of air bag deployment as well as the higher leading edge speed of the 1995 Neon air bag. Air bag design characteristics associated with the number of deployments and air bag leading edge speed were changed for the 1996 Neon. These changes will likely reduce the air bag induced injuries in low to moderate severity crashes, while maintaining air bag performance in higher speed crashes.

Parametric Model of Elastomeric Bolt Isolators Under Large Deformation

Zhi-Quan Hu, T. Y. Chen, and Gary Novak
Fel-Pro Inc.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

In an integrated noise isolation system, both gasket and bolt isolators play an important role in the resultant total load, contact stress, and system static and dynamic stiffness. One standard approach to design is based on using a shape factor in conjunction with a simple stress-strain relation. This approach can produce reasonable results under small deformation. But the deviation is so large that it is not appropriate to use it for reliable designs under large deformation. Experimental approaches and finite element methods are effective at characterizing the load-deflection relationship of bolt isolators under large compressive deformation. In this paper, a parameter study of a sequence of finite element analyses will be presented and a parametric model will be determined based on the FEA results to best represent the isolator load-deflection behavior under large compression. The resulting formula can be used to quickly and accurately determine the isolator static and dynamic stiffness. The parametric model was compared to experimental measurements with very good agreement.

INTRODUCTION

Bolt isolators and gasket are key components in an oil pan or rocker cover isolation system (illustrated in Figure 1). The function of a bolt isolator is to avoid direct contact between the bolt and the cover, and form an integrated isolation system with the gasket. The gasket isolation system has the dual function of sealing and isolation. Both the gasket and the isolator should be well designed to realize good performance in sealing and isolation[1]. To achieve the appropriate sealing stress, the elastomer gasket should be compressed to a level such that adequate sealing stress will always be maintained under a large range of temperature fluctuation, flange bending, and sealing surface out-of-flatness. The force required to compress the gasket to the compression level must be determined. Knowing the number of isolators required in the system, the amount of force required from each isolator is known. The isolators must also survive the harsh operating environment. Therefore, the load must be achieved at an appropriate level of compression. If the compression is too much, the isolator may break; if too little, it may lose load due to out-of-flatness and aging. The isolators must also fit in the space provided by the cover flange. Once the compression levels for the gasket and isolators have been determined, the grip length for the bolts are fixed based on the compressed rubber thickness of gasket and isolators, the flange thickness, gasket carrier thickness, and the isolator washer thickness. When assembled, the total compressed rubber thickness is a constant

$$l_g(1 - c_g) + l_i(1 - c_i) = C \qquad (1)$$

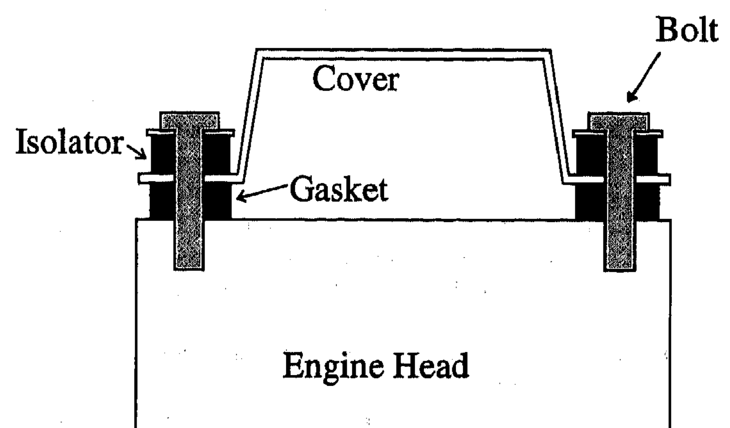

Figure 1: Illustration of a rocker cover to engine block isolation/sealing system

where l_g and l_i are the uncompressed thicknesses, and c_g and c_i are the compression levels, for the gasket and the isolators respectively, and C is a constant. Any change in the isolator compression will result in a corresponding change in the gasket compression in the opposite direction. The sealing and isolation performances will be affected. It is generally accepted that the material properties of elastomers change with many factors. But it is always advantageous to get as accurate a result as possible. Good analytical models are the key to a better system design.

The gasket design calculation can be done with the parametric modeling approach[2]. Analytical models for rubber mounts or bearings has been developed to predict the load–deflection or stress–strain relationship under special conditions. The linear elastic theory is commonly used with infinitesimal strains and incompressible materials. Under these assumptions, the following linear stress–strain equation[3]

$$\sigma = E(1 + 2s^2)\epsilon \tag{2}$$

was derived as an approximate solution to the fundamental equation:

$$\frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial y^2} - \frac{12p}{t^2}\frac{G}{K} = -\frac{12G\epsilon}{t^2} \tag{3}$$

where E, G, and K are the Young's modulus, shear modulus, and bulk modulus of the material, t is the thickness of the bearing, $p(x, y)$ is the hydrostatic pressure as a function of the coordinate (x, y), ϵ is the average vertical strain, and s is the shape factor of the sample. The approximation is done over a very large range of shape factors. Bearings tested to high compressive strains display a nonlinear, stiffening load-deflection curve. The non-linear large strain models provide better approximation under finite strain. The following three theories have been proposed (see Stanton and Roeder[4] for a more detailed review);

1. Holownia[5]

$$\sigma = E_c \frac{\epsilon}{(1-\epsilon)^3} \tag{4}$$

2. Based on the kinetic theory of rubber-like solids, Gent[6] proposed

$$\sigma = -\frac{E_c}{3}(\lambda - \lambda^{-2}) \tag{5}$$

3. The third formula is a constant modulus, E, which relates incremental uniaxial stress and strain

$$\sigma = -E_c(1 - \frac{1}{\lambda}) \tag{6}$$

For small strains, all three equations reduce to

$$\sigma = E_c\epsilon \tag{7}$$

But, for large deformation, the computed stresses from the three equations could be quite different. The three non-linear models and the linear elastic model are compared in Figure 2. The three non–linear models are very close to the linear model at small strain. The difference between the four models are very large at large strain. Comparison with actual test data tell us that the linear model will under predict load, while the Holownia model will over predict load. The kinetic theory model and the incremental stress–strain model generally give better results. Still, the error can be significantly large when the shape factor is very small (less than 0.2). The apparent modulus E_c used in the models was obtained by multiplying the material Young's modulus by $1 + 2s^2$. But the constitutive theories do not describe the full complexity of the material behavior. Gent and Linley[5] found that the best fit with experimental results was obtained by introducing an empirical constant k to give

$$E_c = E * (1 + 2ks^2) \tag{8}$$

The constant k has the value 1.0 for a truly elastic material. Since the value of k is material dependent, it must be experimentally determined before it can be used. Also, the apparent modulus formula was only applicable to bearings with both surfaces bonded to rigid surfaces.

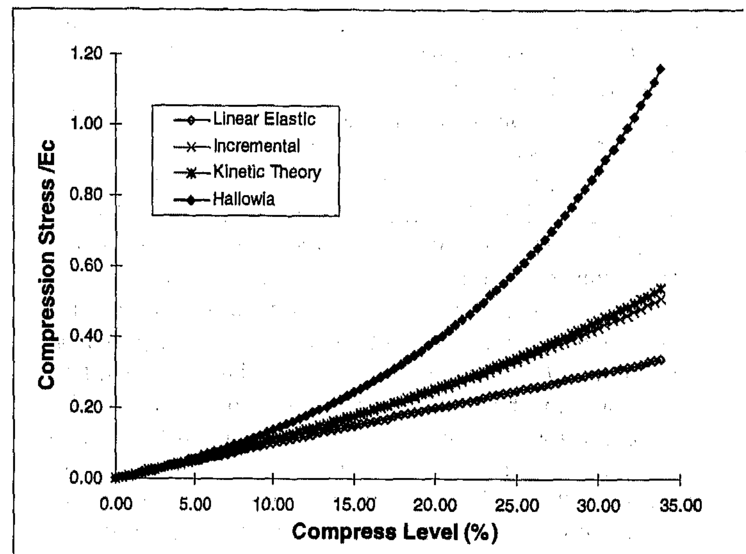

Figure 2: Comparison of the theoretical models

The bolt isolator is a special type of rubber bearing, which usually operates under large compressive strain(20% to 40%). The errors could be significant if the appropriate equation is not used. Also the bolt isolator is only bonded on one surface.

Finite Element Analysis (FEA) is a numerical method which results in an efficient, accurate and comprehensive technique for solving complex design problems. Several constitutive theories, based on strain energy density functions, have been developed for elastomeric materials. The two most widely used models for elastomer analysis are the Mooney–Rivlin model and the Ogden model. In this

paper, the axisymmetric element and the Mooney-Rivlin model are used for the FEA simulation to calculate load, deflection and the stress field. Pure shear, uni-axial tensile, and compressive tests of the elastomeric specimens are performed to provide the material properties for FEA.

FEA can deal with complex shapes and boundary conditions and eliminate the need for actual prototypes. The load–deflection curves created by FEA simulation match experimentally generated data. Figure 3 shows an empirical and an FEA simulated load-deflection curve. There is close correlation between the two methods when strain is less than 10% There are some errors when the strain is larger than 10%, but the difference is well within 15%. Since FEA result is very close to the test result, it is used as a virtual test to perform simulation on samples of different shapes.

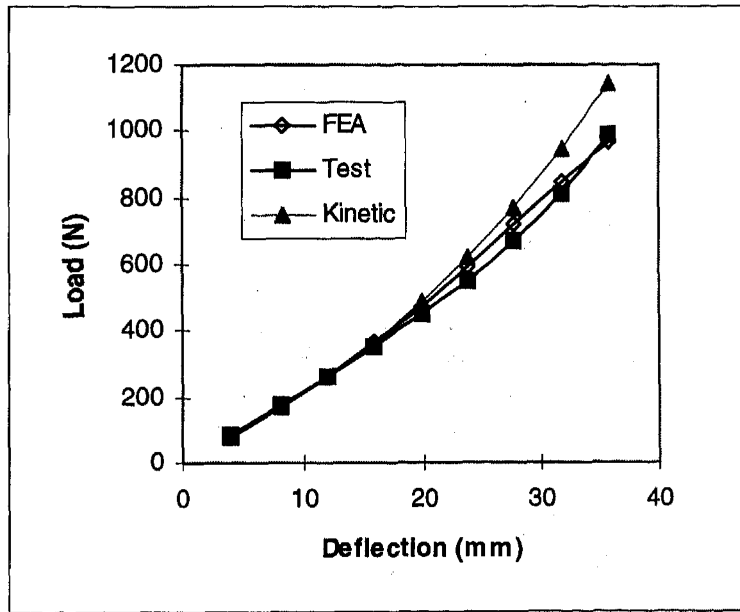

Figure 3: Comparison of FEA result with test result

PARAMETRIC MODEL

A typical bolt isolator which is illustrated in Figure 4 can be described geometrically by three parameters, the bolt hole diameter, d, the outer diameter, D, and the height, h. When a uniaxial load, F, is applied vertically at a temperature, T, the isolator will deform to a height of h_1. The load, F, is a function of the geometric parameters and material property. Mathematically, it can be written as

$$F = F(D, d, h, h_1, T, E) = \frac{\pi(D^2 - d^2)}{4}\sigma \qquad (9)$$

Since the kinetic theory model and the incremental stress–strain model are closer to the test result, and the incremental stress–strain model is simpler, the parametric model will be derived based on the incremental stress–strain model. Substituting $\lambda = 1 - \epsilon$ into equation 6, it becomes

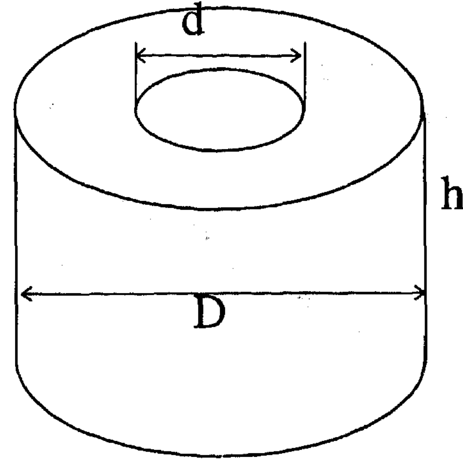

Figure 4: Illustration of a typical isolator

$$\sigma = E_c \frac{\epsilon}{1 - \epsilon} = E(1 + 2ks^2)\frac{\epsilon}{1 - \epsilon} \qquad (10)$$

or

$$\frac{\sigma}{E} = (1 + 2ks^2)\frac{\epsilon}{1 - \epsilon} \qquad (11)$$

The above equation says that for a specific material, the stress–strain relationship is only a function of shape factor s. Empirical data and FEA simulation suggest that isolators of the same shape factor, with different geometries, may not have the same stress–strain relationship Figure 5 shows the stress–strain plot of two isolators of the same shape-factor of 0.25. The difference between the stresses at 30% strain is approximately 13%. Apparently, the shape factor does not truly reflect the effect of geometry. To fix this problem, the term $(1 + 2ks^2)$ is replaced with a coefficient $\alpha(D, d, h)$, which is a function of geometric parameter. Equation 11 becomes

$$\frac{\sigma}{E} = \frac{\alpha(D, d, h)\epsilon}{1 - \epsilon} \qquad (12)$$

Fitting the FEA simulated data to the above equation resulted in a poor fit. To achieve a better curve fit, a new coefficient, $\beta(D, d, h)$, has been introduced.

$$\frac{\sigma}{E} = \frac{\alpha(D, d, h)\epsilon}{1 - \beta(D, d, h)\epsilon} \qquad (13)$$

or

$$\sigma = E\epsilon \frac{\alpha(D, d, h)}{1 - \beta(D, d, h)\epsilon} \qquad (14)$$

This is the general model for a bolt isolator. The material property is represented by E, and the effect of geometry by the two coefficients α and β as functions of D, d, and h. The temperature effect can be represented by a temperature dependent modulus E.

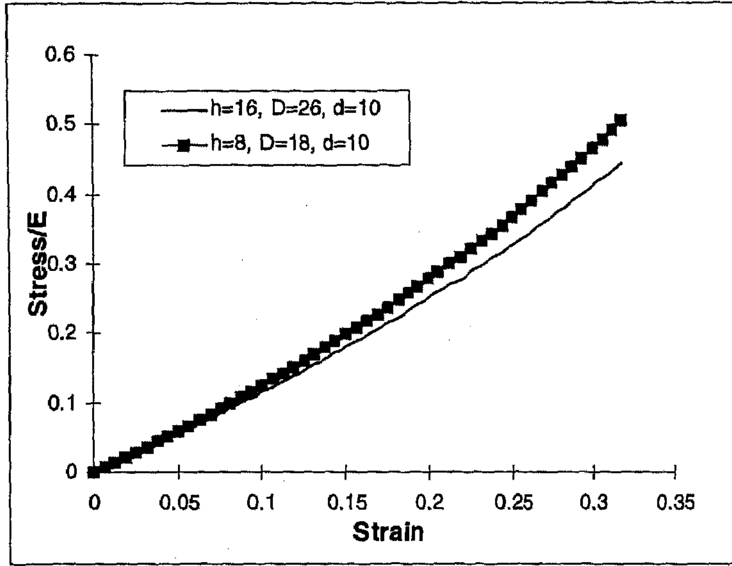

Figure 5: Stress–strain plot of two isolators of the same shape factor

This model is expected to work in a practical range of $D_{min} < D < D_{max}$, $d_{min} < d < d_{max}$, and $h_{min} < h < h_{max}$. The limit values D_{min},D_{max}, d_{min},d_{max}, h_{min} and h_{max} are determined by the type of application. In the cover and oil pan application, e.g., the outer diameter is rarely smaller than $15mm$ or larger than $30mm$. The bolt hole diameter should be between $10mm$ to $15mm$, and the height between $8mm$ to $16mm$.

The recommended modeling procedures are as follows:

1. For a given material, and any given set of geometric parameters D, d, and h, obtain the engineering stress-strain data through FEA simulation.

2. Fit the stress-strain data to the function

$$\sigma = E\epsilon\frac{\alpha}{1-\beta\epsilon} \tag{15}$$

   and obtain the two coefficients α and β.

3. Fit the coefficient α and β to the parameters D, d, and h to get the equation

$$\alpha = \alpha(D, d, h) \tag{16}$$

$$\beta = \beta(D, d, h) \tag{17}$$

A MODELLING EXAMPLE

Let the bolt hole diameter $d = 10mm$, $D_{min} = 16mm$, $D_{max} = 26mm$, $h_{min} = 8mm$, and $h_{max} = 16mm$. There are 30 combinations of parameters if ΔD and Δh are both $2mm$. For isolators of each size, perform FEA simulation and obtain the stress–strain curves. The coefficients α and β were determined by fitting the stress–strain curves to equation 15. Table 1 listed some selected coefficients.

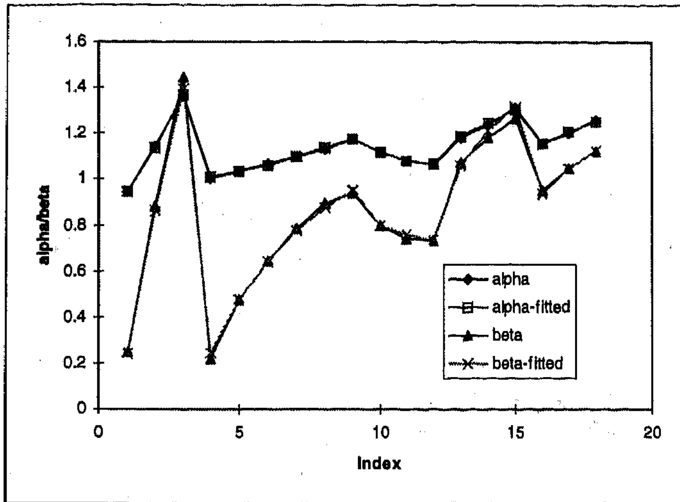

Figure 6: Fitted results of α and β

two isolators, one with both sides bonded and the other with one side bonded and one side lubricated. For the two conditions, the structure of the models are the same (equation 15). But the coefficients that relate α and β to the geometric parameters D, h, and d are different. Both parametric models fit the FEA results very closely, while the other models differ significantly.

It has been demonstrated that FEA simulation results closely agree with test results, and the parametric model derived from FEA simulated load–deflection curves matches FEA results. Therefore, it is expected that the parametric model will match the actual test result. Two one–side bonded isolators of dimensions ($D = 26mm$, $d = 11.68mm$, $h = 8.8mm$) and ($D = 22.6mm$, $d = 9.8mm$, $h = 10.03mm$) and Young's modulus of $5.85MPa$ were tested and compared with the parametric model. As demonstrated in Figure 11, the same model closely matches the test results in both test cases. The maximum error is within 10% of the test results. The error is the accumulation of errors from FEA simulation to test and parametric model to FEA simulation. If the parametric model were derived from test data instead of FEA simulated data, the error would be smaller. But the advantage of simulating many different isolators without actually making the parts would be lost.

APPLICATION

The FEA simulation can produce a result which is very close to the test result, and the parametric model is in close agreement with with the FEA simulation. Therefore, it is safe to conclude that the parametric model also agrees with the test result. Once a load-deflection model is determined, the stiffness can be determined mathematically from the load-deflection model. A design engineer can use

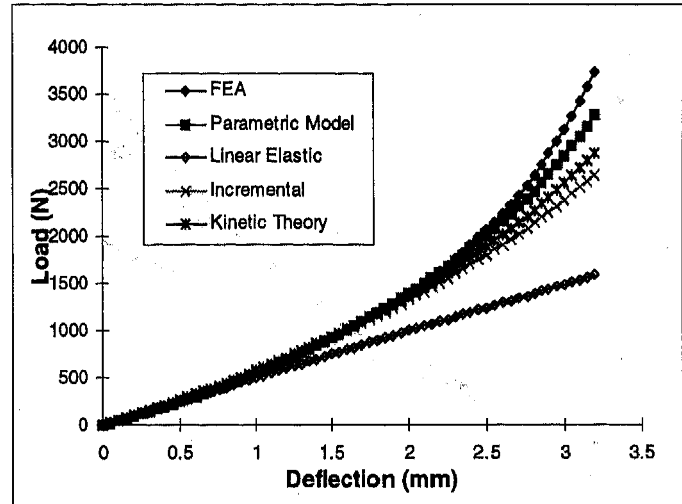

Figure 7: Comparison of Parametric Model with Linear and Non-Linear Models (D=26mm, d=10mm, h=8mm, E=5.85MPa)

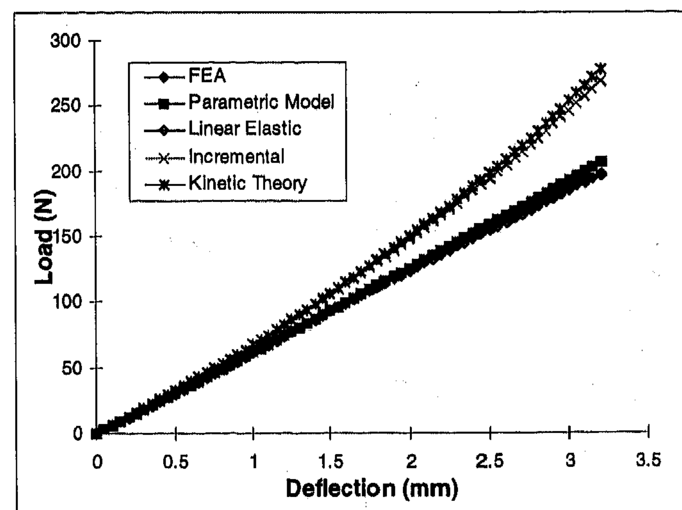

Figure 8: Comparison of Parametric Model with Linear and Non-Linear Models (D=16mm, d=10mm, h=12mm, E=5.85MPa)

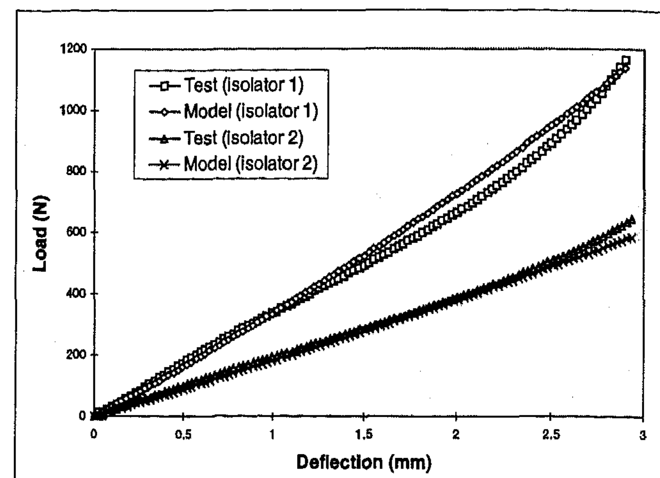

Figure 11: Comparison of Parametric model with test results

the model to determine the desired geometry and select the appropriate material based on the load required at a specific deflection. The one-time FEA modeling of a few samples of one material is extended to many different geometries and materials. The resultant parametric model can be used repeatedly in design and analysis.

CONCLUSION

FEA model can be used to generate load-deflection data which is very close to the actual test data from a load frame. Based on the large strain non-linear stress-strain model, a modified stress-strain relationship was established to better represent the test and FEA simulated data. The modified stress-strain equation determines the basic structure of the parametric model. The relationship between the coefficient of the stress-strain equation and the geometric parameters were determined through curve fitting. The resultant model agrees with the FEA and test results. The parametric model can be used in engineering design without repeated employment of FEA and can be used as an engineering tool for design, analysis, and optimization.

The Effect of Flange Flexibility on the Response of Gasketed Bolted Joints Subjected to External Forces

Gary Novak, Zhi-Quan Hu, Michael Sadowski, and Edward Widder
Fel-Pro Inc.

Copyright 1997 Society of Automotive Engineers, Inc.

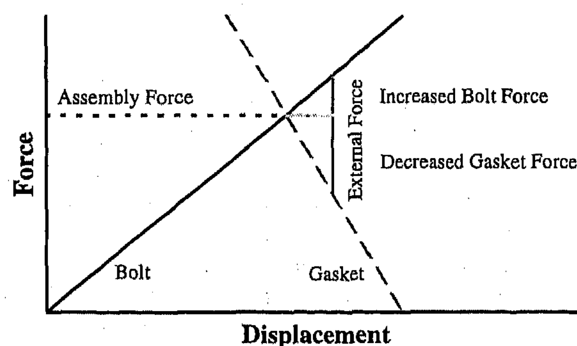
ABSTRACT

The response of a gasketed, bolted joint to an external load is understood to be effected by all components involved in the joint. The analysis involves the equilibrium of the gasket compressive force with the bolt tension force and the forces external to the bolted joint. Geometric compatibility is maintained when the change in the stretch of the bolt caused by an external force is equal to the change in compressed thickness of the gasket. When the flanges are treated as nondeformable, the classical joint diagram analysis indicates that externally applied loads, which unload the gasket, increase bolt tension. In this paper, the effect of flexible flanges is included in the analysis of simple gasketed bolted flanges. The results show that bolt tension response can deviate significantly from the rigid flange behavior. In certain situations where flanges have a relatively high level of flexibility, external joint forces that unload the gasket also unload the bolt.

INTRODUCTION

The need to predict gasket stresses is driven by goals to optimize design, maximize performance, reduce design iterations, and compress overall product development time and cost. The assembly condition and the load cases that are expected to cause extreme gasket loads need to be evaluated. Gasket stresses under these conditions can be used to evaluate the expected performance of the gasket as both a structural member and seal. Initial as assembled, in service operation, and long term performance can be estimated by using initial geometry and material properties, end of life geometries and material properties, failure models that look at stresses and deflections at a point in time, or failure criteria that include time effects such as Weibull or cumulative damage methods. Regardless of which analysis is being conducted, an accurate prediction of gasket forces or stresses is needed.

The gasket is one part of the bolted joint that also includes the fasteners and the flanges. The flanges can be very complex structural components such as cylinder blocks or heads. The performance of all of these components must be considered when evaluating the performance under load of any one component. Joint diagram analysis [1] and finite element analysis, FEA, [2] are two approaches that are commonly used to evaluate bolted joints subject to a variety of assembly and operational loads. Both approaches are used to predict fastener and gasket deformation and load distribution when a bolted joint is subjected to various loading conditions.



In this work, a combination of experiment and FEA was used to study the effect of flange flexibility on the response of gasketed bolted joints subjected to external forces. The work demonstrated significant differences between the flexible flange mechanics and the idealized behavior modeled by the joint diagram. Two examples were analyzed and experimentally verified to show how flange flexibility can cause bolt force levels to be less than values predicted by joint diagram analysis. Both analysis and experiment demonstrate a decrease in bolt tension in response to a joint separating force under certain conditions.

BACKGROUND

Joint diagram models are extremely effective at predicting the joint equilibrium forces and deformation of idealized joints. These idealized

conditions require that the flanges are rigid or that the flange deformation is uniform around the joint. Joint diagrams predict equilibrium assembly bolt stretch and gasket compression when total fastener tension, fastener stiffness, gasket stiffness, and idealized flange stiffness are specified. Nonlinear gasket material models with inelastic recovery can be included in joint diagram analysis [3]. Joint diagrams are used to redistribute external forces between the fastener and the gasket to determine increases and decreases in fastener and gasket total force (Figure 1). These external forces include both joint separating forces such as in-cylinder combustion forces and forces that tend to increase gasket compression. Joint diagrams have even been used to predict the effects of thermal expansion on the equilibrium of forces and geometric compatibility in these idealized bolted joints.

Figure 1
Joint Diagram

In many real world applications of gasketed bolted joints, flanged connections do not behave as the idealized bolted joints with rigid uniform flanges or uniform flange deflection. In these cases, the flange deflection is significant and varies along the sealing path of a gasket, flange thickness and stiffness varies, or there is a significant out of flatness that can cause the gasket loading to vary significantly around the sealing path. The joint diagram cannot accurately predict the gasket contact stress distribution or gasket and fastener equilibrium conditions. The joint diagram analysis does not include the effects of nonuniform flange deflection, flange flatness, bolt load nonuniformity, or gasket nonuniformity. Joint diagrams have been used to qualitatively describe the behavior of a bolted joint when flange deformation effects are included [4,5]. The response of a bolted joint to an external force is predicted by joint diagram analysis as being split between the gasket and fastener in proportion to their relative stiffness. An external force that separates the flanges increases the bolt force and decreases the gasket compressive force while maintaining force equilibrium; gasket compressive force plus external force equals bolt force. Conversely, an external force that tends to compress the flanges decreases the bolt force and increases the gasket compressive force in proportion to their relative stiffness while also maintaining force equilibrium. Joint diagram analysis indicates that separating forces increase total fastener tensile force while decreasing total gasket compression force.

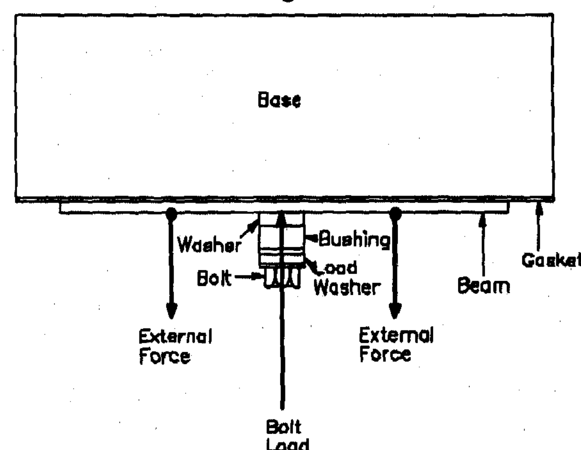
In situations where flange deformation is significant and large variation in gasket contact stresses occur, joint diagram methods are not effective. Analytical methods involving the simulation of deformable flanges have been used in these situations through closed form solutions, approximate methods, and customized computer formulations[6,7,8]. Finite element analysis, FEA, is a numerical analysis technique that is widely used to analyze problems involving complicated geometries where material models, loading conditions, or nonlinearities make closed form solutions or custom programs difficult or impossible to use. FEA has been used to include the effects of flange flexibility in the analysis of gasketed bolted joints [1,9]. Nonlinear material properties, deformation due to complex flange geometry, and flange flatness have been included in these analyses. The gasket contact stresses and compression distributions are the primary outputs of an FEA; while the total gasket force and the gasket compression are determined from a joint diagram analysis of a rigid or uniform deformable flange system.

Gasket compressive deformation is in equilibrium with the bolt stretch and the flange deflection. Under the bolt, flange deflection is due to the through thickness flange compressibility. Between bolts, bending causes flange deformation. In the cases where flanges are relatively thin, under the bolt flange compression is negligible compared to the very significant bending effect that takes place away from the bolts. Less gasket compression develops at locations farther away from the bolts than occurs at locations closer to the fasteners; because thin flexible flanges cause the midspan flange deformation to be large. For uniform thickness gaskets, gasket compressive stresses are maximal near the fasteners where high levels of gasket deformation cause high compressive strain levels. Stresses are lower at those areas farther from the fasteners where gasket compressive strain levels are reduced compared to the levels under the bolt. Flange flexibility effects cause the total gasket and bolt forces to be less than the values that would be predicted by the rigid flange models when the joint is assembled to a specific level of interference (under the bolt gasket compression plus bolt stretch). When

external loads are applied to a bolted joint, flange flexibility affects the way that the unloading gasket clamp force is distributed. The force is not applied as a uniform stress acting over the total contact area. Changes in the total gasket and bolt forces can be significantly different from those predicted through joint diagram type analysis. Bolts force increases, in response to joint separating forces, are less than those predicted by joint diagram effects. In certain situations of flexible flanges with high stiffness fasteners, separating forces can decrease bolt tensions rather than increase them.

GASKETED JOINT SAMPLE PROBLEM

There are many applications where external loads are introduced into a gasketed bolted joint. The external load changes the joint conditions and affects the sealing performance of the joint. External loads are often introduced into a joint when the internal pressure within a bolted joint changes. The effect of the external load is predicted through traditional joint mechanics, where forces and displacements must balance. Joint diagrams are often used to represent these fundamental relationships between forces and displacements. In a rigid flange model, the interactions between the external force and the joint can be readily predicted and even depicted on a joint diagram. On the other hand, when the deflection of the flange becomes significant, a more complex joint model is necessary to predict the reactions in the joint. To demonstrate this complex interrelationship between the joint and the external load, a simple sample joint was designed. This sample joint will be used to demonstrate the impact an external load has on the joint equilibrium.



The sample joint consists of two flanges connected together with a single bolt at the center. Each flange is 25 mm (1 inch) wide and 260 mm (10.25 inches) long. One flange was 102 mm (4 inches) thick and represents a rigid foundation. A single layer of a gasket facing was placed between the flanges; the gasket facing was 0.76 mm (0.030 inches) thick. This joint was assembled with a 12.7 mm (0.5 inch) bolt to a load of 4448 N (1,000 lbs). Two 118 N (26.5 lb) external lifting loads were placed on the thinner flange on either side of the bolt. The loads were located 3 inches from the center of the bolt. The 118 N (26.5 pound) loads interact with the joint producing changes in bolt load, gasket load and flange deflection.

ANALYTICAL MODEL OF SAMPLE JOINT - The sample joint was analyzed by modeling the joint and applying the external loads. The analytical model includes flange deflections, non uniform load distributions on the gasket, non-linear gasket material properties, and a linear spring model for the bolt. The beam was divided into 100 nodes along its length for the analysis. The sample problem was analyzed with both a 50.8 mm (2 inch) thick flange and with a 6.35 mm (0.25 inch) thick flange.

In the analysis of the rigid 50.8 mm (2 inch) thick beam, the bolt load increased when the external load was applied. The bolt load increased from 4448 N (1,000 pounds) to 4461 N (1003 pounds) in response to the 236 N (53 pound) external load. In contrast, when the external load was applied to the flexible beam, the bolt load decreased. The initial load of 4448 N (1,000 pounds) dropped to 4186 N (941 pounds) with the addition of the 236 N (53 pound) external load.

EMPIRICAL RESULTS OF SAMPLE JOINT - To verify the gasketed bolted joint phenomena exhibited by the analysis, an experiment was devised to provide the application of an external load to a bolted joint. The bolted joint had the same configuration of the sample joint described earlier. The external loads were applied through a pair of eye bolts that were attached to the beam, equidistant from the bolt. The applied bolt load was measured using a bolt load washer transducer. A spacer bushing was placed between the beam and the load transducer to reduce the effects of non-uniform loading on the transducer due to beam bending. The external load was applied to the beam using a dead weight hung by a cable arrangement. This fixture insured that the load was distributed equally on either side of the bolt. This test arrangement is depicted schematically in Figure 2; the actual test fixture configuration is shown in Photo 1.

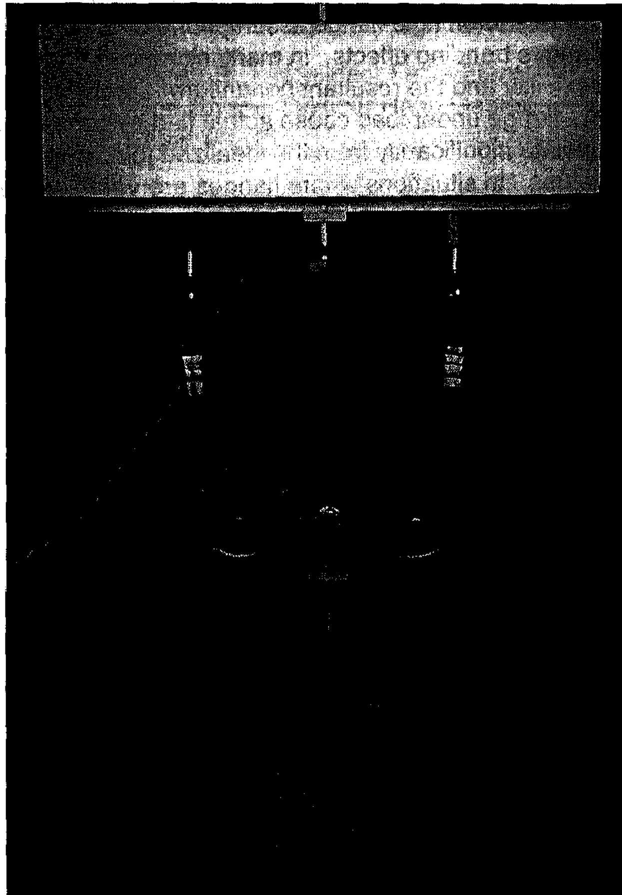


Figure 2

Following the tightening of the bolt, the applied load is observed to decrease with time. This behavior is typical of creep-relaxation characteristics

of gasketed, bolted joint systems. In order to reduce the effect of this time dependent load decay, the bolted assembly was allowed to stabilize for 2 hours, before the external load was introduced.

Photo 1

A bolt load of 4448 N is initially applied to the beam. When an external load of 236 N is applied in an opposite direction to the beam flange, the change in bolt load is measured, also using the bolt load washer transducer. This change in bolt load was recorded for two different flange thicknesses, 6 and 51 mm, for the same conditions of applied bolt load and external load. The thicker flange approaches the stiffness of an infinitely rigid beam, for the dimensional and loading conditions of this experiment. It can be observed that, with the thinner flange, the bolt load is seen to decrease when the external load is applied. The magnitude of this load loss decreases with increasing flange (beam) thickness. With a very thick flange, the observed load change is positive, but still less than the external load value, which is consistent with rigid flange joint mechanics theory.

DISCUSSION OF RESULTS

Both the analytical model and the empirical tests demonstrated the importance of including flange deflection into a joint analysis. The flange deflections significantly affect the load balance within the joint. A comparison between the analytical results and the empirical results for both a rigid flange and a flexible flange, are shown in Table 1. The rigid flange model represents the results that would be predicted through simple joint mechanics. The flexible flange model demonstrates the importance of including the flange deflection into the joint analysis.

Table 1
Change in Bolt Load After the Addition of a 236 N External Load

	Analytical Model	**Empirical Test**
Rigid Flange		
mean	+13 N (+3 lbs)	+18 N (+4 lbs)
SD		9 N (2 lbs)
Flexible Flange		
mean	-262 N (-59 lbs)	-156 N (-35 lbs)
SD		18 N (4 lbs)

In a rigid flange model, the impact of the external load can be predicted through joint mechanics or through a joint diagram. Prior to the addition of the external load, force equilibrium requires the total load on the gasket to equal the total load on the bolt. After the external force is added, force equilibrium requires that the total load on the gasket plus the external load must equal the bolt load. The redistribution of the loads within the rigid joint is a function of the stiffness ratio between the bolt and the gasket. Part of the 236 N (53 pound) external load will increase the bolt load and part of the 236 N (53 pound) external load will decrease the total gasket load. The rigid sample problem demonstrated the traditional response to an external load. When the external load was applied, the bolt load increased by a fraction of the applied load. The analytical model predicted an increase of 13 N (3 pounds). The empirical test showed an increase of 18 N (4 pounds). The balance of the 236 N (53 pound) external load appears as a decrease in load on the gasket.

In the more complex situation with a flexible flange, the redistribution of load is more complicated. When the flange is only 6.35 mm (0.25 inches) thick, it becomes very difficult to predict the effect of the external load through simple joint mechanics or a joint diagram. In the analytical model the bolt showed a decrease in load of 262 N (59 pounds) when the

external load was applied. Likewise, the empirical tests showed a decrease of 156 N (35 pounds). When the external load was applied, the flexible flange produced a decrease in bolt load rather than the increase in bolt load that was observed with the rigid flange. With the decrease in bolt load, the gasket load also drops. The gasket looses both the 262 N (59 pounds) that the bolt lost and the additional 236 N (53 pounds) from the external load for a total loss of 498 N (112 pounds).

As demonstrated, the reaction of a joint to an external load can vary significantly depending on the joint configuration. In the previous example, the effect of the flange stiffness on the joint interactions was demonstrated. Whenever there is a change in the deflection profile of the flange, there is a change in the joint balance. In the case of a rigid joint, the external loads do not significantly change the deflection profile or the distribution of load. Under these conditions, the effects of the external loads are easy to incorporate into the joint using convention joint mechanics or the joint diagram. However, when the flange thickness was reduced, the external loads caused large changes in the deflection profile of the flange. It was the change in the flange deflection profile that redistributed the loads in the joint and produced a significant change in the joint balance. In this example, the load was redistributed toward the bolt. The increase in gasket compression force under the bolt decreased the gasket thickness which produced a loss in bolt stretch.

To further demonstrate the impact of changing the deflection profile of the flange, a second comparison was modeled. In this comparison, the deflection profile was changed by moving the location of the external loads instead of changing the flange thickness. In both cases, a 6.35 mm (0.25 inch) thick flange was used with the rigid foundation. In the first case, two 118 N (26.5 pound) loads were placed at a distance of 114 mm (4.5 inches) from the bolt. The bolt load decreased from 4448 N (1,000 pounds) to 3861 N (868 pounds) and the gasket load decreased from 4448 N (1,000 pounds) to 3625 N (815 pounds). The external load had a significant impact at changing the deflection profile of the flange. In the second case, the external loads were applied at 12.7 mm (0.5 inches) from the bolt. In this case, the bolt load increased from 4448 N (1,000 pounds) to 4586 N (1031 lbs) and the gasket load decreased by 98 N (22 pounds). The application of the external loads at positions where they have little effect on the deflection profile of the flange caused the total gasket load to decrease 98 N (22 pounds) instead of 823 N (185 pounds).

CONCLUSION

The gasket and fastener forces predicted by joint diagram analysis are based on force equilibrium and geometric compatibility between the gasket, fasteners, and flanges. Joint diagram constructions are based on rigid flange assumptions or uniform flanges bending effects. In many situations flange flexibility and the resultant nonuniform deformation of the flange under load cause actual flange behavior to deviate significantly from the idealized joint diagram values. In situations where flanges are very flexible, the deviation between the rigid flange approximation and the actual behavior can be significant. In this study, FEA and experiment demonstrated that predicted increases in bolt tensions due to a separating external force were less than the increases predicted by the rigid flange analysis. It was further demonstrated both empirically and analytically that under conditions of low flange stiffness and high bolt stiffness, a separating external force can cause bolt tension to decrease. An analysis technique that includes the effects of flange flexibility should be used to simulate the as-assembled and loaded conditions of bolted joints.

ABSTRACT

A proprietary refrigerant, called Ikon®-12, was evaluated as an alternative to HFC (hydrofluorocarbon)-134a for automotive air conditioning. The evaluation was motivated by concern over the relatively high global warming potential of HFC-134a. In preliminary tests, Ikon®-12 was found to be compatible with a polyolester lubricant and engineering materials. Refrigeration capacity and efficiency for Ikon®-12 compared favorably to those for HFC-134a. In a preliminary durability test, Ikon®-12 refrigerant showed no significant chemical breakdown after extended operation with an elevated compressor discharge temperature. Further testing would be required to determine if stability and materials compatibility are acceptable for long-term use.

INTRODUCTION

HFC-134a is currently used as the refrigerant in new and retrofitted motor vehicle air conditioners, replacing the stratospheric ozone depleting refrigerant, CFC (chlorofluorocarbon)-12. Although HFC-134a has no ozone depletion potential, it has a global warming potential approximately 3300 times that of CO_2 (carbon dioxide) over a 20 year time horizon, 1300 times that of CO_2 over a 100 year time horizon, or 420 times that of CO_2 over a 500 year time horizon.[1] By the year 2005, approximately 260 million vehicles with HFC-134a air conditioners will be in service in developed countries and will require an estimated 74,800 metric tons of refrigerant annually including 33,400 metric tons for new vehicles and 41,400 metric tons for service usage.[2] Refrigerant emissions due to service usage represent an annual, CO_2-equivalent of 53.8 million metric tons, based on a 100 year time horizon. In 1994, the estimated total U.S. greenhouse gas emissions were 6109 million metric tons CO_2-equivalent.[3] Increased concern over global climate change could eventually lead to restrictions on HFC-134a consumption. For this reason, the U.S. EPA (Environmental Protection Agency) has evaluated alternatives for HFC-134a in motor vehicle air conditioning.[4]

A proprietary, near-azeotropic blend of an FIC (fluoroiodocarbon) and an HFC, called Ikon®-12, has been proposed as a refrigerant for automotive air conditioning and other applications.[5] The global warming potential for Ikon®-12 has been reported to be 4 percent of that for HFC-134a.[5] Ikon®-12 has been reported to be nonflammable according to testing based on ASTM (American Society for Testing and Materials) methods E681-85 and E918-83.[6-7] Extensive toxicity testing has been reported for both components of the refrigerant blend. Reported results have been generally favorable, although toxicity may be somewhat higher than for HFC-134a. Under EPA's SNAP (Significant New Alternatives Policy) Program, Ikon®-12 has been approved for use in motor vehicles subject to use conditions including the use of unique fittings, the use of descriptive labels, a prohibition against topping off one refrigerant with another, and appropriate recovery or recycling equipment.[8]

LUBRICANT MISCIBILITY

Miscibility was tested for the Ikon®-12 refrigerant with a PAG (polyalkylene glycol) lubricant and a POE (polyolester) lubricant. The PAG lubricant was supplied by an OEM (original equipment manufacturer). Its viscosity was reported to be 135 cSt at 40°C and 25 cSt at 100°C. It was reported to contain proprietary additives. The POE lubricant was supplied by a chemical manufacturer. Its viscosity was reported to be 134 cSt at 40°C and 15 cSt at 100°C. It also contained proprietary additives. Sealed glass tubes were prepared with the Ikon®-12 refrigerant and lubricant at lubricant concentrations of 2, 5, 10, 20, and 30 weight percent.

Complete miscibility with the PAG lubricant was found at low temperatures with all sample concentrations remaining miscible down to -45°C. However, separation of the refrigerant and PAG lubricant occurred at approximately 95°C for the 2 and 5 weight percent samples. The 10, 20, and 30 weight percent samples remained miscible up to 125°C, at which point the test was terminated.

Miscibility with the POE lubricant was tested over the temperature range of -45 to +115°C. No phase separation was observed for all concentrations, indicating complete miscibility of the Ikon®-12 refrigerant and the POE lubricant at the conditions tested.

STABILITY AND MATERIALS COMPATIBILITY

As a preliminary evaluation of the thermal and hydrolytic stability of Ikon®-12 and its compatibility with common materials of construction used in automotive air conditioners, sets of sealed glass tube samples were prepared. Materials were selected in preparation for testing the refrigerant in an automotive air-conditioning system designed for HFC-134a. Materials compatibility and stability were tested in accordance with the methods described in ANSI/ASHRAE Standard 97-1989.[9] Stability tests were conducted by sustained heating of the Ikon®-12 refrigerant by itself and with copper, aluminum, and steel in sealed glass tubes at 175°C for 14 days. Compatibility tests were conducted by sustained heating of elastomers, polymers, desiccant, cast iron, and brass with the refrigerant at 125°C for 14 days. One set of tubes was prepared without any lubricant, one set was prepared with PAG lubricant, and one set was prepared with POE lubricant. Duplicate samples were prepared and tested for each combination.

Sealed tubes containing Ikon®-12 refrigerant by itself were visually inspected after sustained heating at 175°C for 14 days. The fluid changed from colorless to purple color, indicating the presence of iodine. Volatiles released upon breaking the tubes under vacuum were analyzed by gas chromatography, mass spectrometry, and infrared spectrometry. The resultant chromatograms and spectra were compared to those obtained for pure refrigerant. A small amount of breakdown of the FIC was found as evidenced by the formation of a minute quantity of CF_3H (trifluoromethane). The addition of copper, aluminum, and steel did not affect the results significantly. The addition of a small amount of water also did not affect the results.

Sealed tubes containing Ikon®-12 refrigerant in combination individually with buna-n, neoprene, 6/6 nylon, Teflon, cast iron, and brass were maintained at a temperature of 125°C for 14 days. Chemical analysis of the volatiles released from those tubes indicated the formation of a minute amount of CF_3H.

Visual inspection of sealed tubes containing Ikon®-12 and PAG lubricant showed substantial decomposition as evidenced by the presence of carbonized solids after the 14-day aging period. Vapor-phase contents of one tube containing only the Ikon®-12 and PAG lubricant were analyzed by gas chromatography and mass spectrometry. A host of degradation products were evident from the analyses indicating that the incompatibility of Ikon®-12 and PAG lubricant was independent of the presence of other materials. Vapor-phase components identified from the analyses suggest that the PAG lubricant and both components of the Ikon®-12 blend decomposed. Analysis of the contents of other tubes containing materials with the PAG lubricant was not continued because of the obvious instability. The PAG lubricant was considered unacceptable for use with the Ikon®-12 refrigerant.

Sealed tubes containing Ikon®-12 and the POE lubricant appeared from visual inspection to have better chemical stability than the tubes containing the PAG lubricant. Stability of the refrigerant and lubricant combination was tested by sustained heating at 175°C for 14 days. Volatiles released upon breaking the tubes were analyzed. The addition of the POE lubricant resulted in a greater decomposition of the FIC than without the lubricant, but only a relatively small amount of decomposition was found. Further work would be required to quantify the decomposition. For comparison, HFC-134a with PAG lubricant typically has no discernible breakdown at 175°C. However, mineral oil lubricant used with CFC-12 refrigerant typically has substantial breakdown at 175°C.

When copper, aluminum, and steel were added to the mixture of refrigerant and lubricant, greater decomposition of the FIC was found as evidenced by the formation of larger concentrations of CF_3H and the deposition of salts on the metal surfaces. The combination of Ikon®-12, POE lubricant, and metals also yielded trace amounts of CO (carbon monoxide) and monofluoroethene. The presence of the monofluoroethene indicated a probable degradation of the HFC component of the refrigerant blend.

Sealed tubes containing Ikon®-12 and the POE lubricant in combination individually with buna-n, neoprene, 6/6 nylon, Teflon, XH-7 desiccant, cast iron, and brass were maintained at a temperature of 125°C for 14 days. Chemical analysis of the volatiles released from those tubes indicated a small amount of decomposition of the refrigerant. In the presence of the desiccant, there was a very slight formation of monofluoroethene, again indicating a probable degradation of the HFC component of the refrigerant blend.

Data for materials tested with Ikon®-12 in sealed tubes with and without POE lubricant are summarized in Table 1. Average values for each pair of tubes are reported. Hardness values were not obtained for nylon

Table 1. Materials Compatibility Test Results

Material	Weight Change (Percent)	Volume Change (Percent)	Linear Swell (Percent)	Dia. Change (Percent)	Hard. Change (Percent)
Buna-N	+ 37.2	+ 8.4	+ 9.6	+ 4.1	+ 7.3
Buna-N (with POE lube)	+ 20.1	+ 10.0	+ 5.7	+ 4.9	+ 12.9
Neoprene	+12.5	+7.5	+2.8	+2.3	+13.7
Neoprene (with POE lube)	+7.3	+10.2	+2.7	+4.1	+2.1
Teflon	+ 4.8	- 8.9	+ 5.2	- 4.6	not tested
Teflon (with POE lube)	+ 2.7	- 6.4	+ 4.7	- 3.3	not tested
Nylon 6/6	+ 12.9	+ 5.8	+ 1.1	not tested	not tested
Nylon 6/6 (with POE lube)	- 9.4	- 10.1	- 4.4	not tested	not tested

and Teflon since these harder materials were not amenable to the test method. With the POE lubricant, both Teflon and nylon shrank in volume while buna-n swelled in volume. For Teflon and nylon, volume change was excessive compared to generally accepted criteria for volume change from -5 to +25 percent.

It was concluded that the stability and compatibility of the Ikon®-12 refrigerant and POE lubricant combination were adequate to proceed with performance testing at temperatures not exceeding 125°C. Further laboratory and field testing would be required to determine if stability and materials compatibility are acceptable for long-term use.

REFRIGERATION CAPACITY AND ENERGY EFFICIENCY

Refrigeration capacity and COP (coefficient of performance) were experimentally determined for Ikon®-12 and for HFC-134a with an instrumented, automotive air-conditioning system. Instrumentation was similar to that described in a previous paper.[10] The automotive air-conditioning system was an OEM unit designed for HFC-134a. Refrigeration capacity was measured with an uncertainty of approximately ±100W and a repeatability of approximately ±30W. COP was determined from the measured power input to the compressor with an uncertainty of approximately ±75W and a repeatability of ±50W.

The OEM air-conditioning system had a suction line accumulator and orifice tube expansion device. Refrigerant was added to the system until liquid was present in the accumulator as indicated by minimal superheat at the compressor inlet. The refrigerant charge size was 920 g for HFC-134a and 1520 g for Ikon®-12. The same orifice tube was used for both refrigerants. Approximately the same amount of subcooling was measured at the orifice tube inlet for both refrigerants at each test condition. Test results are shown in Figure 1. Refrigeration capacity and COP for Ikon®-12 and HFC-134a were measured at three compressor rotational speeds, three evaporating temperatures, and three condensing temperatures. Over the range of test conditions, refrigeration capacity for Ikon®-12 averaged 5 percent higher than for HFC-134a. COP for Ikon®-12 averaged 11 percent higher than for HFC-134a. Compressor discharge temperatures with Ikon®-12 averaged 2°C higher than with HFC-134a. Over the range of test conditions, the compressor discharge temperature with Ikon®-12 varied from 0.8°C lower to 6°C higher than with HFC-134a.

DURABILITY

Following the performance tests, the test system was run for an extended period of time with an elevated compressor discharge temperature to determine if refrigerant decomposition would occur. Test conditions were adjusted to obtain a compressor discharge temperature of 110°C. Compressor suction pressure was 338 kPa and discharge pressure was 2614 kPa. Compressor rotational speed was 2050 rpm, and compressor ambient temperature was 70°C. After 192 hours of continuous operation at those conditions, mechanical failure of a compressor suction reed valve occurred. The Ikon®-12 refrigerant was recovered from the system, and the compressor was disassembled and inspected. The broken reed valve damaged the cylinder surface, but there was no evidence of excessive wear or any other problem. Failure of the reed valve was apparently caused by metal fatigue due to the severe operating conditions. The lubricant remained clear, and no deposits were found on the internal surfaces of the compressor.

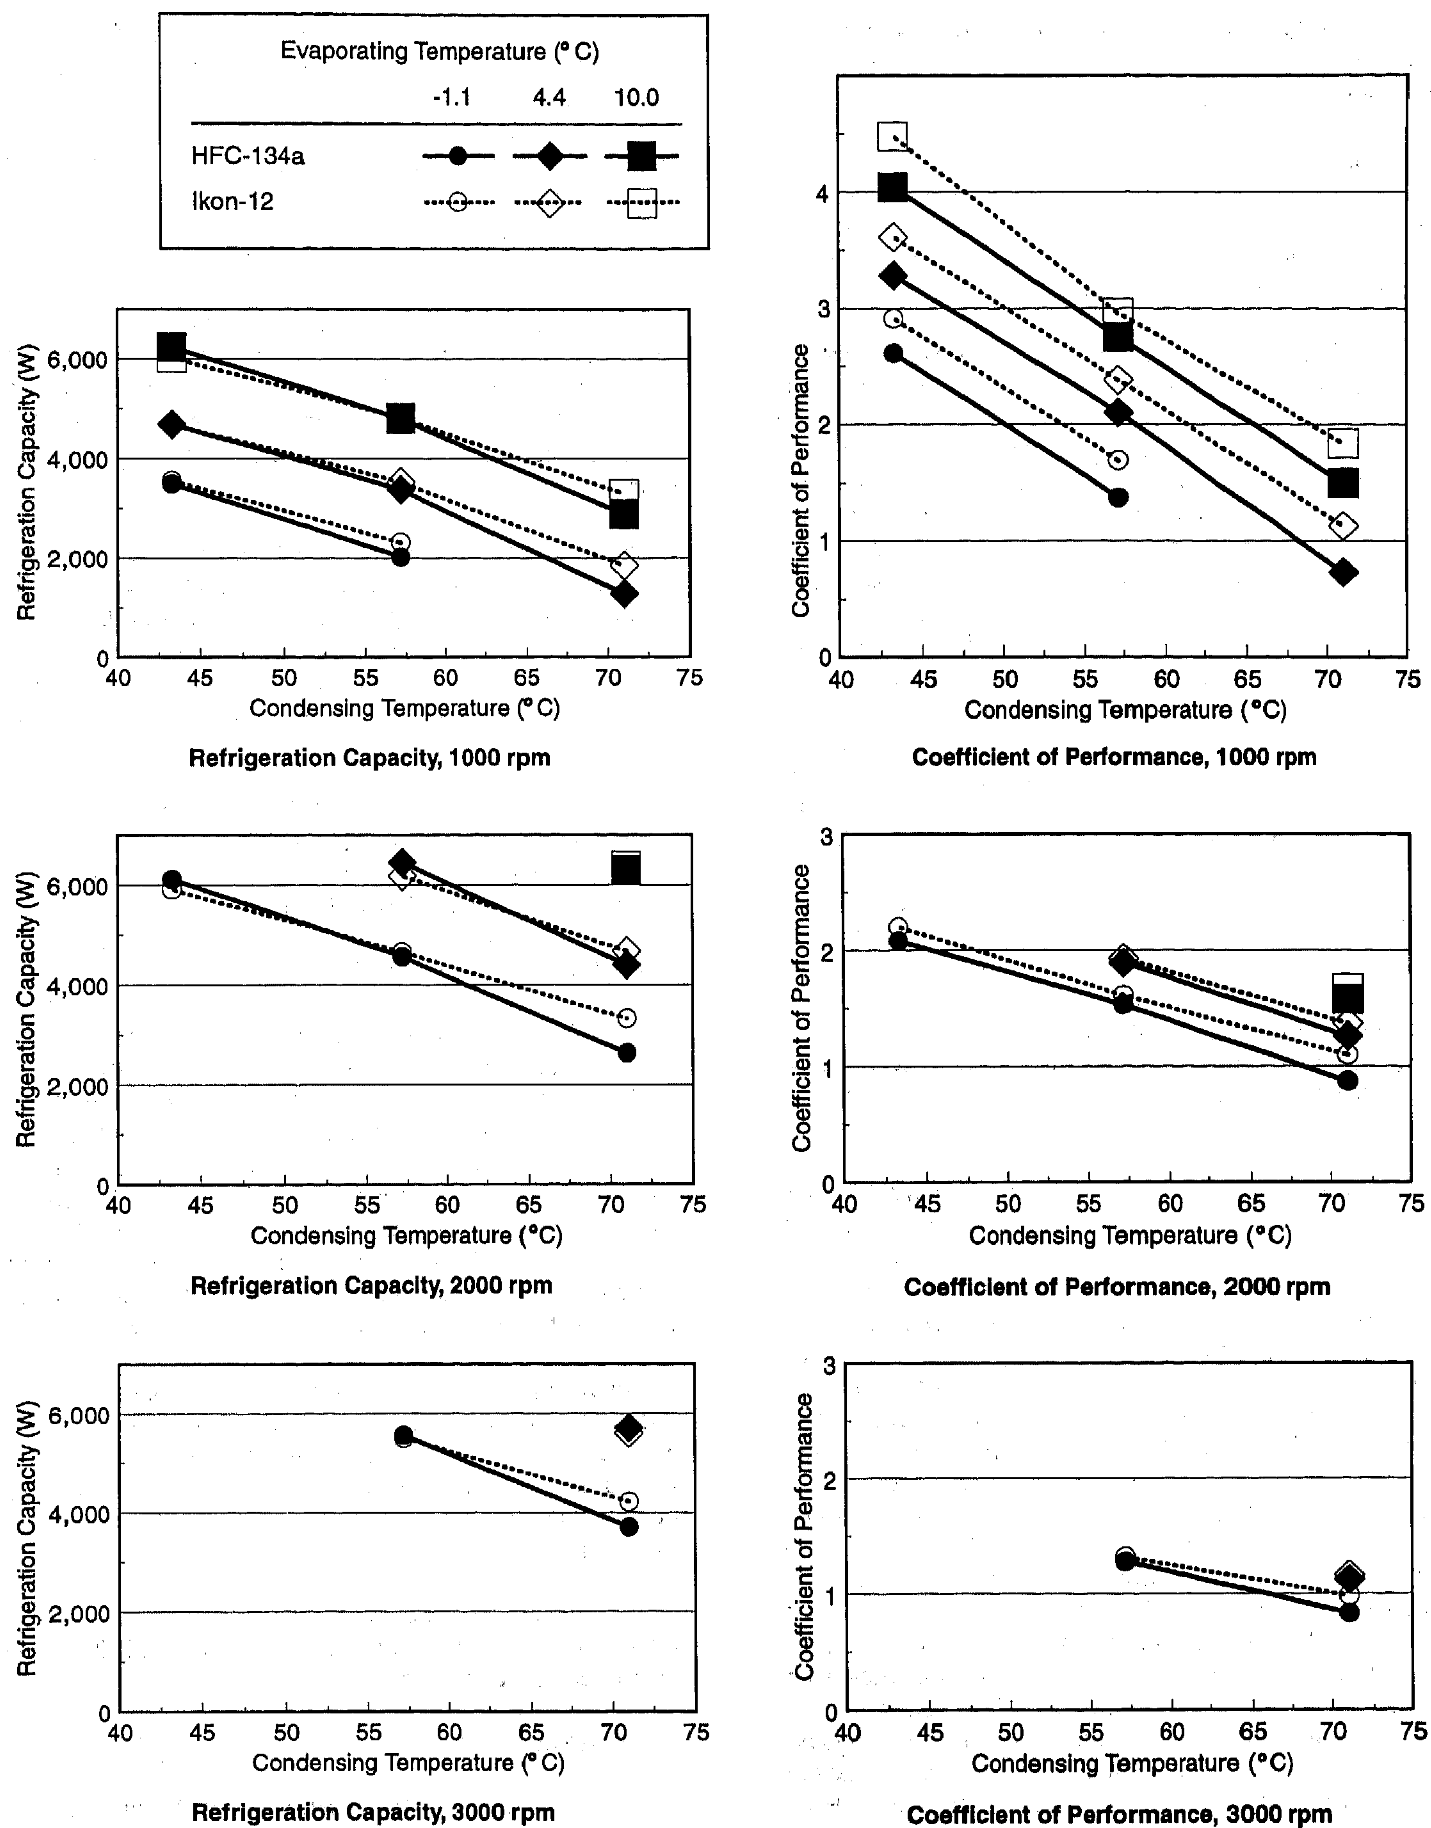

Figure 1. Refrigeration Capacity and Coefficient of Performance of Ikon-12 Compared to HFC-134a

Following the compressor failure, samples of refrigerant and lubricant were analyzed. Vapor- and liquid-phase materials were analyzed with gas chromatography, mass spectrometry, and infrared spectrometry. The resultant chromatograms and spectra were compared to those obtained for pure refrigerant and lubricant. There was no evidence of refrigerant breakdown in the vapor or liquid. Purity of the Ikon®-12 was greater than 99.5 percent.

The failed compressor was replaced with a similar, new compressor. Before installation, PAG lubricant was flushed from the new compressor with POE lubricant, and approximately 40 ml of the new POE lubricant was added to the new compressor to replace the amount removed with the failed compressor. The total amount of lubricant in the air-conditioning system was approximately 240 ml. The same Ikon®-12 refrigerant used for the previous testing was recharged into the system. Test conditions were adjusted to maintain the 110°C compressor discharge temperature, but the compressor rotational speed was reduced to prevent premature failure of the valves. Compressor rotational speed was 1000 rpm, and compressor ambient temperature was 90°C. Compressor suction pressure was 479 kPa and discharge pressure was 2867 kPa.

Refrigerant and lubricant samples were analyzed after 467 hours and again after 632 hours of operation, including the 192 hours of operation on the first compressor. Gas chromatography/mass spectrometry analyses of the refrigerant vapor and gas chromatography/Fourier transform infrared analyses of the lubricant showed no significant changes over the 632 hour period.

After 732 hours of operation, a leak in a refrigerant line resulted in the loss of the refrigerant charge. A lubricant sample was analyzed with gas chromatography/Fourier transform infrared, and no significant change was found. During inspection of the test system, it was found that the compressor shaft could not be rotated by hand. When torque was applied to the compressor shaft with a wrench, the moving parts loosened, and the shaft could then be turned by hand. The compressor was disassembled and inspected. A dark, viscous fluid was found in small quantities on some bearing surfaces and in some cavities inside the compressor. No excessive wear was found on any surfaces, and no indication of mechanical failure was observed. Lubricant found inside the compressor remained clear. Since no similar dark substance was found inside the first compressor after 192 hours of operation, and since Ikon®-12 refrigerant was known to be incompatible with PAG lubricant, it was suspected that the foreign substance resulted from a small amount of PAG lubricant remaining in the second compressor after flushing. An infrared spectral analysis of the dark, viscous fluid exhibited general features resembling both PAG and POE lubricants. However, the fluid could not be unambiguously traced to residual PAG lubricant left in the compressor. Further durability testing and chemical analyses were beyond the scope of the project. Further testing would be required to determine if stability and durability are acceptable for long-term use.

SUMMARY

1. A proprietary, near-azeotropic, low-GWP, refrigerant blend of an FIC and an HFC, called Ikon®-12, was evaluated as an alternative to HFC-134a for automotive air conditioning. The evaluation was motivated by concern over the relatively high global warming potential of HFC-134a.

2. Ikon®-12 was not compatible with a PAG lubricant, but was sufficiently compatible and stable with a POE lubricant and engineering materials to proceed with testing in an automotive air-conditioning system. Over the temperature range of -35 to +100°C, the Ikon®-12 refrigerant was completely miscible with the POE lubricant.

3. Refrigeration capacity and COP were determined experimentally with an instrumented, OEM, automotive air-conditioning system. Refrigeration capacity for Ikon®-12 averaged 5 percent higher than for HFC-134a over the range of test conditions. COP for Ikon®-12 averaged 11 percent higher than for HFC-134a.

4. Durability of the refrigerant and lubricant was tested by operating the test system with an elevated compressor discharge temperature. During the course of the testing, a compressor suction reed valve was broken. Failure of the reed was apparently caused by metal fatigue due to the severe operating conditions. After 632 hours of operation with a discharge temperature of 110°C, no significant breakdown of the refrigerant or lubricant was detected from chemical analyses by gas chromatography, mass spectroscopy, and infrared spectroscopy.

5. Following the durability test, the compressor was disassembled and inspected. A small quantity of dark, viscous fluid was found inside the compressor and may have been caused by residual PAG lubricant. However, the fluid could not be positively identified by chemical analyses.

6. Further laboratory and field testing would be required to determine if stability and materials compatibility are acceptable for long-term use.

Total Environmental Warming Impact (TEWI) Calculations for Alternative Automotive Air-Conditioning Systems

Steven K. Fischer and James R. Sand
Oak Ridge National Lab.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The Montreal Protocol phase-out of chlorofluorocarbons (CFCs) has led manufacturers to develop refrigeration and air-conditioning systems that use refrigerants that do not damage stratospheric ozone. Most refrigeration industries have adapted their designs to use hydrochlorofluorocarbon (HCFC) or hydrofluorocarbon (HFC) refrigerants; new automobile air-conditioning systems use HFC-134a. These industries are now being affected by scientific investigations of greenhouse warming and questions about the effects of refrigerants on global warming. Automobile air-conditioning has three separate impacts on global warming; 1) the effects of refrigerant inadvertently released to the atmosphere from accidents, servicing, and leakage; 2) the efficiency of the cooling equipment (due to the emission of CO_2 from burning fuel to power the system); and 3) the emission of CO_2 from burning fuel to transport the system. The Total Equivalent Warming Impact (TEWI) is an index that should be used to compare the global warming effects of alternative air-conditioning systems because it includes these contributions from the refrigerant, cooling efficiency, and weight.

This paper compares the TEWI of current air-conditioning systems using HFC-134a with that of transcritical vapor compression system using carbon dioxide and systems using flammable refrigerants with secondary heat transfer loops. Results are found to depend on both climate and projected efficiency of CO_2 and flammable refrigerant systems. Performance data on manufacturing prototype systems are needed to verify the potential reductions in TEWI. Extensive field testing is also required to determine the performance, reliability, and "serviceability" of each alternative to HFC-134a to establish whether the potential reduction of TEWI can be achieved in a viable consumer product.

INTRODUCTION

The Montreal Protocol phase-out of chlorofluorocarbons (CFCs) has led manufacturers to develop refrigeration and air-conditioning systems that use refrigerants that do not damage stratospheric ozone. The automobile industry responded to these requirements by developing air-conditioning equipment based on HFC-134a that provided comparable or better performance than the preceding generation of air conditioners using CFC-12. Worldwide concerns are now being raised about the impact of using fluorocarbon refrigerants if they are released to the atmosphere because of their global warming potentials (GWPs). When considering the global warming impact of any refrigeration system, however, it is essential to remember that factors other than the GWP of the refrigerant are important, or even dominant for some refrigeration systems.

Automobile air-conditioning has three separate impacts on global warming; 1) the effects of refrigerant inadvertently released to the atmosphere from accidents, servicing, and leakage; 2) the efficiency of the cooling equipment (due to the emission of CO_2 from burning fuel to power the system); and 3) the emission of CO_2 from burning fuel to transport the system. The Total Equivalent Warming Impact (TEWI) is an index that can be used to compare the global warming effects of alternative air-conditioning systems.

ASSUMPTIONS

This paper examines the TEWI of hypothetical automobile air conditioners using HFC-134a, isobutane (HC-600a), propane (HC-290), and carbon dioxide (R-744). The system with HFC-134a is assumed to use the "conventional" components (e.g. belt driven open compressor, direct expansion evaporator, air-cooled condenser) with "representative" component efficiencies. The two air conditioners using hydrocarbons as refrigerants are assumed to be similar to the HFC-134a system with the notable exception of employing a secondary heat transfer loop to isolate the flammable refrigerant from

the passenger compartment. This addition results in a thermodynamic loss because of the additional ΔT imposed by the secondary loop, extra weight (due to the heat exchanger, hoses, and pump), and pumping energy. The air conditioner using CO_2 has been frequently in the literature [1,2,3] and resembles a conventional vapor compression system with the notable exception that the high side heat exchanger operates above the critical point and hence is a gas cooler; there is no condensation from vapor to liquid in the high side gas cooler (above the critical temperature, 31 °C).

Previous papers have compared TEWI of alternative technologies by computing energy use from system COP at a single design condition and a fixed number of equivalent full load hours [4,5]. This simplified approach has been criticized as being unrealistic because of the broad range of variables affecting actual system performance and energy use. The analysis described in this paper takes a first step toward expanding upon previous analysis to incorporate information on vehicle speed and regional climate, though there are still simplifying assumptions that could be improved.

Several basic assumptions affect the calculation of TEWI irrespective of system configuration or vehicle air-conditioning load. These include:

- 57 liters gasoline / 100 kg incremental weight / 10,000 km,
- 2.32 kg CO_2 released / liter fuel consumed,
- 0.243 kg CO_2 released / kWh heat energy into the engine,
- 25% engine efficiency, and
- 85% of vehicle operating time at engine speeds above 16.1 km/h (10 mph), 15% of time at idle conditions

Other assumptions are independent of the climate, but vary with the choice of refrigerant. They include the evaporating temperature, refrigerant GWP, system weight, and the high side refrigerant temperature. These are summarized in Table 1. The analysis performed in this paper assumes that there is a temperature difference, the approach ΔT, between the ambient air temperature and the high-side refrigerant temperature. Two sets of values have been chosen that depend only on compressor shaft speed; two ΔT's are used for the subcritical systems (HFC-134a, HC-600a, HC-290) and two smaller ΔT's for the transcritical system [2].

Other parameters, such as the design capacity and driving distance, vary between Europe and the U.S. These are summarized in Table 2. Typical meteorological binned weather data has been used for cities in four different geographic regions in the U.S. [6] and typical meteorological year binned data were averaged for several cities in each of five European countries for use in the energy input calculations. These data are shown in Figures 1 and 2.

Siewert published a distribution for vehicle speed during 50,000 miles (80,500 km) of use [7]. These data indicate 15% of vehicle use is at or below 16 kph (10 mph) and that 85% is at higher speeds; consequently it is assumed that 15% of compressor operation is at a low shaft speed and 85% is at a high speed. Siewert's data are also used to estimate the number of hours of vehicle use per year. These results are summarized in Table 3.

Figure 3 shows the dependence of air-conditioner operation on average daily temperature [8]. A compromise in accuracy was made by applying this correlation to binned hourly weather data instead of average daily temperature; future work should employ a correlation of on-time with ambient temperature instead of average daily temperature.

System COPs were computed for each of the refrigerants using a commercial software package designed for solving thermodynamic problems [9]. The subcritical systems were evaluated using calculated refrigerant properties at:

- the compressor inlet,
- the compressor exit,
- the condenser exit
- the evaporator inlet, and
- saturated vapor leaving the evaporator.

The analysis of the supercritical CO_2 system includes the use of intermediate heat exchange between high and low-side, although this does not provide useful cooling, and pressures that give the maximum COP. The calculated COPs are shown in Figs. 4 and 5.

METHODOLOGY

The global warming effects of the energy to operate and transport the air conditioner and from emissions of refrigerant are calculated separately. Energy input is computed from annual cooling provided divided by the temperature dependent COPs. The number of annual vehicle operating hours

in Table 3 are combined with the temperature distributions in Figs. 2 and 3 to estimate hours of vehicle operation as functions of the ambient temperature (the temperature distributions are first converted from hours/year at each temperature to percentage of year). The derived distribution of hours of vehicle operation as a function of temperature are then combined with the compressor on-time in Fig. 3 and design capacity to calculate air-conditioner cooling output as functions of ambient temperature. Highway speed and idle condition energy inputs are computed at each temperature by dividing the cooling output by the corresponding COP and summed over the year. The average annual energy input is computed as 85% of the highway speed a/c energy use and 15% of the idle condition energy use. Air conditioner energy input, in kWh, is converted to lifetime CO_2 emissions using the assumed engine efficiency (25%), 0.243 kg CO_2 /kWh input, and the assumed lifetime.

Fuel consumption for transporting the weight of the air conditioning system is computed using 57 liters/100 kg/10,000 km for incremental fuel use for weight increases. This value is combined with the assumed vehicle use for the U.S. and Europe and the air-conditioner lifetime. Lifetime fuel use for the weight of the air conditioner is converted to CO_2 emissions using 2.32 kg CO_2/liter of gasoline.

Refrigerant emissions are based on the assumed lifetimes of the air conditioners and average refrigerant losses of 55 grams/year [10,11] and the assumption that 95% of the refrigerant charge is recovered after the useful lifetime of the system. No practical experience is available for leakage from either the hydrocarbon or carbon dioxide air conditioners, but the effect on TEWI is insignificant because of the extremely low GWPs of these gases.

RESULTS

The results of the analyses are shown in Figures 6 and 7 for the four regions of the U.S. and the five European countries. There is a separate bar for each of the refrigerants in each of the countries and regions; each bar has a segment for CO_2 emissions resulting from power input to the compressor, belt/clutch assembly, and fan; a segment corresponding to fuel consumption for transporting the weight of the air conditioner assembly, and a segment for the direct global warming effect of refrigerant emissions. Each bar for the transcritical CO_2 system (R-744) also contains a segment resulting from unknowns in the operating efficiency. The first segment for energy use for CO_2 is determined using small approach temperatures for the gas cooler (i.e. 17°C idle and 3°C highway) which is believed achievable by at least one manufacturer. The second segment is additional energy required using the same approach temperatures assumed for the subcritical systems. The segments of each bar due to weight are nearly the same for all of the systems and direct effects of refrigerant emissions are only visible on the bars for HFC-134a. The direct effects are so small for the hydrocarbon refrigerants and transcritical system that they do not show up on these drawings.

In regions of the U.S. with high cooling demands, the hydrocarbon systems have TEWI comparable to HFC-134a systems. Recent information about prototype testing indicates that the transcritical system could have steady state COPs similar to or better than the current COPs for HFC-134a [12, 13]. If this is the case, the transcritical system would have a TEWI lower than any of the other systems; although efficiency of systems using HFC-134a can be improved if it is optimized to reduce energy use.

CONCLUSION

Several conclusions can be drawn from the results in Figs. 6 and 7. First, there may or may not be a lower TEWI using a flammable refrigerant depending on the system size and annual cooling load. There is no significant reduction in TEWI for the hydrocarbon refrigerants in the U.S. The CO_2 system has a comparable to higher TEWI than HFC-134a in the U.S. under the current assumptions for COPs and though higher than the hydrocarbons, it is not significantly higher using the low values of the approach temperatures.

A Critical Look at R-744 and R-134a Mobile Air Conditioning Systems

M. S. Bhatti
General Motors Corp.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

There is intense research activity to appraise the merits of the carbon dioxide (R-744) mobile air conditioning system due to its perceived amelioratory effect on the total global warming impact which comprises two components: direct global warming due to refrigerant leakage into the atmosphere and indirect global warming due to power consumption by the system. While the direct global warming impact of R-744 is negligible compared to that of R-134a, the indirect global warming impact of the R-744 system is intrinsically higher than that of the R-134a system. In order to quantify the indirect global warming impact of the R-744 system, an accurate assessment of its coefficient of performance (COP) *vis-a-vis* COP of the present baseline R-134a system is necessary. Presented in this paper is the critical assessment of the R-744 system, including its COP under realistic operating conditions, heat exchanger and compressor characteristics, total global warming impact, and historical evidence that suggests that the proposal to replace R-134a by R-744 is untenable in view of lower energy efficiency and 5 to 12 times higher operating pressure for the R-744 system.

INTRODUCTION

The specter of ozone depletion and global warming has revivified carbon dioxide which at one time (1890 to 1930) was the preferred refrigerant for vapor compression machines despite its unfavorable thermodynamic characteristics (high critical pressure and *ipso facto* high operating pressure) [1-30]. The main appeal of carbon dioxide at the time was that its toxicity and flammability characteristics were superior to those of other available refrigerants like sulfur dioxide, ammonia, methyl chloride, and butane. However, it could not compete with the chlorofluorocarbon refrigerants which emerged in 1930 [31]. The rapid demise of the carbon dioxide systems thereafter is attributable to their lower energy efficiency and higher operating pressure compared to those of the chlorofluorocarbon systems. In this paper, we will review the historic evidence that suggests that the *locus standi* of the R-744 system against the present R-134a system is rather tenuous for the same reasons which led to its phase out starting back in the 1930s.

Up until the 1970s, environmental concerns like ozone depletion and global warming were not even considered in the context of anthropogenic refrigerants. However, the picture changed in 1974 when two scientists named Molina and Rowland revealed the phenomenon of destruction of the stratospheric ozone layer that shields the Earth from the harmful effects of the sun's ultraviolet rays. They theorized that the destruction of the ozone layer is catalyzed by molecules containing chlorine that are propelled to the stratosphere by extremely stable chlorofluorocarbon compounds with inordinately long atmospheric lives of the order of 100 years [32]. In 1995, Molina and Rowland along with a third scientist named Crutzen received the Nobel Prize for their work on the stratospheric ozone depletion [33-35].

As a direct result of the work by Molina *et al.*, production and use of the chlorofluorocarbon refrigerants, including R-12, was banned as mandated by the Montreal Protocol in 1981

[36]. After considerable research between 1986 and 1992, R-134a emerged as the preferred replacement for R-12 in mobile air conditioning systems and beginning in 1992 automakers around the world started replacing R-12 with R-134a. An indirect consequence of the work by Molina *et al.* has been that it heightened our awareness of other environmental concerns such as acid rain and global warming particularly the latter since the strong ozone depleting gases are also generally strong greenhouse gases responsible for global warming.

Recent interest in carbon dioxide as a replacement for R-134a stems from the fact that although the ozone depletion potential of R-134a is zero, its global warming potential is not zero. Carbon dioxide, on the other hand, has zero ozone depletion potential coupled with practically zero global warming potential. Based on the favorable global warming potential index alone, it cannot be asserted *a priori* that the global warming impact of the R-744 system will be less than that of the R-134a system. This is predicated on the realization that there are two components of the global warming impact equation, *viz.*, direct global warming due to refrigerant leakage into the atmosphere and indirect global warming due to power consumption by the system incorporating the refrigerant. The issue of the total global warming impact of the R-744 and R-134a systems will be explored at length in this paper.

As a prelude to assessment of the two systems, the comparative characteristics of the two refrigerants (*vide* Table 1) are reviewed as they shed considerable light on the relative performance of the systems. Following these introductory remarks, the subject matter is covered under four distinct captions: (1) Historical Background, (2) System Performance, (3) Heat Exchanger and Compressor Characteristics, and (4) Global Warming Impact. Substantiated conclusions of the analysis are then clearly stated at end of the paper.

HISTORICAL BACKGROUND

There is a long history of the use of carbon dioxide in the refrigeration and air conditioning industry. It was first proposed as a refrigerant for the vapor compression machines by an American named Alexander Catlin Twining (1801-1884) of New Haven, Connecticut in 1850 [37]. The vapor compression system itself was proposed by another American named Oliver Evans (1755-1819) of Philadelphia, Pennsylvania in the postscript to a treatise bearing the curious title: *The Abortion of the Young Steam Engineer's Guide* published in 1805 [38]. Nearly three decades after its original proposal, Jacob Perkins (1766-1849), a friend of Oliver Evans, patented the vapor compression system obtaining the British Patent No. 6662 on August 14, 1834 [39].

Although there are earlier patents proposing the use of carbon dioxide in vapor compression machines [40], the first use of carbon dioxide in a commercially successful machine is attributed to an American named Thaddeus Sobeski Carlincourt Lowe (1832-1913) of Jefferson, New Hampshire whose fame rests on the construction of the military balloons with carbon dioxide as inflation gas. In 1867, he obtained the British Patent No. 952 for an ice machine with carbon dioxide as refrigerant [41]. He made commercial ice with his machines in Dallas, Texas and in Jackson, Mississippi in 1866. He also constructed a machine on board a ship for transport of frozen meat across the Gulf of Mexico [37].

Karl von Linde (1842-1934) of Germany also experimented with carbon dioxide when he designed a machine for F. Krupp at Essen, Germany in 1882 [42]. In 1884, Wilhelm Raydt of Hanover, Germany received the British Patent No. 15,475 for a carbon dioxide ice--making machine [43]. Also, in 1884, James Harrison (1816-1893) of Australia took out the British Patent No. 1890 on the improvements in the production and use of carbon dioxide for refrigeration and air conditioning [44].

The use of carbon dioxide did not advance significantly until Franz Windhausen (1829-1904) of Brunswick, Germany designed a carbon dioxide compressor receiving the British Patent No. 2864 in 1886 [45]. The following year, this patent was purchased by J&E Hall of Great Britain who improved it further and commenced manufacture of the compressor in 1890 [46]. The British ship *Highland Chief* was the first to be outfitted with Hall's carbon dioxide vapor compression machine in 1890 and thereafter these machines found widespread use on the refrigerated marine cargo ships. Of 356 ships worldwide in 1900, 37% used air cycle machines, 37% ammonia absorption machines, and 25% carbon dioxide vapor compression machines. By 1930, 80% of the ships were outfitted with the carbon dioxide machines and the remaining 20% with the ammonia machines [47]. The last of the ships with carbon dioxide machine went out of service in 1950 due to

Table 1. Comparative Characteristics of R-744 and R-134a Refrigerants

Characteristic	R-744	R-134a	Remarks
Chemical formula	CO_2	$C_2H_2F_4$	Unlike R-134a, R-744 occurs in nature.
Molecular weight, lb_m/lb mole	44	102	Being colligative in nature, the refrigerant charge for R-744 system is 44/102 = 0.43 times that for R-134a system.
Triple point temperature, ^oF	- 69.8	- 153.9	It is the lowest temperature at which the liquid phase exists.
Triple point pressure, psia	75.12	0.06	It is the lowest pressure at which the liquid phase exists.
Molar latent heat of evaporation at triple point, Btu/lb mole	6,553	11,549	The higher the molar latent heat of evaporation the higher is the cooling capacity.
Normal sublimation or boiling point, ^oF	- 109.3	- 15.7	R-744 sublimes at atmospheric pressure. Hence it has no normal boiling point.
Vapor pressure at 32 ^oF	505	43	This suggests that operating pressure of R-744 system is 505/43 = 11.7 times that of R-134a system.
Molar latent heat of evaporation at 32 ^oF, Btu/lb mole	4,384	8,648	This suggests that COP of R-744 system is half (4,384/8,648) COP of R-134a system for fixed compressor power.
Critical temperature, ^oF	87.9	214.0	The higher the critical temperature the higher the cooling capacity generally.
Critical pressure, psia	1,070	590	The higher the critical pressure the higher the operating pressure generally.
Global warming potential (GWP)	1	1,300	It is a measure of the potency of a gas to absorb infrared rays responsible for global warming.
Ozone depletion potential (ODP)	0	0	It is a measure of the potency of a gas to destroy the ozone layer that shields the Earth from harmful effects of the sun's ultraviolet rays.

emergence of the chlorofluorocarbon refrigerants (*vide infra*).

Between 1890 and 1897, several unsuccessful attempts were made to introduce the carbon dioxide refrigeration machines in the USA. Eventually, the first successful machine was installed in 1897 under the supervision of Fred Whittenmier who was engaged by Grommes & Ulrich of Chicago to install a carbon dioxide machine for cooling the wine cellar located in Marquette building in Chicago. The machine was imported from Germany and was built by Scharrer & Gross of Nurnburg. Its refrigeration capacity was 2 tons which was rather inadequate for the intended purpose [48].

On July 30, 1897, the Kroeschell Bros. Ice

Machine Co. was organized at Chicago with Fred Whittenmier as Manager. The company started manufacturing small carbon dioxide compressors using the patents of Julius Sedlacek of Linz, Austria [49]. In 1918, Fred Whittenmier left the employ of Kroeschell Bros. to form his own company called Whittenmier Machinery Company, Chicago. This company successfully installed a number of carbon dioxide refrigeration and air conditioning systems.

Use of carbon dioxide for comfort cooling lagged by three decades its use for refrigeration. It was not until 1919 that carbon dioxide vapor compression machines found widespread use for comfort cooling applications such as air conditioning of theaters (1919), department stores (1919), churches (1920), offices (1927), residences (1930), and later practically all types of commercial establishments and public buildings [50-51]. While the high pressure carbon dioxide systems were acceptable for such stationary applications, they never received consideration for mobile air conditioning ostensibly due to the containment problems which are greatly accentuated in a mobile system.

Development of the first mobile air conditioning system was prompted by the invention of chlorofluorocarbon refrigerants in 1928 by Midgley *et al.* of the Frigidaire Division of General Motors Corporation [52]. On September 23, 1932 a proposal was prepared by the General Motors Research Staff to develop a self-contained automobile air conditioning system with R-12 refrigerant. However, it was not until the summer of 1933 that the work got underway with Charles F. Kettering offering the use of his 1933 Cadillac V-12 Town Sedan to estimate the cooling capacity of the proposed system. Eventually, a prototype self-contained system was built and installed in the trunk of a 1939 Cadillac. While General Motors Corporation was evaluating its trunk-mounted unit, Packard Motor Car Company made history by exhibiting its trunk-mounted automobile air conditioning system on November 4, 1939 at the Chicago Auto Show [53].

The modern day automobile air conditioning system for underhood installation with R-12 refrigerant and a single front-mounted condenser was developed in 1953 by Harrison Radiator Division (now known as Delphi Harrison Thermal Systems) in collaboration with Pontiac Division of General Motors Corporation [54]. The same year, Airtemp unit of Chrysler Corporation introduced an automobile air conditioning system with R-12 refrigerant and two front-mounted condensers rather than one as in present practice [55].

A literature review from 1930 to 1990, reveals that there are practically no patents or technical papers on the carbon dioxide refrigeration or air conditioning systems as they were rapidly supplanted by the R-12 systems. Carbon dioxide systems simply could not compete with the R-12 systems from an energy efficiency viewpoint and high operating pressure which undermined the system integrity and cooling capacity at high ambient temperatures. Although it ceased to be used as a working fluid of vapor compression machines, carbon dioxide gained wide acceptance, between 1930 and the present time, in solid form called dry ice in a variety of cryogenic applications including production and storage of ice cream and other perishable food products [56]. Dry ice was independently discovered in 1835 by a French physicist named Charles Saint-Ange Thilorier (1797-1852) and a Scottish chemist named Kenneth Kemp (1807-1843) [37].

Recent interest in the carbon dioxide air conditioning system [57] is in large measure due to the efforts launched in 1989 by Gustav Lorentzen and his associates at Norwegian Institute of Technology, Trondheim, Norway with funding from Hydro Aluminium a. s., Oslo, Norway. Motivated by the consideration that carbon dioxide is a natural refrigerant and its direct global warming impact is negligible compared to that of R-134a, they initiated a theoretical and experimental investigation which culminated in the establishment of a BMW-led European consortium to explore merits of the carbon dioxide system in 1994. In 1993, Lorentzen *et al.* also succeeded in securing the U. S. Patent No. 5,245,836 relating to pressure regulation in the carbon dioxide system [58]. The particular pressure regulation technique covered by this patent has been known since 1928 [26].

A few remarks about the history of the relatively new refrigerant R-134a are in order, Its invention falls within the overarching scope of a series of patents secured between 1930 and 1940 by Midgley, Henne, and McNary of General Motors Corporation [52]. In 1936, Henne and Renoll [59] synthesized R-134a for the first time at Ohio State University, Columbus, Ohio apparently to prove the point made in the aforesaid patents that the compounds like R-134a

are not as stable as R-12. In view of this consideration, R-134a emerged as the natural substitute for R-12 after the alarm was sounded in 1974 that chlorofluorocarbon refrigerants were powerful ozone depleters *ibid.* [32]. After considerable research between 1978 and 1992, car makers around the world started replacing R-12 with R-134a in 1992. DuPont and ICI were the first chemical companies to start up the world's commercial plants to manufacture R-134a in the last quarter of 1990 at Corpus Christi, Texas, USA and Runcorn, England, respectively.

In view of the foregoing appraisement of the historical facts, there is a compelling reason to believe *a fortiori* that R-744 is not likely to replace R-134a in mobile air conditioning system since R-134a is similar to R-12 as regarded operating pressure and energy efficiency.

SYSTEM PERFORMANCE

The underlying principle of the R-744 as well as R-134a system is the vapor compression cycle first proposed by Evans in 1805 and sometimes alluded to as the Evans-Perkins vapor compression cycle [38-39]. However, there is a significant difference between the two systems from an operational viewpoint. The operating pressure of the R-744 system is significantly higher than that of the R-134a system. The R-744 system is a supercritical system with its compressor discharge pressure greater than the critical pressure of carbon dioxide (1,070 psia). The R-134a system, on the other hand, is a subcritical system with its compressor discharge pressure lower than the critical pressure of R-134a (590 psia). The relative magnitudes of the compressor discharge pressures in the two systems requires that in the supercritical system the high pressure side heat exchanger (gas cooler) must carry single-phase (vapor) refrigerant while in a subcritical system the high pressure side heat exchanger (condenser) must carry a two-phase (liquid + vapor) refrigerant.

Presented in this section is the complete theoretical performance of the R-744 and R-134a mobile air conditioning systems comprehending air as well as refrigerant side of the systems. The calculations were performed both for realistic as well as idealized air conditioning systems. In order to provide performance results over the entire operating range of the vehicle, the results were generated both under idle (0 MPH vehicle speed) and down-the-road (50 MPH vehicle speed) steady state conditions. Since the air conditioning system load is higher in ventilation rather than in recirculation mode, the calculations were executed for the former mode. The computations were performed with the aid of a special Delphi Thermal computer code that has been extensively validated by comparing its predictions with the wind tunnel measurements performed on the R-12 and R-134a mobile air conditioning systems.

REALISTIC DESIGN CONDITIONS

There appears to be considerable confusion in some quarters as to what constitutes a realistic set of design conditions for a mobile air conditioning system. This has led to misrecokening of the coefficient of performance and compounding of misapprehension as to the power consumption by the R-744 system. With this in mind, stated below are the realistic design conditions.

1. The nominal cooling capacity of the mobile air conditioning system is 2 tons which is equivalent to 400 Btu/min.

2. Under down-the-road conditions, the standard dry bulb temperature of the outside air is 100 °F with 40% relative humidity which corresponds to an absolute humidity of 0.0167 lb_m H_2O / lb_m dry air. Under idle conditions, on the other hand, there is 20 °F rise in the dry bulb temperature with absolute humidity remaining the same. This translates to a relative humidity of 22.4%.

3. The dry bulb temperature of the evaporator-conditioned air is 70 °F under idle and 50 °F under down-the-road conditions.

4. The evaporator air volume flow rate is 250 ft^3/min both under idle and down-the-road conditions. This translates to the air mass flow rate of 16.6 lb_m/min under idle and 17.3 lb_m/min under down-the-road conditions.

5. The condenser or gas cooler air volume flow rate is 600 ft^3/min under idle and 2,000 ft^3/min under down-the-road conditions. This translates to the air mass flow rate of 40 lb_m/min under idle and 138 lb_m/min under down-the-road conditions.

SYSTEM IRREVERSIBILITIES

In a real life system, we have to contend with various system irreversibilities that lower

the overall system efficiency. Based on our experience, the following irreversibilities are deemed appropriate for the systems under consideration:

1. The power consumption by the air conditioning system blower is 250 watts which, with an alternator efficiency of 55%, translates to 26 Btu/min.

2. The power transmission loss of the air conditioning system mechanical drive is 3% of the compressor power.

3. The pressure drop in the R-134a evaporator is 10% of the mean evaporating pressure. Likewise the pressure drop in the R-134a condenser is 5% of the mean condensing refrigerant pressure. For the R-744 system, the pressure drop in the two heat exchangers is negligible as elaborated on pp. 12 *et seq.*

4. The pressure drop in the accumulator used to store excess refrigerant charge is 10% of the evaporator out pressure.

5. The isentropic efficiency of the R-134a system compressor is 65% under idle and 60% under down-the road conditions. The isentropic efficiency of the R-744 system is 70% under idle and 65% under down-the road conditions.

6. With orifice tube as the expansion device, there is no evaporator out superheat either under idle or under down-the-road conditions. This means that in both cases the evaporator out pressure equals the saturation vapor pressure corresponding to the evaporator out temperature.

7. In the case of the R-134a system, there is no condenser out subcooling under idle conditions but there is 25 °F subcooling under down-the-road conditions.

8. In the case of R-744 system, the gas cooler refrigerant side temperature effectiveness, *i.e.*, ratio of the refrigerant temperature drop to the inlet temperature difference (ITD) between the refrigerant and air stream has been assigned a value of 0.90 both under idle and down-the-road conditions.

9. The evaporator air side temperature effectiveness, *i.e.*, ratio of the air side temperature drop to the inlet temperature difference (ITD) between the refrigerant and air stream has a value of 0.90 under idle conditions and 0.85 under down-the-road conditions for both the systems.

IDEALIZED SYSTEM

As a prelude to the performance calculations for the realistic air conditioning systems with the aforementioned irreversibilities, it is instructive to perform the calculations for an idealized system devoid of the irreversibilities.

An idealized supercritical system embodies the following idealizations: (1) There is no pressure drop in the evaporator, (2) the evaporator temperature effectiveness is unity so that the conditioned air temperature is equal to the refrigerant evaporating temperature, (3) there is no evaporator out superheat so that the compressor suction temperature equals the saturation temperature corresponding to the evaporating pressure, (4) the isentropic efficiency of the compressor is 100% so that there is neither friction nor heat loss during the compression process, (5) there is no pressure drop in the gas cooler, and (6) the gas cooler temperature effectiveness is unity so that the gas cooler air out temperature is equal to the refrigerant out temperature. Such a system is depicted on the pressure-enthalpy diagram in Fig. 1 (a).

In 1928, Inokuty [60-61] presented a singularly lucid graphical method to find the optimum compressor discharge pressure for the idealized supercritical system described above. According to this method, we draw a tangent to the isotherm corresponding to the gas cooler cooling medium temperature (t_m) starting from the point of intersection of the 90% quality line and the suction pressure (P_{suc}) line on the pressure-enthalpy diagram [*vide* Fig. 1 (a)]. Then the pressure given by the point of contact of the tangent with the t_m isotherm directly gives the optimal compressor discharge pressure (P_{dis}) that will yield the maximum coefficient of performance for prescribed evaporating temperature and pressure.

An idealized subcritical system is similar to the supercritical system described above. In this case, the idealizations (5) and (6) are replaced by: (5a) There is no pressure drop in the condenser and (6a) there is no condenser out subcooling and the condenser out refrigerant temperature is equal to the dry bulb temperature of the incoming condenser cooling air. Such a system is depicted on the pressure-enthalpy diagram in Fig. 1 (b). Placed *vis-a-vis* the

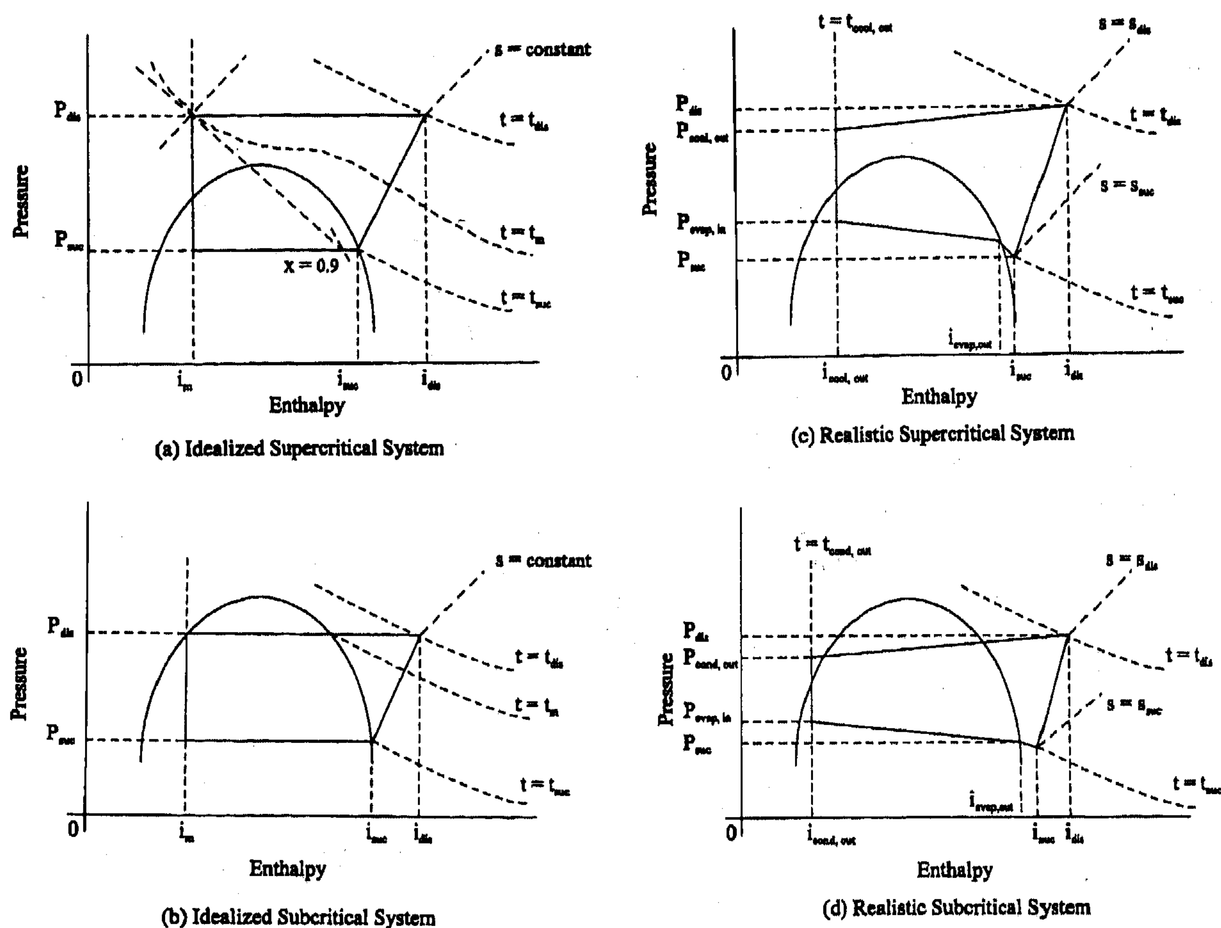

Figure 1. Schematic Representation of (a) Idealized Supercritical, (b) Idealized Subcritical, (c) Realistic Supercritical, and (d) Realistic Subcritical Vapor Compression Systems on the Pressure-Enthalpy Diagram.

corresponding idealized systems in Figs 1(a) and 1(b) are the realistic supercritical and subcritical systems in Figs. 1(c) and 1(d). An examination of these juxtaposed figures clearly elicits the system irreversibilities stated above.

Inokuty's graphical procedure cannot be applied to the idealized subcritical system since it is not possible to draw a tangent from the 90% quality line to the cooling air isotherm which now intersects the two-phase dome as shown in Fig. 1(b). However, in this case simple physical reasoning shows that thermodynamically possible maximum heat transfer from the condenser will occur if the condensing temperature equals the incoming air temperature. Accordingly, the compressor discharge pressure for the optimum coefficient of performance must equal the saturation vapor pressure corresponding to the condenser cooling medium temperature.

A little reflection shows that the idealizations embodied in the foregoing systems are the same as those in the absolute datum called the Carnot cycle with the important difference that the expansion process in these systems is isenthalpic rather than isentropic as in the Carnot Cycle. The implication of the isenthalpic expansion is that the cycle COP of the idealized system will be lower than that of the Carnot cycle. This latter COP is independent of the working fluid and is given simply as $T_l/(T_h - T_l)$ where T_l is the absolute temperature of the low pressure side and T_h that of the high pressure side.

IDEALIZED SYSTEMS PERFORMANCE

Presented in Table 2 is the predicted performance of the idealized R-744 and R-134a systems. The cycle COP's and other quantities in Table 2 must be viewed as the upper bounds that no real life system can exceed. A perusal of the

Table 2. Air Conditioning Performance Comparison of Idealized R-744 and R-134a Systems

Road Load Condition	Idle		Down-the-Road	
Refrigerant	R-744	R-134a	R-744	R-134a
Outside air temperature, °F	120	120	100	100

Compressor discharge pressure, psia	2,000	186	1,500	139
Compressor discharge temperature, °F	182	124	165	105
Compressor isentropic efficiency	1.0	1.0	1.0	1.0
Compressor power, HP	1.20	0.59	2.24	1.04
Condenser/gas cooler out pressure, psia	2,000	186	1,500	139
Condenser/gas cooler out temperature, °F	120	120	100	100
Condenser/gas cooler temperature effectiveness	1.0	1.0	1.0	1.0
Condenser/gas cooler cooling capacity, Btu/min	270	243	477	426
Evaporator in pressure, psia	852	86	653	60
Evaporator in temperature, °F	70	70	50	50
Evaporator out pressure, psia	852	86	653	60
Evaporator out temperature, °F	70	70	50	50
Evaporator temperature effectiveness	1.0	1.0	1.0	1.0
Latent load on evaporator, Btu/min	20	20	175	175
Sensible load on evaporator, Btu/min	199	199	207	207
Evaporator cooling capacity, Btu/min	219	219	382	382
Compressor power, Btu/min	51	25	95	44
Compressor power transmission loss, Btu/min	0	0	0	0
A/C blower power, Btu/min	14	14	14	14
System power, Btu/min	65	39	109	58
Cycle COP	4.26	8.80	4.00	8.71
System COP	3.37	5.62	3.50	6.59

results in Table 2 shows that, for equal cooling capacities, the compressor power for the R-744 system is 2.04 times the compressor power for the R-134a system under idle conditions and 2.16 times under down-the-road steady state conditions. Since, for fixed cooling capacity, the COP varies inversely with compressor power, the COP of the R-744 system is 0.48 times the COP of the R-134a system under idle and 0.46 times under down-the-road conditions. These COP ratios are consistent with the values anticipated from an examination of the molar latent heat of evaporation at 32 °F (*cf.* p. 3).

The numerical values in Table 2 suggest that the cycle COP decreases with increasing cooling capacity q_{cool}. To explore this trend further, a set of calculations was performed varying the dry bulb temperature of the outside air from 60 to 110 °F while keeping the conditioned air temperature fixed at 50 °F. For convenience, only sensible evaporator load was considered for this purpose. The results in Table 3 confirm the before-mentioned trend over a wider temperature and hence cooling capacity range. They also show that R-744 COP is always lower than R-134a COP. Explored subsequently in the paper will be the variation of the global warming impact with the cooling capacity.

Table 3. Variation of COP With Cooling Capacity

Ambient air, °F	q_{cool} Btu/min	R-744 COP	R-134a COP	COP ratio
60	41	16.9	48.4	0.35
70	82	9.4	24.0	0.39
80	124	6.3	15.5	0.40
90	165	4.6	11.3	0.41
100	207	4.0	8.7	0.46
110	248	2.9	7.0	0.42

REALISTIC SYSTEMS PERFORMANCE

Presented in Table 4 is the predicted performance of the realistic R-744 and R-134a systems. These performance comparisons are for the identical cooling capacities both under idle and down-the-road conditions. The compressor power indicated is the power derived from the driveshaft while the system power includes the power loss in the compressor mechanical drive and the evaporator blower power in addition to the compressor power. Two types of COP's are presented, *viz.*, cycle COP and system COP. The cycle COP is calculated taking into account only the compressor power while the system COP is calculated taking into account the system power. In both cases, the power used to force air over the condenser or gas cooler is not charged to the air conditioning system as the engine cooling fan supplying the cooling airflow is a part of the engine cooling system used to cool the radiator located directly behind the condenser or gas cooler.

A perusal of the tabular results shows that for equal cooling capacities, the compressor power consumption by the R-744 system is 1.10 times the power consumption by the R-134a system under idle conditions and 1.96 times the power consumption by the R-134a system under down-the-road conditions. Consistently, the cycle COP's of the R-744 system are 0.94 and 0.53 times those of the R-134a system under idle and down-the-road conditions. Likewise, the system COP's of the R-744 system are 0.92 and 0.54 times those of the R-134a system under idle and down-the-road conditions.

A comparison of the cycle COP's for the idealized systems (Table 2) with the cycle COP's for the realistic system (Table 4) shows that the idealized COP's are significantly higher than the corresponding realistic COP's due to absence of the system irreversibilities. The disparity between idealized and realistic cycle COP's of the R-744 system is seen to be less than that for the R-134a system. This is due to the fact that the compressor discharge pressure of the realistic R-744 system has been optimized as described by Inokuty *op. cit.* If a similar optimization is carried out for the realistic R-134a system, then the disparity between R-134a idealized and realistic COP's will narrow and the realistic R-134a COP's will be even higher than the realistic R-744 COP's.

A measure of the degree of optimization of the system is the ratio of the actual compressor discharge pressure to the idealized compressor discharge pressure. Obviously, for a perfectly optimized system the ratio is unity. It is seen from Tables 2 and 4 that the discharge pressure ratios for the R-744 system are respectively 1.06 and 1.17 under idle and down-the-road conditions. The corresponding discharge pressure ratios for the R-134a system are 2.16 and 2.04 which attest to the extent of unrealized optimization with the R-134a system.

Assuming that the idling time is 15% of the on-road time, the weighted average cycle COP of the realistic R-134a system can be taken as 0.15

Table 4. Air Conditioning Performance Comparison of Realistic R-744 and R-134a Systems

Road Load Condition	Idle		Down-the-Road	
Refrigerant	R-744	R-134a	R-744	R-134a
Outside air temperature, °F	120	120	100	100
Outside air relative humidity, %	22.4	22.4	40	40
Outside air absolute humidity, lb_m H_2O/lb_m dry air	0.0167	0.0167	0.0167	0.0167
Evaporator air volume flow rate, ft^3/min	250	250	250	250
Evaporator air mass flow rate, lb_m/min	16.6	16.6	17.3	17.3
Conditioned air temperature, °F	70	70	50	50
Condenser/gas cooler air volume flow rate, ft^3/min	600	600	2,000	2,000
Condenser/gas cooler air mass flow rate, lb_m/min	40	40	138	138
Condenser/gas cooler air out temperature, °F	162	159	123	118
Refrigerant charge, lb_m	0.917	2.125	0.917	2.125

Compressor isentropic efficiency	0.70	0.65	0.65	0.60
Compressor power, HP	3.83	3.49	9.06	4.60
Condenser/gas cooler out pressure, psia	2,125	381	1,750	269
Condenser/gas cooler out temperature, °F	133	176	116	122
Condenser/gas cooler temperature effectiveness	0.90	0.50	0.90	0.50
Condenser/gas cooler cooling capacity, Btu/min	380	371	759	580
Evaporator in pressure, psia	792	82	578	53
Evaporator in temperature, °F	64.4	67.1	41.0	43.5
Evaporator out pressure, psia	792	74	578	48
Evaporator out temperature, °F	64.4	61.6	41.0	38.5
Evaporator temperature effectiveness	0.90	0.90	0.85	0.85
Latent load on evaporator, Btu/min	20	20	175	175
Sensible load on evaporator, Btu/min	199	199	207	207
Evaporator cooling capacity, Btu/min	219	219	382	382
Compressor power, Btu/min	162	148	382	195
Compressor power transmission loss, Btu/min	5	4	12	6
A/C blower power, Btu/min	26	26	26	26
System power, Btu/min	193	178	420	227
Cycle COP	1.36	1.48	1.03	1.96
System COP	1.13	1.23	0.91	1.68

x 1.48 + 0.85 x 1.96 = 1.89 while that of the R-744 system as 0.15 x 1.36 + 0.85 x 1.00 = 1.08 corresponding to an average cooling capacity of 0.15 x 219 + 0.85 x 382 = 358 Btu/min. This gives the cycle COP ratio as 1.08/1.89 = 0.57. A similar calculation for the system COP's shows the weighted average COP ratio to be 0.94/1.61 = 0.58. This latter COP ratio will be used in the global warming impact analysis presented below.

HEAT EXCHANGER AND COMPRESSOR CHARACTERISTICS

Since the operating pressure and transport properties of R-744 are significantly different from those of R-134a, it is expected that the types of heat exchangers and compressor suitable for the R-744 system will be different from those used in the present R-134a system. In order to bring out the differences between the two sets of components, it is necessary to present first some basic heat transfer and fluid flow relations.

HEAT TRANSFER RATE

The heat transfer rate q (Btu/hr) of a heat exchanger of the type used in the systems under consideration is given by the following relation analogous to Ohm's law [62]:

$$q = \frac{t_h - t_c}{\frac{1}{h_a A_a} + \frac{\delta_w}{k_w A_w} + \frac{1}{h_r A_r}} \qquad (1)$$

where

A_a is the effective air side heat transfer area including that of the fins, ft^2
A_r is the effective refrigerant side heat transfer area including that of the fins, ft^2
h_a is the air side heat transfer coefficient, Btu/hr ft^2 °F
h_r is the refrigerant side heat transfer coefficient, Btu/hr ft^2 °F
k_w is thermal conductivity of the flow passage wall, Btu/hr ft °F
t_c is the cold fluid mean temperature, °F
t_h is the hot fluid mean temperature, °F
δ_w is wall thickness of the flow passage, ft.

The denominator on the right hand side of Eq. (1) represents the total thermal resistance R of the heat exchanger comprising three distinct resistances: the air side resistance $R_a = (1/h_a A_a)$, flow passage wall resistance $R_w = (\delta_w/k_w A_w)$, and refrigerant side resistance $R_r = (1/h_r A_r)$. For the metal heat exchangers of the type used in present mobile air conditioning systems, the approximate values of R_w, R_r, and R_a are $R_w/R = 0.005$, $R_r/R = 0.10$, and $R_a/R = 0.895$.

Introduction of R-744 in the mobile air conditioning system is expected to increase h_r due to superior transport properties and increased refrigerant flow rate. The upshot of this would be to lower $R_r = 1/h_r A_r$. Also, introduction of R-744 is expected to leave R_a unchanged while increasing $R_w = \delta_w/k_w A_w$ due to an increase in δ_w to accommodate higher pressure. This is easy to infer from the following radial stress relation for a thin-walled circular cylinder which shows that for a permissible radial stress, the wall thickness is directly proportional to the internal pressure:

$$\sigma_{rad} = \frac{P_i r_i}{\delta_w} \qquad (2)$$

where

P_i is the internal pressure, lb_f/ft^2
r_i is the inside radius of the cylinder, ft
δ_w is the wall thickness of the cylinder, ft
σ_{rad} is the radial stress, lb_f/ft^2.

The effect of refrigerant flow rate, flow passage geometry, and refrigerant transport properties on h_r can be inferred from an appropriate turbulent flow correlation for the Nusselt number. An exhaustive compendium of all available turbulent flow correlations has been prepared by Bhatti and Shah [63]. For the purpose of the present analysis, the following correlation due to Dittus and Boelter has been selected in view of its simplicity:

$$Nu = 0.024 Re^{4/5} Pr^{2/5} \qquad (3)$$

where

Nu is the dimensionless Nusselt number = hd_h/k,
Pr is the dimensionless Prandtl number = $\mu c_p/k$,
Re is the dimensionless Reynolds number = $\rho u_m d_h/\mu$,
c_p is isobaric specific heat of the fluid, Btu/lb_m°R
d_h is the flow passage hydraulic diameter, ft
h is the heat transfer coefficient, Btu/hr ft^2 °R
k is thermal conductivity of the fluid, Btu/hr ft °R

u_m is the fluid mean velocity, ft/hr
μ is dynamic viscosity of the fluid, lb_m/hr ft
ρ is the fluid density, lb_m/ft^3.

Introducing the defining relations for Nu, Re, and Pr into Eq. (3), we obtain the following expression for the heat transfer coefficient:

$$h = 0.024 u_m^{4/5} d_h^{-1/5} c_p^{2/5} k^{3/5} \rho^{4/5} \mu^{-2/5} \quad (4)$$

The fluid mean velocity u_m is expressible in terms of fluid mass flow rate $\dot{m}$ (lb_m/hr) as

$$u_m = \frac{4\dot{m}}{\pi \rho d_h^2} \quad (5)$$

Introducing Eq. (5) into Eq. (4) and denoting the resulting combination of transport properties by

$$\Phi_h = c_p^{2/5} k^{3/5} \mu^{-2/5} \quad (6)$$

we obtain,

$$h = 0.06 \dot{m}^{4/5} d_h^{-9/5} \Phi_h \quad (7)$$

which brings out with illuminating distinctness dependence of h on the fluid mass flow rate ($\dot{m}$), flow passage geometry (d_h), and fluid transport properties (Φ_h).

Applying Eq. (7) to the two systems with identical geometry (d_h), we obtain

$$\frac{h_{744}}{h_{134}} = \left(\frac{\dot{m}_{744}}{\dot{m}_{134}}\right)^{4/5} \left(\frac{\Phi_{h,744}}{\Phi_{h,134}}\right) \quad (8)$$

It is also useful to obtain an expression for the relative total thermal resistance of the two systems

$$\frac{R_{744}}{R_{134}} = \frac{R_{a,744} + R_{w,744} + R_{r,744}}{R_{a,134} + R_{w,134} + R_{r,134}} \quad (9)$$

where in view of the foregoing considerations

$$R_{a,744} = R_{a,134} \quad (10)$$

$$R_{w,744} = \left(\frac{P_{744}}{P_{134}}\right) R_{w,134} \quad (11)$$

$$R_{r,744} = \left(\frac{h_{134}}{h_{744}}\right) R_{r,134} \quad (12)$$

Knowing relative thermal resistance from Eqs. (9) through (12) in terms of the resistances of the baseline system, the relative heat transfer rate follows from Eq. (1) as

$$\frac{\dot{q}_{744}}{\dot{q}_{134}} = \left(\frac{\Delta t_{744}}{\Delta t_{134}}\right) \left(\frac{R_{134}}{R_{744}}\right) \quad (13)$$

where Δt is the difference between the hot and cold fluid mean temperatures.

PRESSURE DROP

The pressure drop Δp (lb_f/ft^2) in the flow passage of a heat exchanger of the type used in the systems under consideration is given by [62]

$$\Delta p = \frac{2 f l \rho u_m^2}{g_c d_h} \quad (14)$$

where ρ, u_m, and d_h are previously defined and the remaining symbols have the following meanings:

f is the dimensionless Fanning friction factor,
g_c is the proportionality constant in Newton's second law of motion = 32.174 x $3{,}600^2$ lb_m ft/lb_f hr^2
l is the flow passage length, ft.

There are a number correlations for the turbulent flow Fanning friction factor which have been brought together by Bhatti and Shah *op. cit.* For the purpose of the present analysis, the following correlation due to Blausius has been selected owing to its simplicity and accuracy:

$$f = \frac{0.0791}{Re^{1/4}} \quad (15)$$

where the dimensionless Reynolds number Re has been previously defined as $Re = \rho u_m d_h / \mu$.

Combining Eqs. (5), (14), (15) and denoting the resulting combination of transport properties by

$$\Phi_p = \rho^{-1}\mu^{1/4} \quad (16)$$

we obtain,

$$\Delta p = \frac{0.2414}{g_c} \dot{m}^{7/4} \frac{l}{d_h^{19/4}} \Phi_p \quad (17)$$

which shows with illuminating distinctness dependence of Δp on the fluid mass flow rate ($\dot{m}$), flow passage geometry (l, d_h), and fluid transport properties (Φ_p).

Applying Eq. (17) to the two systems with identical geometry (l, d_h), we obtain

$$\frac{\Delta p_{744}}{\Delta p_{134}} = \left(\frac{\dot{m}_{744}}{\dot{m}_{134}}\right)^{7/4} \left(\frac{\Phi_{p,744}}{\Phi_{p,134}}\right) \quad (18)$$

Table 5. Transport Properties of R-744 and R-134a [64-66]

	40 °F		120 °F	
Property	R-744	R-134a	R-744	R-134a
$c_{p,f}$, Btu/lb$_m$°F	0.6560	0.3276	-	0.3660
$c_{p,g}$, Btu/lb$_m$°F	0.4940	0.1967	1.2045	0.2260
k_f, Btu/hr ft°F	0.0610	0.0542	-	0.0434
k_g, Btu/hr ft°F	0.0114	0.0069	0.0438	0.0093
ρ_f, lb$_m$/ft^3	56.099	79.577	-	68.139
ρ_g, lb$_m$/ft^3	7.0240	1.0560	35.226	4.0323
μ_f, lb$_m$/ft hr	0.2270	0.5978	-	0.4829
μ_g, lb$_m$/ft hr	0.0392	0.0315	0.1037	0.0378
$\Phi_{h,f}$	0.2855	0.1367	-	0.1363
$\Phi_{h,g}$	0.1880	0.1051	0.4082	0.1235
Mean Φ_h	0.2368	0.1209	0.4082	0.1299
$\Phi_{p,f}$	0.0123	0.0110	-	0.0122
$\Phi_{p,g}$	0.0634	0.3989	0.0161	0.1094
Mean Φ_p	0.0379	0.2050	0.0161	0.0608

It is apparent from Eqs (8) and (18) that in order to determine the relative values of h and Δp for the two systems, we need the values of the transport property dimensional parameters Φ_h (Btu/lb$_m^{4/5}$ hr$^{1/5}$ °R) and Φ_p (ft$^{11/4}$/lb$_m^{3/4}$ hr$^{1/4}$) defined in Eqs. (6) and (16). These values are presented in Table 5 together with the precursor transport properties. The property values are given at two temperatures of 40 and 120 °F which are close to the evaporating and gas cooling or condensing temperatures under down-the-road conditions of Table 4. The subscripts f and g respectively denote liquid and vapor. Also, it may be noted that the tabular results for R-744 at 120 °F are those of superheated vapor corresponding to 1,750 psia whereas the remaining results are for saturated liquid and vapor for both the refrigerants.

EVAPORATOR HEAT TRANSFER RATE AND PRESSURE DROP

From Table 4 we note that $\dot{m}_{744}/\dot{m}_{134}$ = 9.04/6.97 under down-the-road conditions. Also from Table 5 we note that $\Phi_{h,744}/\Phi_{h,134}$ = 0.2368/0.1209 for the evaporator at 40 °F. With this value, Eq. (8) yields h_{744}/h_{134} = 2.50 for the evaporator. This dramatic increase in h_r for R-744 does not result in a dramatic decrease in $R = R_a + R_w + R_r$ since $R_r = 1/h_r A_r$ is not the dominant resistance. Moreover, for R-744 there is an increase in $R_w = \delta_w/k_w A_w$ due to increased δ_w which wipes out part of the gain due to increased h_r.

To provide a quantitative idea about the effect of increase in h_r, we note that for the evaporator $R_{a,134}$ = 0.0797 hr °F/Btu, $R_{w,134}$ = 0.0004 hr °F/Btu, and $R_{r,134}$ = 0.0089 hr °F/Btu. Introducing these values in Eqs. (9) through (12) together with P_{744}/P_{134} = 578/53 (*vide* Table 4) and h_{744}/h_{134} = 2.50, we obtain R_{744}/R_{134} = 0.0877/0.0890 = 0.99 which shows that there is only marginal reduction in overall thermal resistance of the R-744 system evaporator. According to Eq. (13), with R_{744}/R_{134} = 0.99 and $\Delta t_{744}/\Delta t_{134}$ = 34/34 (*vide* Table 4), we get $\dot{q}_{744}/\dot{q}_{134}$ = 1.01 indicating practically no change in the heat transfer rate of the R-744 system evaporator compared to that of the R-134a system. Since the required cooling capacity (heat transfer rate) of the R-744 as well as R-134a evaporator is the same, *viz.*, 382 Btu/min (*vide* Table 4), it follows from $\dot{q}_{744}/\dot{q}_{134}$ = 1.01 that despite favorable value of h_{744}/h_{134} = 2.50 there is no scope to reduce the thermal size of the R-744 evaporator.

We note from Table 5 that $\Phi_{p,744}/\Phi_{p,134}$ = 0.0379/0.2050 for the evaporator at 40 °F. With this value together with the previously stated value of $\dot{m}_{744}/\dot{m}_{134}$ = 9.04/6.97, Eq. (18) yields $\Delta p_{744}/\Delta p_{134}$ = 0.29 for the evaporator. This result shows that the pressure drop of the R-744 system evaporator is significantly lower than that of the R-134a system evaporator. This fact was taken into account in executing the calculations reported in Table 4.

CONDENSER OR GAS COOLER HEAT TRANSFER RATE AND PRESSURE DROP

From Table 4 we note that $\dot{m}_{744}/\dot{m}_{134}$ = 9.04/6.97 under down-the-road conditions. Also from Table 5 we note that $\Phi_{h,744}/\Phi_{h,134}$ = 0.4082/0.1299 for the condenser or gas cooler at 120 °F. With this value, Eq. (8) yields h_{744}/h_{134} = 3.87 for the condenser or gas cooler.

We note that for the condenser $R_{a,134}$ = 0.0814 hr °F/Btu, $R_{w,134}$ = 0.0005 hr °F/Btu, and $R_{r,134}$ = 0.0081 hr °F/Btu. Introducing these values in Eq. (9) through (12) together with P_{744}/P_{134} = 1,750/283 (*vide* Table 4) and h_{744}/h_{134} = 3.87, we obtain R_{744}/R_{134} = 0.0866/0.0900 = 0.96 which shows that there is only marginal reduction in overall thermal resistance of the R-744 system gas cooler. According to Eq. (13), with R_{744}/R_{134} = 0.96 and $\Delta t_{744}/\Delta t_{134}$ = 74.5/52.5 (*vide* Table 4), we get $\dot{q}_{744}/\dot{q}_{134}$ = 1.48 indicating that there is significant increase in the heat transfer rate of the R-744 system gas cooler compared to the R-134a system condenser. However, the required cooling capacity of the R-744 gas cooler is 382 + 382 = 764 Btu/min compared to the 382 + 195 = 577 Btu/min for the R-134a condenser (*vide* Table 4). This gives required value of $\dot{q}_{744}/\dot{q}_{134}$ = 1.32 compared to the achievable value of 1.48 with the R-744 gas cooler of the same thermal size as the condenser of the R-134a system. Thus in this case there is some scope for designing a more compact gas cooler for the R-744 system.

We note from Table 5 that $\Phi_{p,744}/\Phi_{p,134}$ = 0.0161/0.0608 for the condenser or gas cooler at 120 °F. With this value together with the previously stated value of $\dot{m}_{744}/\dot{m}_{134}$ = 9.04/6.97, Eq. (18) yields $\Delta p_{744}/\Delta p_{134}$ = 0.42 for the condenser or gas cooler. This result shows that the pressure drop of the R-744 system gas cooler is significantly lower than that of the R-134a condenser. This fact was taken into account in executing the calculations reported in Table 4.

COMPRESSOR EFFICIENCY

By definition, the isentropic efficiency η of the compressor is given by

$$\eta = \frac{\Delta i_o}{\Delta i} \qquad (19)$$

where

Δi_o is the enthalpy change across compressor for the adiabatic isentropic compression, Btu/lb_m
Δi is the enthalpy change across compressor for the actual compression process, Btu/lb_m.

For the compression process involving real gases, the expressions for Δi_o and Δi in terms of absolute temperature T (°R) and pressure P (lb_f/ft^2) are complex. However, for the ideal gas the expressions are simple and provide a good idea of the dependence of η on P_{dis}/P_{suc} and T_{dis}/T_{suc} where the subscripts $_{dis}$ and $_{suc}$ refer to the compressor discharge and suction sides respectively.

For the ideal gas with equation of state

$$Pv = RT \qquad (20)$$

undergoing adiabatic isentropic compression under the constraint imposed by the polytropic equation

$$Pv^{\gamma} = \text{constant} \qquad (21)$$

it can be shown that [67]

$$\Delta i_o = \left(\frac{\gamma}{\gamma - 1}\right)\left(\frac{RT_{suc}}{J}\right)\left[\left(\frac{P_{dis}}{P_{suc}}\right)^{(\gamma - 1)/\gamma} - 1\right] \qquad (22)$$

where

J is the mechanical-to-thermal energy conversion factor = 778.163 ft lb_f/Btu,
R = R_u/M is the gas constant, lb_f ft/lb_m °R,
R_u is the universal gas constant = 1545.32 lb_f ft/lb mole °R,
M is the molecular weight, lb_m/lb mole
v is the specific volume, ft^3/lb_m
γ is the specific heat ratio = c_p/c_v,

c_v is the isochoric specific heat, Btu/lb_m°R.

It may be noted that the polytropic equation [Eq. (21)] is merely a process equation connecting the process endpoints such that

$$P_{suc}v_{suc}^{\gamma} = P_{dis}v_{dis}^{\gamma} \qquad (23)$$

As such, it is distinct from the equation of state [Eq. (20)] which is applicable everywhere. Also it may be noted that Eq. (21) is a good representation of the adiabatic isentropic compression even for real gases.

For the ideal gas, the enthalpy change Δi entering Eq. (19) is exclusively a function of temperature being given by

$$\Delta i = A_o ln\left[\frac{T_{dis}}{T_{suc}}\right] + B_o(T_{dis}-T_{suc}) + \frac{C_o}{2}(T_{dis}^2-T_{suc}^2)$$

$$+ \frac{D_o}{3}(T_{dis}^3-T_{suc}^3) + \frac{E_o}{4}(T_{dis}^4-T_{suc}^4) \qquad (24)$$

where A_o, B_o, C_o, D_o, and E_o are the experimentally determined constants of the zero-pressure isobaric specific heat represented by

$$c_p = \frac{A_o}{T} + B_o + C_oT + D_oT^2 + E_oT^3 \qquad (25)$$

The experimental values of A_o through E_o, in English units, for the two refrigerants are as follows. $A_o = 0$, $B_o = 0.1076$, $C_o = 2.1867 \times 10^{-4}$, $D_o = -8.9232 \times 10^{-8}$, $E_o = 1.3871 \times 10^{-11}$ for R-744 [67] and $A_o = 6.8021$, $B_o = -1.2557 \times 10^{-3}$, $C_o = 4.3743 \times 10^{-4}$, $D_o = -1.4811 \times 10^{-7}$, $E_o = 0$ for R-134a [68].

For R-744, $\gamma = 1.10$, R = 35.1209 lb_f ft/lb_m °R, and typical value of T_{suc} = 500 °R and P_{dis}/P_{suc} = 3.5. For R-134a, on the other hand, $\gamma = 1.11$, R = 15.1457 lb_f ft/lb_m °R, and typical value of T_{suc} = 500 °R and P_{dis}/P_{suc} = 6.5. Equation (19) in conjunction with Eq. (22) shows that for high η, R as well as P_{dis}/P_{suc} should be as high as possible. An examination of the just-mentioned values then reveals that while higher R is a definite advantage low P_{dis}/P_{suc} is a disadvantage to the R-744 system compared to the R-134a system. Since $R = R_u/M$, we can state that lower molecule weight M of R-744 is a decided advantage as far as isentropic efficiency is concerned.

In order to obtain the numerical values of η for the two systems, we have the following data from Table 4 under down-the-road conditions: T_{suc} = 501 °R, T_{dis} = 716 °R, P_{dis}/P_{suc} = 1,750/518 = 3.38 for the R-744 system while T_{suc} = 498.5 °R, T_{dis} = 661 °R, P_{dis}/P_{suc} = 283/44 = 6.43 for the R-134a system. Using these values in Eqs. (19), (22), and (24) together with the values of the constants A_o through E_o, we obtain η = 28.69/45.26 = 0.63 for R-744 and η = 19.86/34.75 = 0.57 for R-134a. Carrying out a similar calculation under idle conditions of Table 4, we obtain η = 26.78/39.51 = 0.68 for R-744 and η = 19.90/34.44 = 0.58 for R-134a. The higher isentropic efficiency of the R-744 compressor was taken into account in performing the calculations reported in Table 4.

GLOBAL WARMING IMPACT

The global warming impact of a mobile air conditioning system is attributable to two sources: refrigerant leakage from the air conditioning system (direct impact) and fraction of the tailpipe emissions chargeable to the air conditioning system (indirect impact). As a prelude to the global warming impact analysis, certain preliminary information is presented below. It pertains to the refrigerant emission rate, emission of the tailpipe gases, fuel consumption, and global warming potential.

RATE OF REFRIGERANT EMISSION FROM THE AIR CONDITIONING SYSTEMS

According to the estimates developed by the car makers around the world, the emission rate of R-134a from the R-134a system into the atmosphere is 55 gms per year [69]. Since the average refrigerant charge for the R-134a system is 1,000 gms, this annual emission rate amounts to 5.5% of the refrigerant charge.

As per Table 1, the refrigerant charge for the R-744 system should be 430 gms which is 43% the refrigerant charge for the R-134a. Assuming the R-744 emission rate to be the same fraction of the refrigerant charge as for R-134a while ignoring higher pressure of R-744, the emission rate of R-744 can be taken as 24 gms per year. For ready reference, these values together with the corresponding values for R-134a system are presented in Table 6.

EMISSION RATES OF THE TAILPIPE GREENHOUSE GASES

The principal greenhouse gas issuing from

the gasoline-powered motor vehicle is R-744, *i.e.*, CO_2. Its average emission rate is taken as 8,868 gms per gallon of gasoline. This value is arrived at as follows. Gasoline is a blend of hundreds of chemical compounds called hydrocarbons. For the purpose of stoichiometric calculations, it is assigned the formula C_7H_{13} and accordingly the chemical equation for the complete oxidation of gasoline can be written as

$$4C_7H_{13} + 41O_2 \rightarrow 28CO_2 + 26H_2O + \Delta H$$

where ΔH is the heat of combustion of gasoline. It has a value of 18,515 Btu per lb_m of gasoline which translates to 114,000 Btu per gallon of gasoline since one gallon of gasoline has a mass of 6.2 lb_m (*vide infra*).

Table 6. Refrigerant Charge and Annual Emission Rates for the R-134a and R-744 A/C Systems

A/C system	Refrigerant charge, gm	Emission rate, gm/yr
R-134a	1,000	55
R-744	430	24

Noting that the atomic weights of H, C, and O are 1, 12, and 16, respectively, we see from the preceding equation that 388 lb_m of gasoline (C_7H_{13}) combine with 1,312 lb_m of O_2 to produce 1,232 lb_m of CO_2 and 468 lb_m of H_2O. Thus upon complete combustion, one lb_m of gasoline produces 2,716/388 = 3.2 lb_m of CO_2. Since 1 gallon = 0.13368 ft^3 and density of gasoline is 46.1 lb_m/ft^3, we see that mass of one gallon of gasoline is 6.2 lb_m. Thus complete combustion of one gallon of gasoline produces 3.2 x 6.2 = 19.6 lb_m or equivalently 8,868 gms of CO_2.

In addition to CO_2, two more greenhouse gases, *viz.*, methane (CH_4) and nitrous oxide (N_2O) issue from the tailpipe and their amounts, determined from the chemical composition of the tailpipe gases, are 0.29 and 0.15 gm per gallon, respectively. For ready reference, the foregoing emission rates are collected in Table 7.

FUEL CONSUMPTION BY THE AIR CONDITIONING SYSTEMS

The annual fuel consumption by the R-134a mobile air conditioning system is taken as 23.5 gallons. This value is arrived at as follows. The average power consumption over the course of the year by the R-134a mobile air conditioning system is 2.5 HP which is 50% of the rated power to provide 2 tons of comfort cooling. Since 1 HP = 42.41 Btu/min, it is expressible as 2.5 x 42.41 = 106 Btu/min. This power is derived from the combustion of gasoline in the internal combustion engine with an average energy conversion efficiency of 27.5% so that the actual power consumption by the air conditioning system is 106/0.275 = 386 Btu/min.

Table 7. Emission Rates of the Principal Greenhouse Gases Issuing from the Tailpipe of a Gasoline-Powered Motor Vehicle

Greenhouse gas	Emission rate, gm/gallon
R-744 (CO_2)	8,868
CH_4	0.29
N_2O	0.15

Now on an average a vehicle in the USA is driven 10,000 miles per year. The cooling period being 1/3rd the driving season, the vehicle is driven 10,000/3 = 3,333 miles during the cooling period. The amount of time the air conditioning system is used for defrosting purposes is negligible compared to the time for comfort cooling. In order to determine the length of time the air conditioning system is on, the weighted average vehicle speed can be taken as 33 MPH which is the mean of idling and maximum legal speed limit of 65 MPH in the USA. As seen from Table 8, this value is in consonance with the value 0.45 x 48.24 + 0.55 x 20.23 = 32.9 MPH which follows from the U. S. Environment Protection Agency (EPA) test procedure to measure fuel consumption and emission for the corporate average fuel economy (CAFE) calculation [70].

Table 8. Particulars of the EPA Test Procedure

Test particular	Highway schedule	Urban schedule
Relative weighting	0.45	0.55
Total distance, miles	10.25	7.46
Total time, sec	765	1,327
Speed, MPH	48.24	20.23

With average vehicle speed of 33 MPH, the air conditioning system is on for 3,333/33 = 101 hrs, *i. e.*, 6,060 mins per year. Based upon actual average customer usage profile across the nation, the number of hours the mobile air conditioning system compressor is on is

approximately 100 hrs in substantial agreement with the value determined in accordance with the just-described duty cycle.

Taking cognizance of the foregoing duty cycle, we see that the annual energy consumption rate by the air conditioning system is 386 x 6,060 = 2,339,160 Btu/yr. With the calorific value of gasoline as 114,000 Btu/gallon (*vide supra*), the annual fuel consumption to operate the air conditioning system is 2,339,160/114,000 = 20.5 gallons.

According to the fuel economy tests conducted with the air conditioning system "on and off" on a 1994 GM vehicle under high load conditions (95 °F ambient dry bulb temperature, 40% relative humidity, and 850 W/m^2 solar load), the fuel usage rate to operate the air conditioning system was found to be 0.55 fluid oz/min. The same test under low load conditions (75 °F ambient dry bulb temperature, 50% relative humidity, and zero solar load) gave a value of 0.44 fluid oz/min. From these measurements, a useful rule of thumb could be deduced, *viz.*, the average fuel consumption rate to operate the mobile air conditioning system is 0.50 fluid oz/min. In order to compare these values with the estimated fuel usage rate of 20.5 gallons per year (6,060 min of operation), we note that 1 gallon is equal to 128 fluid oz whence the estimated fuel consumption to operate the air conditioning system is expressible as 128 x 20.5/6,060 = 0.43 fluid oz/min in good accord with the experimental values.

There is an additional source of fuel consumption to carry the air conditioning system year round. According to the estimates made by General Motors Corporation and others, 10 gallons of fuel is required for each additional 100 lb_m (45.36 kg) of vehicle mass per 10,000 miles [69]. Since the mass of a typical air conditioning system is 30 lb_m, the annual fuel consumption to carry the air conditioning system year round is 10 x 30/100 = 3 gallons. Adding this to the foregoing contribution, the annual fuel consumption by the R-134a air conditioning system is 23.5 gallons. This value is within the range of 20 to 25 estimated by automakers around the world [69].

Since the fuel consumption to operate the air conditioning system is inversely proportional to its COP, the annual fuel consumption to operate the R-744 system can be taken as 20.5/0.58 = 35.3 gallons since the COP of the realistic R-744 system is 0.58 times the COP of the present R-134a system as established in the preceding section.

Since the high pressure R-744 system is expected to be more robust than the low pressure R-134a system, we take its mass to be 45 lb_m which is 50% more than that of the R-134a system. Using the foregoing rule of thumb, we determine fuel consumption to carry the R-744 system year round as 10 x 45/100 = 4.5 gallons. Adding this to the foregoing contribution, the annual fuel consumption by the R-744 system is 39.8 gallons/yr. For ready reference, various computed results are presented in Table 9.

Table 9. Annual Fuel Consumption by the Air Conditioning Systems

	Fuel consumption, gallons		
A/C system	To operate A/C system	To carry A/C system	Total
R-134a	20.5	3.0	23.5
R-744	35.3	4.5	39.8

GLOBAL WARMING POTENTIAL OF SOME GREENHOUSE GASES

Table 10. Atmospheric Lives and Global Warming Potentials of Some Greenhouse Gases [71]

Greenhouse gas	Atmospheric life, yrs	GWP (mass basis)
R-744	50 - 200	1.0
CH_4	14.5	24.5
N_2O	120.0	320
R-134a	14.0	1,300
R-12	102.0	8,500

The global warming potential (GWP) of a greenhouse gas is a measure of its potency to absorb long wavelength infrared rays compared to the potency of the reference gas R-744. This unit of measurement was developed by the Intergovernmental Panel on Climate Change (IPCC). The GWP index varies with the timeframe called integration time horizon over which the gas is compared with R-744. A shorter timeframe emphasizes the climate forcing potential of shorter lived gases while the longer timeframe is more representative of the cumulative effect of a gas on climate change over its lifetime. Table 10 contains the values of atmospheric lives and GWP indices of the greenhouse gases based on an integration time horizon of 100

years as recommended by IPCC [71]. It may be noted that no single atmospheric life can be assigned to R-744 in view of different uptake rates of this gas by multiple sink processes.

GLOBAL WARMING IMPACT OF THE R-134A SYSTEM

As shown in Table 9, the annual fuel consumption by the R-134a air conditioning system is 23.5 gallons. Using the emission rates from Table 7, we get the absolute amounts of R-744, CH_4, and N_2O attributable to R-134a system as 208.4051 x 10^3, 6.8150, and 3.5250 gm/yr, respectively. Factoring in the GWP values of CH_4 and N_2O from Table 10, we obtain R-744 equivalent amounts of CH_4 and N_2O as 166.97 and 1,128.00 gm/yr, respectively. Adding these values, we obtain the indirect equivalent warming impact of the R-134a system as (208.4051 + 0.1670 + 1.1280) x 10^3 = 209.7 kg/yr. This shows that the equivalent warming impact of one gallon of gasoline is 209.7/23.5 = 8.9 kg/yr.

In order to estimate the direct global warming impact of the R-134a system, we note that the emission rate of R-134a system is 55 gm/yr (*vide* Table 6). Factoring in the GWP value of the R-134a from Table 10, this translates to direct equivalent warming impact of the R-134a system as 71.5 kg/yr. Adding the direct and indirect equivalent warming contributions, we see that total equivalent warming impact of the R-134a system is 281.2 kg/yr. For ready reference, various results are collected in Table 11.

Table 11. Global Warming Impact of the R-134a Mobile Air Conditioning System

Green-house gas	GWP	Absolute amount, kg/yr	R-744 equivalent amount, kg/yr
Direct Impact			
R-134a	1,300	0.0550	71.5000
Indirect Impact			
R-744 CH_4 N_2O	1 24.5 320	208.4051 0.0068 0.0035	208.4051 0.1670 1.1280
Total Impact			
R-134a + R-744 + CH_4 + N_2O	-	208.5	281.2

GLOBAL WARMING IMPACT OF THE R-744 SYSTEM

As presented in Table 9, the annual fuel consumption by the R-744 air conditioning system is 39.8 gallons per year. Using the emission rates from Table 7, we get the absolute amounts of R-744, CH_4, and N_2O attributable to the R-744 system as 353.3559 x 10^3, 11.5550, and 5.9767 gm/yr, respectively. Factoring in the GWP values of CH_4 and N_2O from Table 10, we obtain R-744 equivalent amounts of CH_4 and N_2O as 283.10 and 1,912.55 gm/yr, respectively. Adding these values, we obtain the indirect equivalent warming impact of the R-744 system as (353.3559 + 0.2831 + 1.9126) x 10^3 = 355.6 kg/yr.

Adding the direct equivalent warming impact of 24 gm/yr from Table 6, we obtain the total equivalent warming impact of the R-744 system as 355.6 kg/yr. For ready reference, various results are collected in Table 12.

Table 12. Global Warming Impact of the R-744 Mobile Air Conditioning System

Green-house gas	GWP	Absolute amount, kg/yr	R-744 equivalent amount, kg/yr
Direct Impact			
R-744	1	0.0240	0.0240
Indirect Impact			
R-744 CH_4 N_2O	1 24.5 320	353.3559 0.0116 0.0060	353.3559 0.2831 1.9126
Total Impact			
R-744 + CH_4 + N_2O	-	355.4	355.6

RELATIVE WARMING IMPACT OF THE R-134A AND R-744 SYSTEMS

A perusal of Tables 11 and 12 provides an idea about the total equivalent warming impact of the R-134a and R-744 systems. For the sake of clarity, the global warming results relating to direct, indirect, and total equivalent warming impact are brought together in Table 13.

In order to place the total equivalent warming impact of the air conditioning systems in the context of the total equivalent warming impact of the entire gasoline-powered vehicle,

it is instructive to develop an estimate of the latter impact. To that end, it is noted that according to the U. S. Department of Energy, the total fuel consumption by the nationwide fleet comprising 170 million motor vehicles is 118.4 billion gallons per year so that on an average a motor vehicle in the USA consumes 696.5 gallons of fuel per year [72]. Since the total equivalent warming impact of one gallon of gasoline is 8.9 kg/yr, we find that the total equivalent warming impact of the entire vehicle is 8.9 x 696.5/23.5 = 6,215.2 kg/yr.

Table 13. Total Equivalent Warming Impact in kg/yr of the R-134a and R-744 Systems

Equivalent warming	R-134a system	R-744 system	Ratio
Direct	71.5	0.0	0.0
Indirect	209.7	355.6	1.7
Total	281.2	355.6	1.3

Using 6,215.2 kg/yr as base, we see in conjunction with the results in Table 13 that the total equivalent warming impact of the R-134a system is 100 x 281.2/6,215.2 = 4.5% of the total equivalent warming impact of the fuel consumed by the entire vehicle. Similarly, total equivalent warming impact of the R-744 system is 5.7% of the total equivalent warming impact of the fuel consumed by the entire vehicle.

It is also instructive to compare *en passant* the total equivalent warming impact of the recently supplanted R-12 system with that of the R-134a system. To that end, the indirect impact of the R-12 system can be taken as 209.7 kg/yr which is the same as that of the R-134a system (see Table 13). Furthermore, we note that without conservation and containment measures in place, the emission rate of R-12 was 345 gm/yr. Factoring in the GWP value of R-12 from Table 10, this translates to direct equivalent warming impact of 2,932.5 kg/yr. Adding the direct and indirect contributions, we see that total equivalent warming impact of the R-12 system was 3,142.2 kg/yr which amounted to 100 x 2,932.5/6,215.2 = 50.6% of the total equivalent warming impact of the fuel consumed by the entire vehicle. Thus introduction of R-134a has greatly ameliorated the global warming impact of the mobile air conditioning system.

FACTORS GOVERNING GLOBAL WARMING

As a prelude to the sensitivity analysis, it is instructive to derive an analytical expression comprehending various factors governing the global warming impact. To that end, we note that the total equivalent warming impact (TEWI) is the sum of the direct equivalent warming impact (DEWI) due to refrigerant emission, indirect equivalent warming impact due to air conditioning system mass ($IEWI_m$), and indirect equivalent warming impact due to air conditioning system operation ($IEWI_o$).

DEWI is the product of two factors, *viz.*, refrigerant global warming potential (GWP) and refrigerant emission rate (m_{ref}). Likewise, $IEWI_m$ is the product of three factors, *viz.*, volumetric fuel consumption rate to carry unit mass year round (f), equivalent warming impact of unit volume of fuel (e), and air conditioning system mass (m_{sys}). As inferred from the rule of thumb, alluded to above, that 10 gallons of fuel is required per year for each additional 100 lb_m (45.36 kg) of vehicle mass, f = 10/45.36 = 0.22 gallon/kg (*loc. cit.* p. 17). The equivalent warming impact of one gallon of gasoline has already been established as e = 8.9 kg/yr and so is the mass of the air conditioning systems as m_{sys} = 13.6 kg for the R-134a and 20.4 kg for the R-744 system (*vide* pp. 17 *et seq.*).

As regards $IEWI_o$, it is expressible as $IEWI_o = \kappa \dot{q}_{sys}$ where κ [(kg/yr)/(Btu/min)] is the constant of proportionality and $\dot{q}_{sys}$ (Btu/min) is the power consumption by the air conditioning system. $\dot{q}_{sys}$ is expressible in terms of comfort cooling capacity $\dot{q}_{cool}$ (Btu/min) as $\dot{q}_{cool}/COP_{sys}$ where COP_{sys} is the coefficient of performance of the system. Thus $IEWI_o = \kappa \dot{q}_{cool}/COP_{sys}$. In order to find κ, we use the previously reported results for the R-744 system that $IEWI_o$ = 35.3 x 8.9 = 314.2 kg/yr corresponding to a weighted average $\dot{q}_{cool}$ = 358 Btu/min and COP_{sys} = 0.94. These values lead to κ = 0.83 (kg/yr)/(Btu/min). The same value of κ is obtained by using the previously reported results for the R-134a system, *viz.*, $IEWI_o$ = 20.5 x 8.9 = 182.9 kg/yr, $\dot{q}_{cool}$ = 358 Btu/min, and COP_{sys} = 1.61. Physically, κ represents the indirect equivalent warming impact of the unit cooling capacity system.

Taking into account the foregoing contributions, TEWI is expressible as follows in terms of refrigerant global warming potential

(GWP), refrigerant emission rate (m_{ref}), volumetric fuel consumption rate to carry unit mass year round (f), equivalent warming impact of unit volume of fuel (e), system mass (m_{sys}), indirect equivalent warming impact of the unit cooling capacity system (κ), system cooling capacity ($\dot{q}_{cool}$), and system coefficient of performance (COP_{sys}).

$$TEWI = GWPm_{ref} + fem_{sys} + \frac{\kappa \dot{q}_{cool}}{COP_{sys}} \quad (26)$$

This relation is used in performing the sensitivity analysis through appropriate variation of m_{ref}, COP_{sys}, m_{sys}, and $\dot{q}_{cool}$.

EFFECT OF R-134a EMISSION ON TEWI

It is apparent from the foregoing calculations that TEWI of the R-134a system is a strong function of the R-134a emission rate while TEWI of the R-744 system is quite insensitive to the R-744 emission rate. To explore the sensitivity of TEWI to m_{ref}, we assign a series of values to m_{ref} for the R-134a system while keeping all other factors in Eq. (26) fixed. The calculated results are reported in Table 14.

Table 14. Effect of R-134a Emission Rate on Total Equivalent Warming Impact

	TEWI, kg/yr		
m_{134} gm/yr	R-134a system	R-744 system	TEWI ratio
0	211	356	0.59
55	283	356	0.79
110	354	356	0.99
165	426	356	1.20

These results show that if the R-134a emission rate could be reduced to zero, TEWI of the R-134a system would be only 59% of the TEWI of the R-744 system. At the R-134a emission rate of 110 gm/yr, TEWI of the R-134a system just about matches TEWI of the R-744 system while at the R-134a emission rate of 165 gm/yr, TEWI of the R-134a system is 20% more than TEWI of the R-744 system.

EFFECT OF R-134a SYSTEM COP ON TEWI

As noted above, the baseline R-134a system selected for the purpose of the foregoing analysis is unoptimized whereas the R-744 system is optimized. COP_{sys} of the optimized R-134a system will be higher than the value of 1.61 used in the foregoing analysis. To explore the sensitivity of TEWI to COP_{sys}, we assign a series of values to COP_{sys} for the R-134a while keeping all other factors in Eq. (26) fixed. The calculated results are reported in Table 15.

Table 15. Effect of the R-134a System COP on Total Equivalent Warming Impact

	TEWI, kg/yr		
R-134a COP_{sys}	R-134a system	R-744 system	TEWI ratio
1.0	395	356	1.11
1.5	296	356	0.83
2.0	247	356	0.69
2.5	217	356	0.61
3.0	197	356	0.55

These results show that there is considerable scope for reducing TEWI of the R-134a system *vis-a-vis* TEWI of the R-744 system even with modest improvement in the R-134a COP_{sys} through realizable optimization (*loc. cit.* p. 9).

EFFECT OF R-744 SYSTEM MASS ON TEWI

In the foregoing analysis, the mass of the R-744 system was estimated to be 20.4 kg compared to 13.6 kg for the R-134a system. Since the actual mass of the R-744 system has not been definitely established, it is desirable to perform a sensitivity analysis by varying m_{sys} for the R-744 system. This is done in Table 16 with the aid of Eq. (26). The tabular results show that the effect of change in the R-744 system mass is minor.

Table 16. Effect of the R-744 System Mass on Total Equivalent Warming Impact

	TEWI, kg/yr		
R-744 m_{sys}, kg	R-134a system	R-744 system	TEWI ratio
13.6	283	343	0.83
15.0	283	346	0.82
17.5	283	350	0.81
20.0	283	355	0.80
22.5	283	360	0.79

EFFECT OF COOLING CAPACITY ON TEWI

The preceding global warming impact calculations were performed at the standard design point. It is desirable to obtain an idea as to how TEWI varies with the comfort cooling capacity since in practice the air conditioning system operates over a range of the evaporator loads.

In order to calculate TEWI from Eq. (26) for a variable q_{cool}, a knowledge of the corresponding COP_{sys} is essential. The results in Tables 2 and 4 show that there is no definite trend for the variation of COP_{sys} with q_{cool}. Therefore, for the purpose of the present calculation, the average values of COP_{sys} from Table 4, *viz.*, COP_{sys} = 1.46 for the R-134a system and 1.02 for the R-744 system will be used as a *modus vivendi.*

Varying q_{cool} with the above-mentioned values of COP_{sys} and using the same values of GWP, m_{ref}, f, e, and m_{sys} as before in Eq. (26), we obtain the results in Table 17. The tabular results show that at low q_{cool}, TEWI of the R-744 system is lower than that of the R-134a system. However, over the normal operating range of the mobile air conditioning systems (200 to 400 Btu/min), TEWI of the R-134a system is just about equal to or lower than that of the R-744 system.

Table 17. Effect of Comfort Cooling Capacity on Total Equivalent Warming Impact

	TEWI, kg/yr		
q_{cool}, Btu/min	R-134a system	R-744 system	TEWI ratio
100	155	121	1.28
200	212	203	1.04
300	269	284	0.95
400	326	365	0.89
500	382	447	0.85

CONCLUSIONS

Several substantiated conclusions, drawn from the foregoing review of the historical facts, system performance, heat exchanger characteristics, compressor characteristics, and global warming impact analysis, are stated below.

1. There is undeniable historical evidence suggesting that the *locus standi* of the high pressure R-744 system against the low pressure R-134a system is tenuous. At one time (1890 to 1930), R-744 was the preferred refrigerant for vapor compression machines for refrigeration and air conditioning. However, with the proliferation (starting in 1930) of the chlorofluorocarbon refrigerants, R-744 rapidly disappeared from service. On account of its lower COP and higher operating pressure, it could not compete with the chlorofluorocarbon refrigerants notably R-12. Since the COP and operating pressures of the R-134a system are similar to those of the R-12 system, it is reasonable to expect that the R-744 system is unlikely to compete with the R-134a system on these counts.

2. The R-744 system is receiving a great deal of attention due to the fact that it is a natural refrigerant and its direct global warming impact (due to direct release into the atmosphere) is negligible compared to that of the R-134a system. However, its indirect global warming impact (due to fuel consumption by the system) is 70% more than that of the R-134a system. This counterbalancing effect renders its total equivalent warming impact (direct + indirect) 30% more than that of the R-134a system.

3. The total equivalent warming impact (TEWI) of the present day R-134a mobile air conditioning system is no more than 4.5% of TEWI of the fuel consumed by the entire vehicle. This represents a dramatic improvement over TEWI of the recently supplanted R-12 system which was 50.4% of TEWI of the fuel consumed by the entire vehicle.

4. The fuel consumption by the R-744 system is 39.8 gallons/yr compared to 23.5 gallons/yr for the R-134a system. Thus introduction of R-744 would exacerbate the fuel usage at a time when the car makers around the world are striving hard to improve the fuel economy of their vehicles.

5. In the present analysis, an unoptimized R-134a system was used as a base and its performance was compared with an optimized R-744 system. The COP of the optimized R-744 system turns out to be 0.92 times the COP of the baseline R-134a system under idling and 0.54 times the COP of the baseline R-134a system under down-the-road conditions. The higher indirect and *ipso facto* total equivalent warming impact of the R-744 system is directly attributable to its lower COP. The optimization

of the R-134a system would render the outlook for the R-744 system even gloomier. A measure of the degree of optimization of the system is the ratio of the actual compressor discharge pressure to the idealized compressor discharge pressure. For a fully optimized system, this ratio is unity. For the R-744 system the ratio has the values of 1.06 and 1.17 under idling and down-the-road conditions, respectively. The corresponding values for the baseline R-134a system are 2.16 and 2.04 which attest to the extent of as yet unrealized optimization possible with the R-134a system.

6. The operating pressure of the R-744 system is significantly higher than that of the baseline R-134a system. Under idling conditions, the suction and discharge pressures of the R-744 are respectively 10.6 and 5.3 times the corresponding pressures of the baseline R-134a system. Likewise under down-the-road conditions, the suction and discharge pressures of the R-744 system are respectively 11.8 and 6.2 times the corresponding pressures of the baseline R-134a system. Aside from safety concerns, the high operating pressures pose refrigerant containment problems which are particularly accentuated in a mobile system. For this reason, the high pressure R-744 system is apt to be costlier than the low pressure R-134a system.

7. Combination of the transport properties including density, isobaric specific heat, dynamic viscosity, and thermal conductivity favors R-744 over R-134a as far as overall heat transfer rate, pressure drop, and compressor efficiency are concerned. However, these benefits are outweighed by the unfavorable thermodynamic characteristics of R-744 including temperature, pressure, and enthalpy change.

8. TEWI of the R-134a system is a strong function of the emission rate of R-134a while TEWI of the R-744 system is quite insensitive to the emission rate of R-744. If the R-134a emission rate could be reduced to zero, TEWI of the R-134a system would be only 59% of the TEWI of the R-744 system. At the R-134a emission rate of 110 gm/yr, TEWI of the R-134a system just about matches TEWI of the R-744 system while at the R-134a emission rate of 165 gm/yr, TEWI of the R-134a system is 20% more than TEWI of the R-744 system.

9. There is considerable scope for reducing TEWI of the R-134a system *vis-a-vis* TEWI of the R-744 system even with modest improvement in the R-134a COP through realizable optimization. For example, with a COP of 3.00 (attainable through optimization) instead of 1.61, TEWI of the enhanced R-134a system is 55% compared to 79% of TEWI of the optimized R-744 system.

10. The mass of the R-744 system has not been definitely established although there is no gainsaying the fact that it would be more than that of the R-134a system due to higher operating pressure. The sensitivity analysis shows that TEWI of the R-744 system is a weak function of its mass.

11. The effect of a decrease in the comfort cooling capacity is to lower TEWI of the R-744 system compared to TEWI of the R-134a system. However, over the typical operating range of the mobile air conditioning system (200 to 400 Btu/min), TEWI of the R-744 system is just about equal to higher than that of the R-134a system.

Taking due cognizance of the foregoing findings, it is concluded that it would be imprudent to enact the proposal to replace the R-134a system by the R-744 system since upon closer scrutiny the R-744 system is found to consume more fuel and is environmentally less benign. Moreover, being a higher pressure system, it poses significant safety and containment problems *inter alia*. Instead of investing in the R-744 system, our time and resources would be more judiciously spent in continuing to minimize emissions of R-134a from the present system or in exploring some other system that unreservedly could offer a net environmental benefit over the present system.

ACKNOWLEDGEMENT

Throughout the course of preparation of this paper the author has had numerous stimulating discussions with James A. Baker of Delphi Harrison Thermal Systems, General Motors Corporation. The author is appreciative of his useful input and constructive criticism which contributed in no small measure to the value of the paper.

Numerical Simulation of the Flow in a Passenger Compartment and Evaluation of the Thermal Comfort of the Occupants

Joachim Currle
Mercedes-Benz AG

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The present study shows how the application of computational fluid dynamics can help to understand and optimize the flow field in a passenger compartment in order to achieve an optimum of thermal comfort for the occupants.

The flow field and temperature distribution in a passenger compartment have been calculated using the commercial CFD program STAR-CD. In combination with a thermophysiological model for the passengers, the computational results are used to evaluate the thermal comfort of the occupants and compare different geometrical modifications. The computational mesh consisting of around 3 millions hexahedra cells resolves all geometrical details of the car cabin including the air ducts, air nozzles and louvers. Natural convection, heat conduction and radiation are taken into account. One standard climatisation mode, the winter heat-up mode has been simulated. A special emphasis of the numerical investigations is the optimization of the ventilation of the front and rear legroom.

INTRODUCTION

Comfort aspects of passenger cars are a significant sales argument and have become a topic of rising importance during the development process of a new car. One important comfort aspect is the thermal comfort of the driver and other occupants, which is not only a question of comfortable and stress-free driving, but also a question of safety, because a freezing or sweating driver has a reduced concentration for traffic.

The microclimate is established by the heating, ventilation and air-conditioning system of the car (HVAC-system). Cool or warm air is distributed in the air distribution chamber of the HVAC-system to several air ducts, through which the air is directed to the vents located at different regions in the passenger compartment. Apart from the thermal comfort, the HVAC-system has to fulfill other tasks like e.g. optimal defrosting and defogging of the windows. Moreover the reduction of pressure drop and noise in the different components of the HVAC-system is a critical issue in order to achieve maximum overall performance of the whole system.

All these aspects have to be considered during the development of a new car. In the last decades, most of the investigations have been done experimentally by road testing or in wind tunnel facilities and other test rigs. Only recently, a new development tool has gained increased interest, namely computational fluid dynamics (CFD). Several authors have applied numerical flow simulation successfully for the optimization of different components of the HVAC-system [1-5]. Also the flow in the passenger compartment has been calculated by different authors [6-8]. On the other hand, computer programs have been developed to estimate the thermal state of the passengers and to predict the thermal comfort [9-11].

In the present paper, the numerical simulation of the local flow and temperature field in the passenger compartment using the general purpose CFD-code STAR-CD is coupled with an in-house program called TIM [9] to evaluate the thermal comfort of occupants. The paper is based upon extensive investigations with respect to the accuracy of the numerical results [12,13]. The calculated flow and temperature field in an idealized passenger compartment showed good agreement with measurements, not only for the overall flow topology, but also for the local values.

DESCRIPTION OF THE NUMERICAL MODEL

The flow and temperature field in the passenger compartment and in the air ducts is calculated with STAR-CD. The basic conservation equations, namely the Navier-Stokes and the energy equations, are solved numerically using the finite volume technique as implemented in STAR-CD [14]. The turbulent nature of the flow is modeled by the standard k,ε-model with logarithmic law of the wall.

The computational mesh consisting of around 3 million cells (hexahedra) is shown in figure 1. The mesh includes the passenger compartment of a new

Mercedes with four occupants and the air ducts. At every duct, a homogeneous velocity distribution normal to the inlet area is prescribed. At the rear outlets, where the air is extracted from the compartment, an artificial duct extension was added (Fig. 1) to assure numerical convergence.

At the walls of the passenger compartment (windows, floor, roof, doors, dashboard etc.) the ambient temperature together with a heat resistance is used as a thermal boundary condition [14] to model the complete heat transfer to the environment. The specified heat resistance is the sum of the resistance for the heat conduction through the walls and the resistance for the convective and radiative heat transfer from the outer surface to the ambient air. The heat transfer at the inner surface of the wall comes up as a result of the calculation and has not to be specified.

The interchange of thermal radiation between solid surfaces is calculated using the so-called 'discrete beam' approach [14]. In this approach, the solid surfaces, which are assumed to be of the gray Lambert type, are subdivided into contiguous non-overlapping areas or 'patches'. The number and extend of the patches are problem dependent and has to be chosen so as to resolve adequately the surface geometry as well as the radiation flux variations. The incoming and leaving radiation is assumed to be constant in one patch. For the present application, the windscreen, the side windows, the pillars, the doors, the roof and the floor for example are one patch respectively. The 4 occupants are divided into 14 patches, which correspond to the segments used in TIM (see figure 2). The view factor between two patches, which is the fraction of the total radiation leaving one patch that is intercepted by the other, is computed with the help of discrete beams. Over the enclosing unit hemisphere, a user-specified number of equally distributed beams are emitted from the nominal center of each patch. Each beam is traced through the fluid until it intercepts an opposing patch, thus defining a pair that may undergo radiant interchange.

EVALUATION OF THERMAL COMFORT

For the evaluation of the thermal comfort of the occupants an in-house program called TIM (thermo-physiological model of passenger) is used in conjunction with STAR-CD.

TIM is a multi-layer model which allows the computation of the thermal state of any occupant under a given heat load. In the model, the human body is divided into 14 segments as shown in figure 2. All segments are connected with their neighbors through the central blood-vessel system. Each segment consists of 4 layers (core, muscle, fat and skin). Clothes are also taken into account. The computational model comprises the heat transport mechanisms of the body (passive system) and the thermophysiological regulation (active system). The heat loss through the skin could be calculated for each segment individually. A more detailed description of TIM is given in [9]. Results of the program are the skin temperature of the segments and the determination of the thermal comfort of the passenger by using suitable thermal comfort criteria. Apart from global comfort criteria like the predicted mean vote (PMV) [15] and the thermal sensation vote (TSV) [16], also local comfort criteria, like the local equivalent temperature of the segments [17] are implemented. The equivalent temperature is defined as the temperature of an ideal reference room with equal air and enclosure temperature, in which the passenger would emit the same heat as in the real situation under consideration. Because of the strongly inhomogeneous conditions in the passenger compartment, local comfort criteria instead of global ones are of great importance.

Both programs, TIM and STAR-CD are coupled together in an iteration loop. The convective and radiative heat load at the surface of the passengers, as calculated by STAR-CD, is the input for TIM, whereas the calculated temperature at the skin or at the clothes of the occupants, is used as an updated thermal boundary condition for STAR-CD. The iteration loop is shown in figure 3. At the beginning of the loop, a neutral thermal state for the occupants is specified. Normally, 3-5 iterations are sufficient to get a converged result.

RESULTS

The numerical calculations presented in this study refer to a typical winter heat-up situation. Only the steady state is considered so far. Several geometrical modifications for the air ducts have been investigated with regard to the thermal comfort of the passengers. Only two of them will be presented here to show the successful application of the above described numerical method. These two modifications are related to the evaluation of the ventilation of the front and rear legrooms.

Figure 4 shows the two air ducts underneath the dashboard (providing the ventilation of the frontal legrooms) as well as the center console air duct (providing the ventilation of the rear legrooms). In the numerical simulation, only these air ducts are supplied with warm air (60°C). The air mass flux is 100 kg/h for each air duct. The ambient air temperature for the simulation was -20°C and the car is assumed to drive at constant speed of 100 km/h. An air-guiding element is contained in each of the two air duct underneath the dashboard (Fig. 4). The air duct at the driver's side shows three outlets, whereas the air duct at the passenger side has only two (Fig. 4). This corresponds to two different design stages, i.e., by comparing the computational results for the left and right side of the compartment, the two different design stages can be evaluated and compared with each other.

The numerical computation provides a large amount of results. At every cell center of the computational mesh (around 3 millions) values for the three velocity components, pressure, turbulence quantities, density

and temperature are available. Temperature distribution, convective and radiant heat fluxes at solid surfaces (i.e. walls of the compartment, seats and occupants) are also part of the computational results. On the one hand, these results can be used to get a very detailed insight into the local flow and temperature field in the compartment, especially in the proximity of the passengers. Cold or warm air streams at different parts of the body could be traced back to their origin. On the other hand, averaged values like averaged heat fluxes or temperatures for different components (e.g. roof, floor) or certain fluid volumes (e.g. driver's legroom, head region at driver's side) can be derived from the results and used as easy criterias for the comparison of different geometrical modifications during the development process. In the following figures and tables, a brief overview will be given about how the numerical results could be exploited in that sense and how they can be used for practical purposes.

In figure 5, two selected section plots for the velocity field are shown. The section x=390mm clearly shows the air jets coming out of the air outlets in the ducts underneath the dashboard. The third air outlet at the driver's side strongly reduces the amount of air flowing through the outlet in the middle. The section z=200mm gives insight into the ventilation of the rear legroom. The air is guided by 7 louvers at each side and is directed towards the inner foot of the rear passengers.

Figure 6 shows the temperature distribution at the two sections x=390mm and y=-335mm (seat center plane of driver's side). The typical temperature distribution versus the height of the compartment, i.e. higher temperature in the bottom regions and lower temperature in the top regions, is represented in figure 6b.

Very revealing with regard to thermal comfort aspects (see explanations for figure 9) are plots showing the temperature distribution in the vicinity of the occupants (Fig. 7).

The distribution of temperature and convective heat flux is shown in figure 8 for the inner surface of the floor and could be investigated in the same manner for every interesting solid surface. Note, that the negative values for the convective heat flux in figure 8b imply, that the fluid looses heat at the floor. The high negative heat fluxes at the floor of the frontal legrooms lead to a strong cooling of the warm air on its way to the rear.

Table 1 shows averaged values for temperature, convective heat flux and thermal radiation for a selection of solid surfaces.

Concerning the evaluation of the thermal comfort, it has proved reasonable to represent the results of TIM, in diagrams as shown in figure 9 [18]. For every occupant, the local equivalent temperatures for the 14 segments of TIM are plotted together with two borderlines. On top of each diagram, the same is done for the global equivalence temperature. The two borderlines determine the limits, in between 80% of the people will feel comfortable according to the PMV-index of Fanger. Those parts of the body, having local equivalence temperatures outside of the borderlines, reveal, that the ventilation doesn't perform well in this area and should be improved.

Comparing the diagrams for the driver and the passenger clearly shows, that the three outlets in the air duct underneath the dashboard at the driver's side results in better comfort values for the lower parts of the bodies (upper legs, lower legs, feet). The warm left foot of the passenger in figure 9 is also indicated in figure 7. Looking at figure 5a, it can be concluded, that too much warm air is directed towards this foot. The comparison of the top parts of the bodies doesn't appear reasonable, because the opening of the panel vents would change the situation at these parts.

The study of the diagrams for the rear occupants shows, that the ventilation of the rear legroom is far from being optimal, because the feet lying close to the center of the compartment, are experiencing the warm air jets coming out of the center console air duct, whereas the outer feet are to cold (see also figure 5b). Of course this observation is obvious without doing any simulation. Another fact is worth mentioning: The comfort values for the feet are not the same for the driver's and the passenger's side. This is mainly due to the different air flow coming from the frontal legrooms.

CONCLUSIONS

The present study has shown, how computational fluid dynamic can be applied for the evaluation of the thermal comfort of the passengers in car cabins. The computational results are able to give a detailed insight into the complex flow field in the passenger compartment and by this means increase the understanding of the flow physics. The numerical method has proved to be a powerful tool for a systematic comparison of different ventilation concepts and moreover, it allows a sophisticated optimization of different components of the HVAC-system with regard to the microclimate in the compartment and the thermal comfort of the occupants.

An optimal use of the method is believed to be in an early stage of the development process, where no prototypes are available. Thus, the number of

experimental tests as well as time and costs during the development process of new cars could be greatly reduced.

In the future, the method will be applied to a summer cool-down mode, in the course of which also solar radiation will be considered. First numerical tests have shown encouraging results. Moreover, the numerical calculation of the real transient behavior during a winter heat-up or a summer cool-down situation is planned for the near future, including the complete conjugate heat transfer problem.

Measurement of Rubber Elasticity and Correlation with Seal Life

Boris Dinzburg
Chicago Rawhide

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Two new methods will be presented to measure rubber and seal elasticity - Recovery from Bending (RFB) and Loss of Seal Interference (LOSI). It will be demonstrated, the kinetics of rubber elasticity change during immersion in oil with aeration and oil change for different rubber compounds as NBR, HNBR, ACM, AEM, FKM and VMQ. Using the kinetics of Recovery From Bending, the estimation of seal life can be done.

INTRODUCTION

To find a correlation between rubber properties of elastomeric radial lip seal life, it is necessary to know the sealing mechanism. In this case, it is possible to select rubber characteristics which are responsible for seal life and investigate how these properties change in the application environment. Currently, it is possible to formulate the basic seal properties which are responsible for seal life. One of the most important seal properties is seal lip **follow-ability**, or an ability of a seal to follow the shaft wobbling due to the eccentricity caused by Dynamic Run-out (DRO), Shaft-to-Bore Misalignment (STBM), or roughness of the shaft surface. The second factor is seal **pumping ability** - an ability of a seal to pump oil from the air side to the oil side. The third factor is **resistance to wear**, or more importantly, resistance to lubricated wear. A fourth factor is **resistance to swelling** in oil; and a fifth factor is the appearance of **defects at the contact point** during seal usage such as carbonization, blisters, cracks, stick-slip, etc. which are not due to the factors mentioned above. This presentation is dedicated to investigating the influence of rubber properties which are responsible for seal lip follow-ability as a main factor of seal leakage.

BACKGROUND

The first publication about the importance of seal follow-ability was done by Akaoka [1] in 1957. The experiment was conducted on a torque instrument to measure the influence of speed, torque, shaft eccentricity and spring force magnitude. He came to a conclusion that to maintain seal performance, no gap should be between the shaft surface and the seal lip. The material has to provide fast elastic recovery speed. According to Akaoka, the spring has no effect on wobbling action, in fact, a stiff spring has a negative effect.

Later, in 1977, Akaoka and Nitani [2] derived a mathematical model which includes seal parameters, rubber elasticity, and the gap between seal and shaft. They divided the seal into three elements; lip head, lip arm and spring. After simple calculations, they connected all three elements into one mathematical model. From their paper, it is not clear if the mathematical model fits with the experimental data, but the principal statement is correct, "...a gap occurs when the displacement velocity of the seal lip cannot follow the displacement velocity of the shaft." In 1982, Akaoka and Nitani [3] modified the instrument described in [2]. They changed the relative displacement magnitude and the displacement velocity measured by a strain gauge attached to the spring and recorded by an oscilloscope. Displacement of the seal lip was read from the film taken by an optical camera.

The final conclusion drawn from this very accurate experiment is that seal follow-ability is greatly affected by the viscoelastic characteristics of rubber material. The recovery is very fast and the material is quite elastic during the initial process of recovery. The recovery becomes quite slow in the viscoelastic area which takes a long time to recover. Elastic material properties are more effective for seal follow-ability than are viscous properties.

Theoretical and experimental descriptions of dynamic behavior of the seal lip were also made by Prati [4,5]. His experimental study was performed on a device with a static seal and a vibrator. The viscoelastic seal characteristics are determined by applying an oscillatory motion. The loss of contact is evidenced by optical fiber light passing through the narrow gap between the seal and the shaft. The passing light was visualized by a photo detector and oscilloscope.

According to Prati, the dynamic eccentricity produces the oscillatory motion of the seal lip. As the frequency is increased, the seal lip is unable to follow the radial shaft displacement and the lip lifts from the shaft and oscillatory clearance occurs between the seal lip and the

shaft. Horve [6], together with Prati, conducted experiments with seals made from compounds based on NBR, FKM and VMQ rubbers which illustrated the ability of Prati's device to measure seal follow-ability. Horve also made some calculations to fit the experimental data to the analytical models [7]. The conclusion was made that this method can be used to estimate seal follow-ability.

In 1989, Mims [8] created an optical device to measure the oscillatory clearance with rotational motion. The equation was derived which correlated the theory with the experiment. According to Mims, the stress relaxation or creep measurement has to be used to calculate the loss of follow-ability. The silicone compound demonstrated the best follow-ability.

The investigations described above (1-8) were conducted in dry conditions without confirming results of calculation and measurement with actual oil seal leakage. Also, these investigations did not take into account an interaction between oil and rubber.

According to Stakenborg [9], the clearance appearing between the shaft and the seal lip is influenced not only by the rubber viscous properties, but also by the viscoelastohydrodynamic effect of nonuniform fluid film which was created between the seal lip and the shaft.

In Russia, calculations were made to predict oil leakage through the oscillatory clearance when rubber elasticity or recovery was altered by changing the temperature [10]. The lower the temperature was, the lower was the elasticity and the recovery coefficient diminished. The oil leakage was calculated using the modified equation for fluid flow through the static clearance. Experimental data and calculations show a satisfactory correlation.

In spite of the complicated correlation, the experimental data fits very well with the theoretical prediction and provides an ability to use the coefficient of recovery for calculation of the temperature limit of seal leakage. It proves the theoretical statement of correlation between the rate of rubber recovery and the clearance between the seal lip and the shaft..

Works cited here represent only a small portion of the investigations performed in this area. Yet, they once more prove the importance of seal follow-ability or the ability of a seal to maintain a certain extent of elasticity during operational conditions and protecting against seal leakage.

This work tries to address the question of what kind of rubber properties are responsible for seal follow-ability, and what method should be used to measure the loss of elasticity.

There are many different methods for measuring seal elasticity. One of the most popular in the seal industry is to measure elongation change of s specimen during immersion in oil which to some extent represents elasticity, however this method did not show satisfactory correlation with seal life, even when aging times were from 1,000 to 2,000 hours.

A modification of this method was developed by Chicago Rawhide in which the kinetics of elongation loss is measured [11]. The empirical equation was derived which provides a satisfactory correlation of elongation change and seal life during rubber immersion in different oils, temperatures, and aging times.

$$\frac{E_0}{E_t} = \exp(b\,t^{1/2}) \qquad (1)$$

where E_0 = Initial ultimate elongation, %
E_t =Ultimate elongation after aging, %
b =Regression index
t =Aging time, hours

Using Equation (1), straight lines are obtained when ln (E_0/E_t) versus $t^{1/2}$ is plotted. The slope of such a straight line "b" characterizes the kinetics of aging. The Heat Resistance Index (HRI) was calculated as:

$$HRI-e = \frac{1}{b}\ x\ 10^{-1} \qquad (2)$$

This method has some shortcomings. First of all, Equation (1) does not provide good correlation for materials with high heat resistance like FKM and, in some cases, HNBR. For high heat resistance materials, the ultimate elongation did not change much during a long period of aging. Secondly, this method cannot be used for silicone, and sometimes for polyacrylic compounds due to an elongation increase during aging in oil. In spite of these shortcomings, this method is being successfully used to develop some new compounds with high heat resistance, and also to compare aggressiveness of different oil types.

The method of evaluating HRI using the elongation change utilizes the elongation at break. The value of ultimate elongation can reach very high levels, but in seal operating conditions, the deformation does not exceed 5 to 10%. Because the difference between "large" and "small" deformation of rubber is well known, a method was created to measure the stiffness change in bending at small deformation [12]. Using the kinetics of stiffness change, an HRI-s equation analogous to the equation for elongation change can be calculated. This method provides better correlation with seal life [13], but also has the same shortcomings as the method when ultimate elongation change was used. FKM, some HNBR compounds, and VMQ did not show visible change in stiffness.

All methods described above were static methods of measuring the change of rubber elasticity.

Bjork, Dickman and Stenberg from the Sweden Royal Institute of Technology [14], have undertaken a long term study to measure dynamic rubber properties and to correlate them with sealing performance. Cylindrical buttons of equal height and diameter were tested in air and oil for up to 1000 hours. The minimum and the maximum forces were recorded at different temperatures (up to 155°C), frequency (up to 32 Hz), amplitude (up to 10%) and pre-strain (up to 30%). Continuous and intermittent stress relaxation were measured to correlate with dynamic stress relaxation. The experimental results showed that

intermittent and continuous stress relaxation gives only an approximation of the dynamic stress relaxation. However, continuous and intermittent stress relaxation are important characteristics of dynamic seal life. The real seal life was not measured, but the method of dynamic stress relaxation could be very valuable for investigation of rubber properties change during immersion in oil. The experimental equipment required use of only 4 buttons for simultaneous testing and took a long time, up to 1000 hours which did not give a lot of advantages against a regular seal bench test.

EXPERIMENTAL

SAMPLE PREPARATION - The compounds were mixed in the laboratory internal K-1 mixer. The slabs were cured in an electrical press at 177±2°C (350 ±5°F) at t_{90}. The ACM, AEM, VMQ and FKM compounds were post cured according to a standard procedure.

Our first attempt was to measure the classic dynamic rubber characteristics and to determine how these characteristics would change during aging in hot oil. The results did not show much change of dynamic characteristics for the FKM compound when the compound was aged in the oil up to 1,500 hours [25].

Analyzing the dynamic properties change during aging in oil and the seal follow-ability phenomena, an assumption was made that the most important rubber characteristic is the process of rubber recovery. How it was demonstrated in the background section, this assumption is not new and has been investigated previously [7-8].

For this research, the effort was directed to measure not the stress, but the strain relaxation. It is necessary to remember that elasticity is an ability of rubber to sustain large deformation and to come back when the load is removed. The importance of strain relaxation for the seal follow-ability was proven by a special research project jointly made with the University of Akron [15].

Because the seal rotation speed is very high and can reach 8,000 rpm or 0.0075 seconds per one rotation, a special apparatus was designed and fabricated to measure recoverable strain after imposing a constant compressive strain on the rubber sample ("Restrain"). The apparatus can measure the relaxation of rubber button beginning from 0.0067 seconds when the external load was removed. The distance between the top rubber button and the planger head was measured by a Hall effect sensor. Recoverable strain (RS) of a rubber sample was calculated according to the following equation:

$$\epsilon = \frac{h_t - h_1}{h_o - h_1} = \frac{\Delta h}{\Delta h_o}. \quad (3)$$

where ϵ = recoverable strain,
h_t = current height of the sample during recovery,
h_1 = height of samples after 20% of compression,
h_o = initial height of sample.

Using the results of this investigation, some important conclusions can be reached. First, the recoverable strain for HNBR and even for FKM compound changed during aging rubber in air or in oil. Recoverable strain measurement is a lot more sensitive than elongation and stiffness change and dynamic stress relaxation. Second, the comparison of the recovery for FKM and HNBR rubbers did not show a big difference between results taken after 0.02 seconds of relaxation time and one hour, even though the relaxation times differ in a factor of 180,000 (Fig. 1).

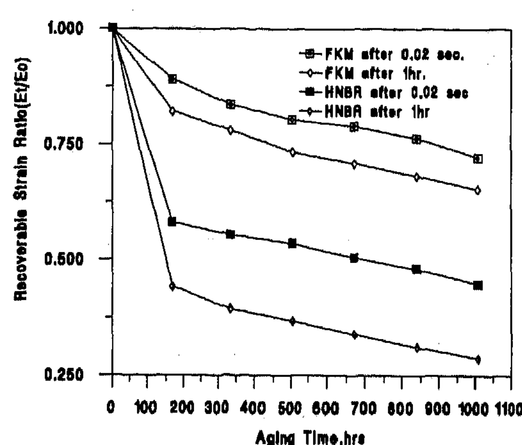

Fig. 1 - Comparison recovery after 0.02 seconds and 1 hour (3,600 seconds).

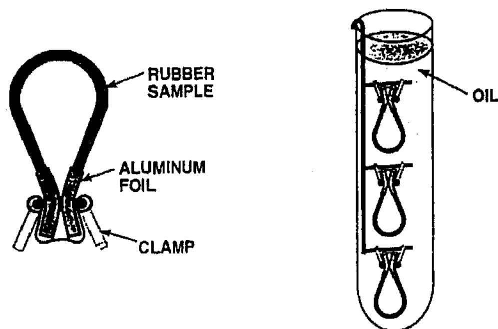
This experiment leads to the conclusion that for technical applications it is possible to compare different compounds after relaxation time or time of recovery longer than a fraction of a second, which does not require complicated instrumentation.



In the present paper, two new methods were introduced which are able to measure strain set deformation after "long" periods of time. One is "Recovery From Bending" (RFB) which can be done on rubber samples, and the second is "Loss of Seal Interference" (LOSI) which can be done on seals.

Bending deformation is the predominant type of deformation which is created in the flex section of the radial lip seal during shaft rotation. Resistance of rubber to bending deformation is one of the most important rubber properties which is responsible for seal elasticity or seal follow-ability. The principle of this method was taken from the SKF Engineering Research Center method of "Permanent Set Measurement".

RECOVERY FROM BENDING

PROCEDURE - A strip 100 mm long, 2 mm thick and 10 mm width was bent and clamped with paper clamps. The clamped sample is immersed in oil as shown in Fig. 2 at the required temperature.

RECOVERY FROM BENDING

MEASUREMENT AND CALCULATION

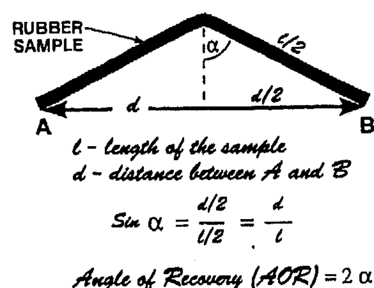


Fig. 2 - Scheme of procedure to measure Recovery From Bending (RFB).

After aging, the sample is cleaned and released from the clamp. After 15 minutes of recovery at ambient temperature, the distance between the end points of the sample are measured. The sample is then placed on the preheated metal plate and put in the preheated oven for 15 minutes at 212°F. After 15 minutes, the distance between the end points is measured while the plate is still hot.

Recovery From Bending (RFB) is calculated as the ratio:

$$R = \frac{l}{d} \tag{4}$$

where d = the distance between the end points of the sample,

l = the length of the sample after immersion in oil and recovery.

The 1/R also represents the sine of recoverable angle (α)

$$\frac{1}{R} = \sin\alpha \tag{5}$$

The Angle of Recovery is 2α. The complete recovery is 180°.

When the strip is bent, the stress is concentrated on the top of the loop. The FEA stress comparison on the RFB loop with the stress on the seal when the seal is installed on the shaft shows the good correlation.

It is very important that the recoverable angle is measured not at ambient temperature, but at the hot temperature which better represents the real temperature of seal usage. Table 1 demonstrates the difference between the recoverable angle measured at ambient temperature and at 212°F. For some seal compounds the difference in percentage of recovery is about two times.

Table 1
Comparison of the angle of recovery after bending for samples swelled at 168 hours at ambient temperature

Compound	After 15 minutes of recovery at ambient temperature		After additional heating at 212°F for 15 minutes	
	Angle of Recovery (°)	% Recovery	Angle of Recovery (°)	% Recovery
NBR	130.6	72.5	171.8	95.4
HNBR	93.5	51.9	171.8	95.4
ACM	124.6	69.2	168.4	93.5
VMQ	148.3	82.3	165.8	92.1
FKM	104.8	58.2	168.4	93.5

The measurement of the Recovery From Bending has an advantage in the accuracy with comparison to the measurement of elongation change after aging in oil.

The RFB demonstrates high reproducibility and less variation. The comparison of these two methods for HNBR after aging in oil for 70 hours at 302°F (ten samples were tested) shows that elongation has a variation coefficient of 12.7%, and the RFB is 1.7%. The absolute variation for elongation was 220% ±40% and for RFB the angle of recovery was 75 ± 2°.

All RFB tests were made after immersion in oil with a small amount of interrupted aeration (2 ml per min. and 3 hours on and 21 hours off) and oil change after 168 hours. The conditions of interrupted aeration was previously investigated and correlated with engine field conditions for passenger cars. The influence of aeration was published in [16, 17, 18].

INFLUENCE OF VOLUME SWELL - Volume swell is a very important rubber property which is responsible for seal life. Usually when the volume swell increases, the elongation diminished and, in a troubleshooting

situation, it is very difficult to determine the cause of seal leakage. A seal can leak due to rubber swell or loss of elasticity.

To verify the influence of volume swell on elasticity change, Recovery From Bending was measured. Three heat resistant compounds: FKM, VMQ and HNBR were tested at a relatively low temperature, 212°F for 70 hours to avoid aging. This condition normally does not change elongation, but is enough to reach maximum swell. Different oils were selected to reach various volume swell.

Test results for Recovery From Bending (Fig. 3) demonstrates that swelling in oil did not diminish rubber elasticity and did not reduce the seal lip follow-ability.

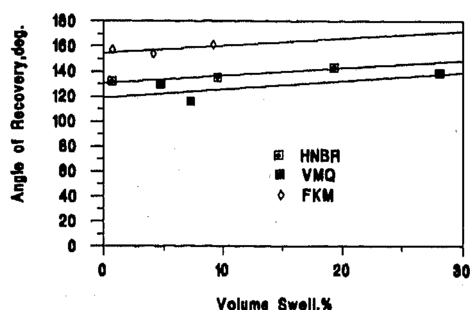

Fig. 3 - Influence of volume swell on Recovery From Bending.

This very important advantage of Recovery From Bending shows the ability to separate the cause of seal leakage due to loss of elasticity or volume swell. When a seal leaks and rubber has high volume swell but Recovery From Bending did not change, the conclusion could be reached that the cause of leakage was not the elasticity loss but different factors. For instance, high swell could deform the lip or change the radial load. This experiment could be used as an explanation for the reason why seals work properly in spite of high volume swell up to 30% because the seals do not lose their elasticity and proper seal design guarantees the necessary radial load and absence of lip deformation.

Fig. 4 shows the angle of recovery for nine tested compounds.

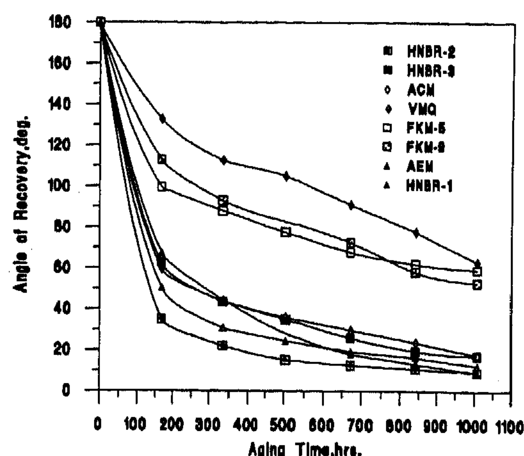

Fig. 4 - Angle of recovery after Recovery From Bending.

RFB is able to measure the change in elasticity for all tested compounds. The silicone compound has the higher elasticity, the FKM compounds are the second highest, the NBR are the lowest, and HNBR, ACM and AEM belong to the middle group. This statement is confirmed in Fig. 5 where the Heat Resistance Index from Recovery From Bending (HRI-r) is calculated using the equations (4) and (5) with replacement of the elongation on the rate of Recovery From Bending.

$$R = \exp(-bt^{\frac{1}{2}}) \qquad (6)$$

and

$$HRI\text{-}r = -\frac{1}{b} \qquad (7)$$

where R = Recovery From Bending,
t = Aging time, hours
b = Coefficient
HRI-r = Heat Resistance Index (calculated from the kinetics of Recovery From Bending).

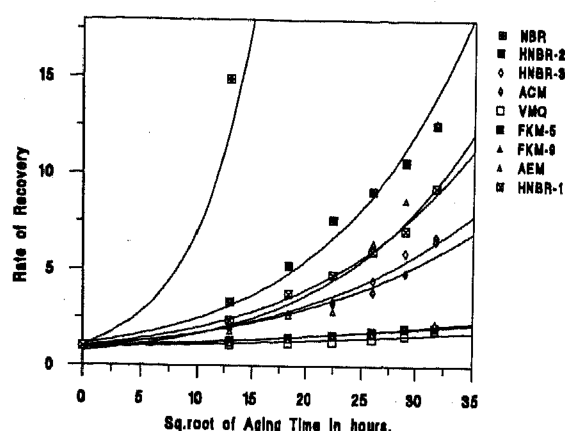

Fig. 5 -Kinetic of recovery change (with aeration and oil change).

The correlation coefficient for RFB is higher than the one for elongation change. The comparison of correlation coefficients for the Heat Resistance Index indexes is shown in Table 2.

Table 2

Comparison of the correlation coefficient for Heat Resistance Index, calculated from kinetic of elongation and Recovery from Bending change

Compound	Elongation	RFB
NBR	0.948	0.991
HNBR-2	0.915	0.987
HNBR-3	0.915	0.990
ACM	0.921	0.989
FKM-5	0.957	0.993
FKM-9	0.889	0.942
AEM	0.987	0.905
HNBR	0.871	0.997
VMQ	—	0.831

In the previous paper [25], the correlation was found between HRI-r, calculated from immersion test with aeration and without oil change, and seals tested in monograde oil SAE-30 at 275°F (135°C) and 2165 rpm. The aim of the present experiment is to find the correlation in more severe conditions using an immersion test with aeration and oil change.

To find a correlation between Recovery From Bending and seal life, 3" CRW seals were molded using the same compounds which were tested above. The seals were tested in the bench test machine with automatic speed and temperature controls. The following parameters were used:

1. Oil: SAE 10w30 multigrade oil (same oil used for immersion test)
2. Temperature: 302°F (150°C)
3. Oil Change: Every 168 hours
4. Speed: 3600 rpm
5. Conditions: First day - 1 hour at 0 rpm and ambient temperature, 9 hours at 1500 rpm, 10 hours at 3600 rpm, 4 hours at 0 rpm. Next days - 20 hours on and 4 hours off.
6. At least 6 seals were tested for each compound.
7. DRO: 0.010" (0.254mm) TIR
8. STBM: 0.010" (0.254mm) TIR

The seal test results and Heat Resistance Index, calculated from RFB are shown in Table 3.

Table 3

Compound	Characteristic Life		HRI-r
	Life, hours	Wiebull Slope	
NBR	90	3.1	5.3
HNBR-2	614	4.4	12.4
ACM	651	2.8	17.7
VMQ	1022	3.2	53.3
FKM-5	2969	3.6	44.0
FKM-9	3349	14.3	38.7
AEM	427	7.4	12.5
HNBR-1	690	11.0	14.4

Compound HNBR-3 was not tested because it was designed for reciprocating applications.

The correlation of HRI-r and seal life is shown in Fig. 6. The correlation coefficient is 0.948.

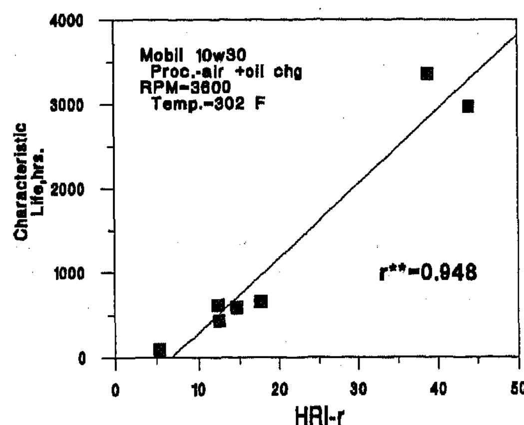

Fig. 6 - Correlation HRI-r with seal life.

This correlation coefficient was reached without excluding the silicone rubber compound VMQ because the failure mode for most of the silicone seals in test conditions was a breakdown in the flex cross-section area. An attempt to use the Seal Life Index (SLI) which was introduced in the previous publication [25] and is HRI-r divided by the Lubricated Wear Index (LWI) did not improve the situation. This experiment demonstrates that the SLI can be used only if the main cause of the leakage is loss of follow-ability and lubricated wear.

LOSS OF SEAL INTERFERENCE (LOSI)

Recovery From Bending provides an ability to test the rubber elasticity change for compounds immersed in different oils. It also helps to select the compound which works best in the required conditions for a given seal application. Seal follow-ability depends not only on rubber elasticity, and resistance of rubber to aging, but on other seal parameters as well.

It is well known that follow-ability changes when the radial load changes. Radial load could change due to a change in interference between the seal and the shaft, change of rubber stiffness or a spring size. To investigate the influence of the factors mentioned above, the Loss of Seal Interference method was designed. The principle of this method is to measure residual deformation after removing the seal from the shaft. The set of deformation indicates loss of elasticity in the same way as the rubber compression set and can be calculated using the following equation:

$$LOSI, \% = \frac{d_a - d_b}{d_m - d_b} \, x \, 100. \qquad (8)$$

where d_b = inside seal diameter before test
d_a = inside seal diameter after test
d_m = diameter of shaft or mandrel

The device used to measure LOSI is shown in Fig. 8. It consists of a holding fixture (Fig. 7A) and a metal container with oil which is installed on a heater with a magnetic stirrer (Fig. 7B).

Fig. 7 - Device used to measure the Loss of Seal Interference (LOSI).

Oil is aerated using a tank of compressed air. The aeration in this experiment was set up on the same oil degradation level as for the rubber immersion test in a glass test tube. Previously the aeration was established on the same level as in a passenger car engine under field conditions [17].

To process the test, the seals were put on the mandrel (Fig. 7A bottom) and inserted into the holding fixture. The holding fixture was dipped in the container of oil. Every 168 hours, the fixture was taken from the oil, the seals were taken off the mandrel and cleaned. The inside diameter and radial load were measured, and the seals were put back in the holding fixture and dipped in a container with fresh oil. The same nine compounds were tested which were described in the previous section. The test results are demonstrated in Figs. 8 and 9.

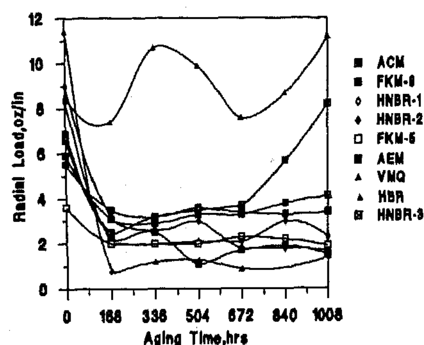

Fig. 8 - Radial load change after immersing seal on mandrel on LOSI device.

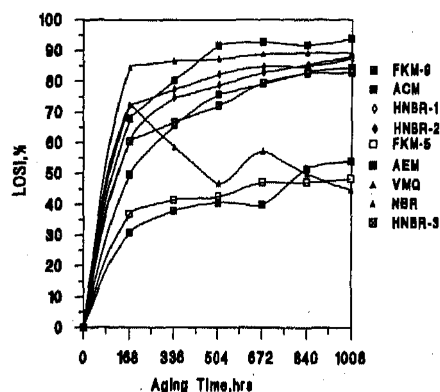

Fig. 9 - LOSI change after immersion in SAE 10w30 at 302°F (150°C) with aeration and oil change.

Fig. 8 shows that the radial load dropped dramatically after 168 hours of aging but did not change a lot for most compounds after that. Only the HNBR-1 compound after reduction of the radial load demonstrated an increase after 672 hours of aging. The NBR compound cannot be taken into account because the seals got hard and cracked at the used aging conditions. The Loss of Seal Interference (Fig. 9) demonstrates a much clearer picture. All seals have the same kinetics of LOSI change, the only exception is for the silicone compound.

The kinetics of LOSI change satisfactorily fits the following logarithmic equation:

$$L = a + b\, Ln\, (T^{1/2}) \qquad (9)$$

where L = LOSI, rate
T = aging time, hours
a,b = coefficients

The Heat Resistance Index from the kinetics of Loss of Seal Interference (HRI-i) can be calculated as:

$$HRI\text{-}i = \frac{1}{b} \qquad (10)$$

The HRI-i correlates well with the seal life (with correlation coefficient 0.984 (Fig. 10) which proves an ability to use the Loss of Seal Interference method not only for compound evaluation, but also to design and select optimum seal parameters.

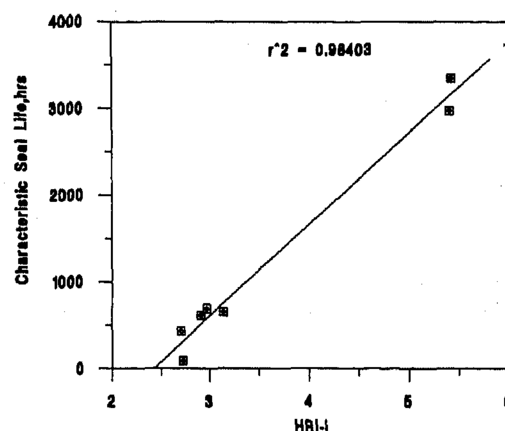

Fig. 10 - Correlation HRI-I with seal life.

The LOSI correlates also with Recovery From Bending (Fig. 11) which demonstrates the same character of elasticity change for slabs using RFB and seals using LOSI. It is necessary to point out that data obtained for the LOSI and RFB methods fit to one master curve with the exception of one AEM compound, although the AEM compound also shows satisfactory correlation RFB with LOSI.

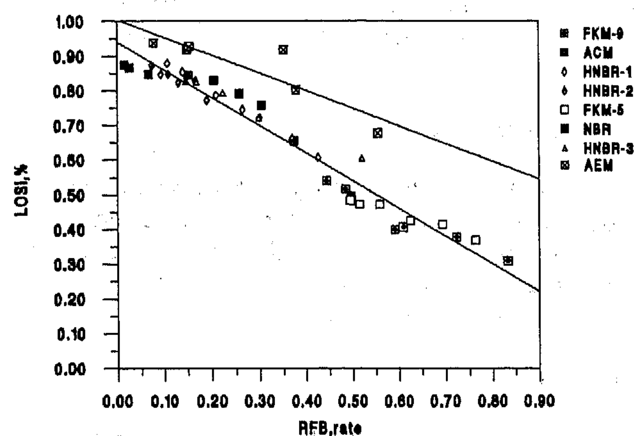

Fig. 11 - Recovery From Bending vs. Loss of Seal Interference.

DISCUSSION

The most important factors which are responsible for dynamic shaft seal life are seal design, type of elastomer compound, and testing conditions including type of oil, underlip temperature and shaft roughness. Even with the correct seal design and shaft roughness, the properties of the elastomer compound can provide the most valuable influence on seal life.

The elasticity of the elastomer compound provides the dynamic shaft seal with the ability to follow the shaft eccentricity and shaft roughness which is called follow-ability. Additional properties such as resistance to lubricated wear, resistance to swell in oil, resistance to create defects on the seal lip area like carbonization, etc., and pumping ability or the ability of the seal to pump oil from the air side to the oil side are the most important properties responsible for seal life.

In spite of many factors which influence the seal life, one of the most important is seal follow-ability. When rubber loses a certain amount of elasticity and the lip cannot follow the shaft, a gap is created between the lip and shaft, and this could be a cause of seal leakage. This raises a question of the size of the clearance causing seal leakage. According of Akoaka and Nitani [3], the occurrence of leakage is not determined by the gap alone. The leakage is affected by different internal and external parameters like oil pressure, viscosity and dynamic pressure. Shimoi [19] also demonstrated that it is possible to completely avoid seal leakage when a small gap occurs between the shaft and the lip, even if the oil viscosity is low.

This phenomena can be explained with pumping effect. If clearance is not very large, the oil could pump from the air side to the oil side and prevent seal leakage. The pumping effect was discovered by Jagger in 1957 [20]. Later, many investigations were conducted which introduced different theories. The historical reviews connected with the pumping mechanism are well known and broadly published [21 - 23].

Currently, it is well established that in most cases if a rubber lip seal is not able to pump oil from the air side to the oil side, the seal will instantly leak. Although there is no direct correlation between pumping rate or pump index with seal life, the pumping rate does improve service reliability [24]. The seal with high pumping ability could compensate the leakage which occurs due to the loss of elasticity or small rate of recovery.

In this paper, two methods are introduced that can provide the ability to select, create, or compare different compounds, and analyze the aggressiveness of oil and the seal design. The first method is Recovery From Bending (RFB) and the second is Loss of Seal Interference (LOSI). Using these two methods, it is possible to reduce the time for the seal bench testing and also to estimate the seal life. Fig. 12 shows a correlation of the Heat Resistance Index for different rubber compounds tested in different oils and different test conditions with seal life. One set of seals (#1) tested in SAE multigrade oil 10w30 at 302°F (150°C) and 3600 rpm with oil change every 168 hours (one week) (Fig. 2). The second set (#2) which was described in the previous paper [25] was tested in less aggressive conditions in monograde oil, SAE- 30 at 275°F (135°C) and 2165 rpm without oil change. The first curve fit into the equation:

$$Y = 544.1 + 87.6X \qquad r^2 = 0.959$$

The second fits into another equation

$$Y = 310.5 + 91.3X \qquad r^2 = 0.899$$

where Y = Seal life in hours
X = Heat Resistance Index calculated from kinetic of Recovery From Bending in suitable oil immersion test.

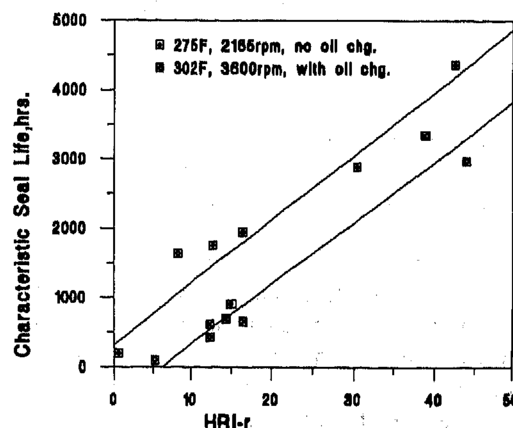

Fig. 12 - Correlation HRI-r with seal life.

Using an assumption that an average speed of a passenger car is about 35 miles per hour and the total mileage per year is about 12,000 miles, the following seal life prediction can be done:

Table 4
Estimation of Seal Life

Compound	Set #1 302°F, 3600 rpm, with oil change		
	HRI-r	Calculated Seal Life, Hrs	Seal Life Prediction, Yrs
NBR	5.3	-79	0
HNBR-2	12.4	542	1.6
ACM	16.3	883	2.6
FKM-5	44.0	3,310	9.7
FKM-9	38.8	2,854	8.3
AEM	12.5	551	1.6
HNBR-1	14.4	717	2.1
Compound	**Set #2 275°F, 2165 rpm, no oil change**		
	HRI-r	Calculated Seal Life, Hrs	Seal Life Prediction, Yrs
NBR	0.7	374	1.1
HNBR-2	8.3	1,068	3.1
ACM	16.3	1,799	5.2
FKM-5	42.5	4,190	12.2
FKM-9	30.4	3,086	9.0
AEM	15.0	1,680	4.9
HNBR-1	12.8	1,479	4.3

It is necessary to take into account that bench test conditions are very severe (20 hours on, 4 hours off). In real field conditions, an average passenger car runs no more than 1 to 2 hours per day and 22 - 23 hours in a static condition. In this case, the predicted seal life can be named as "minimum seal life in extreme conditions".

SUMMARY

Although the sealing mechanism is complicated and many factors can be the cause of seal leakage, one of the most important properties responsible for seal life is seal lip follow-ability. Follow-ability has a direct correlation with rubber elasticity - "the ability of rubber to sustain a large deformation without breaking and coming back to its original configuration when the deforming stress is removed." The Recovery from Bending and Loss of Seal Interference methods can be used to measure the change of elasticity during aging rubber or seals in oil. These methods, to a higher extent, reproduce the seal stress tension in the seal flex area; they do not require special equipment, provide high reproducibility and low variation, and finally, they are easy to use.

Recovery From Bending provides an ability to estimate the seal life and Loss of Seal Interference, to select the seal design, seal interference, spring size, and seal design.

ABSTRACT

System contamination caused by contaminates or small particles built-in, self-generated, or inhaled from environment presents severe problems. The problems include but are not limited to the malfunctioning of valves, pumps, seals and injectors or lock-up of these components; increased wear of bearings, piston rings, and other friction components; and degradated machine performance. In general, system contamination changes a deterministic system into a stochastic system and shortens machinery service life. In this paper, these contamination problems are discussed in categories and associated analysis, testing and computer modeling methodologies are also discussed.

INTRODUCTION

In the past decades, many researchers [1] [2] have studied contamination related machinery behavior and developed theories and analytical tools in the academic arena. Contamination analysis and control have received more and more attention in industry in recent years [3,4]. People nowadays have come to realize that system contamination caused by contaminants or small particles built-in, self-generated, or inhaled from environment presents severe problems. For example, lubricant contamination changes the requirement of lubricating film thickness and increases friction component wear rates; air, hydraulic or fuel delivery systems contamination causes valves to stick, pumps to leak, seals to break, and injectors to jam; and electronic system contamination causes circuit boards to short, hard disks to fail, information to be lost and systems to malfunction. In general, system contamination changes a deterministic system into a stochastic system and shortens machinery service life. However, contamination analysis, testing, modeling and simulation methodologies will help alleviate or find remedies for these problems. This will help manufacturer and users to:

- Design To Allowable Contamination Levels with Cost Justification
- Obtain Proper Design Parameters with Contamination Consideration
- Define Key Contamination Sensitive Parameters and Components
- Obtain Realistic Service Life Estimates in a Short Period of Time
- Achieve Targeted Service Life

CONTAMINATION ANALYSIS

CONTAMINATION SENSITIVITY DEFINITIONS—An ideal system without contamination may be described by the following formula:

$$Q(t) = F(x,p,t) \qquad (1)$$

where

- t - Generalized time
- x - Operational parameters
- p - Operational commands
- Q(t) - Desired performance index, which is a function of x, p, and t.
- F - Generic functions

When a system becomes contaminated, its operational parameters change into stochastic or random processes such that

$$Q_s(t) = F(x + \Delta x(t), p, t) \qquad (2)$$

where

- $\Delta x(t)$ - Contamination caused fluctuation of operational parameters
- $Q_s(t)$ - Performance index of the contaminated system

Since contamination causes uncertainty in the operational parameters, making them become stochastic processes, the system performance index, $Q_S(t)$, also becomes stochastic. This implies that the performance of contaminated systems is best judged by statistical measures, such as mean value and variance, rather than by more traditional instantaneous measures.

Accordingly, one can define

$$S_p = \frac{E[Q_s(t)] - Q(t)}{Q(t)} \qquad (3)$$

and

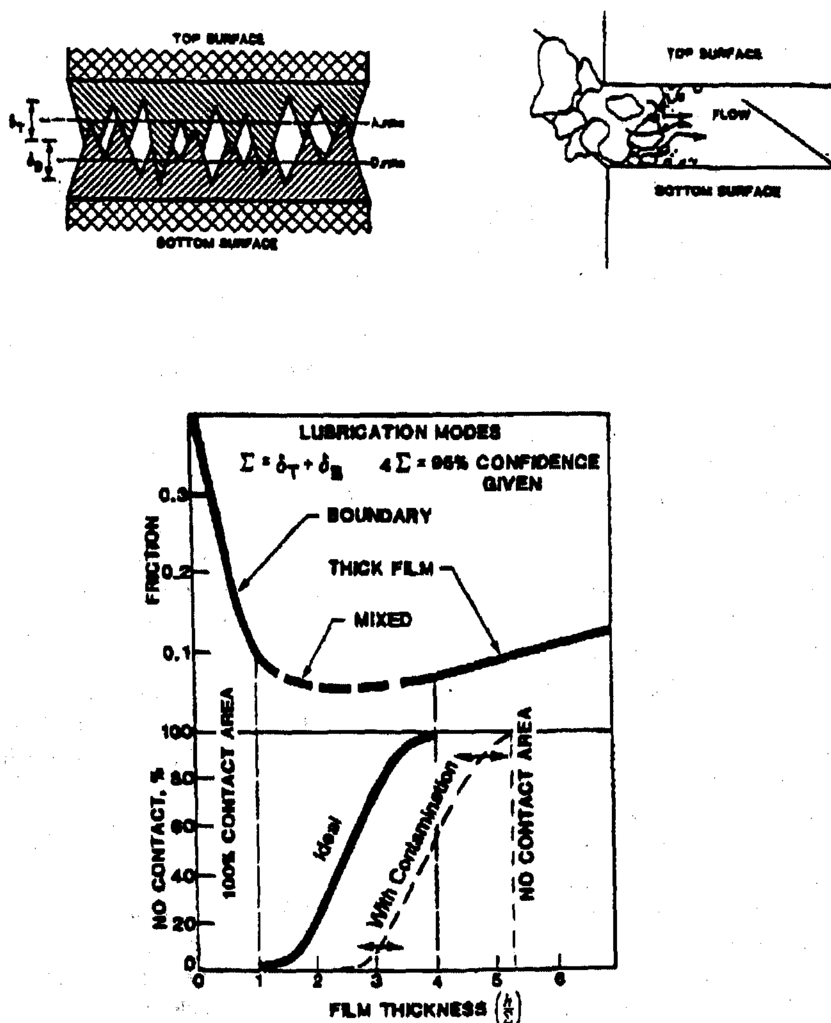
$$S_m = \frac{E[(Q_s(t) - Q(t))^2]}{Q^2(t)} \qquad (4)$$

as contamination sensitivity for performance degradation and contamination sensitivity for motion malfunction, respectfully, where E [ ] is the ensemble average of the referenced argument in the brackets. As shown later, specific contamination sensitivities may be evaluated using these formulas. For example, contamination caused bearing, piston ring, and pump performance degradation may be evaluated by formula (3), whereas, automatic transmission valve stick may be evaluated using formula (4). On average, over time, an old contaminated automatic transmission may have the same performance as that of a non-contaminated transmission and equation (3) may give an indication of zero sensitivity. However, at any specific time, no matter how hard one presses the accelerator pedal, it is likely to take a recognizable period of time for the contaminated transmission to shift gears. This difference will definitely show contamination sensitivity when equation (4) is used.

CONTAMINATION CAUSED FAILURE—Contamination caused mechanical failures in general fall into two categories, (a) cumulative performance degradation and (b) motion or functional failure. In the first category, failure occurs in a progressive manner, whereas in the latter, failure occurs often in an unexpected or dramatic form and does not follow an exact repetitive pattern.

Cumulative Performance Degradation—There are two commonly observed failure modes in this category:

a. *Tribological or Wear Failure.* One of the major causes of this failure is due to the fact that contamination in a lubricant changes the lubr-



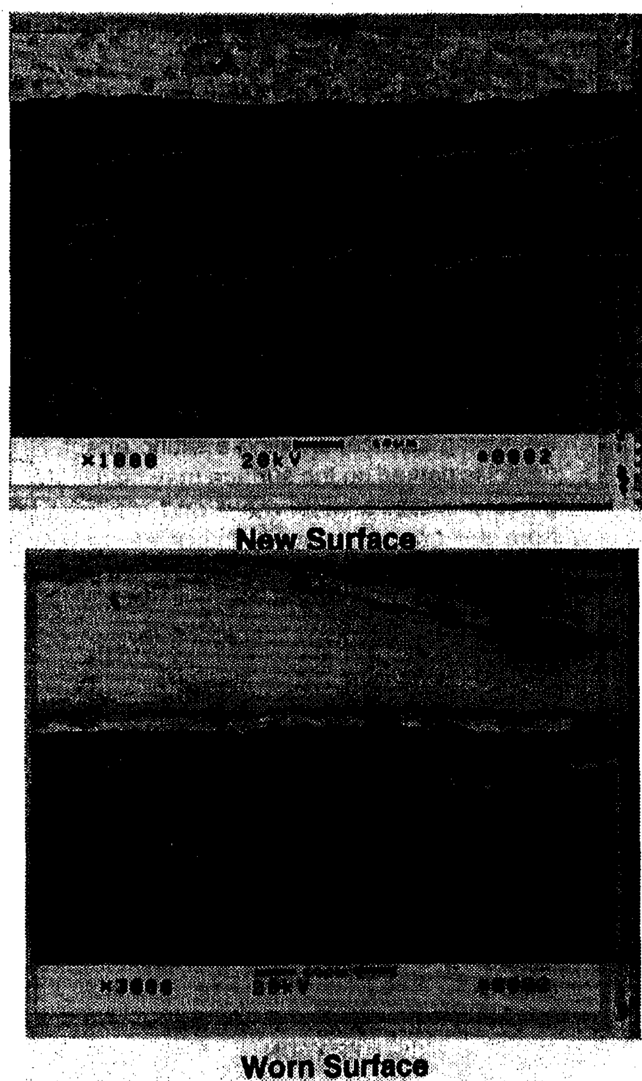


Fig 1. Contamination influence on film thickness

icating film thickness requirements. As shown in Figure 1, conventional lubrication film design uses the four sigma rule to achieve noncontact film thickness. This rule is based on the surface roughness of the contacting friction pair and assumes a statistical confidence level of 95%. Under ideal lubricant conditions, the required noncontact condition may be achieved by such a design. However, when contaminants come into play, the noncontact percentage boundary shown in this curve will shift and increased wear could occur. In addition, different surface treatments will, in general, either increase or decrease this wear process. Figure 2a shows a typical new wear surface and Figure 2b shows the same surface worn by contaminants.

b. *Premature Loading of Filtration System.* A filtration system is often designed to give a certain dust holding capacity when measured by some standard test dust, such as, AC and SAE Fine (FTD). System integrators often utilize this capacity value to design for a required service interval or in some cases, to design a filtration system that will last the whole system life span. These standard test dusts, however, may not represent local real-world dusts in terms of their geometrical shape, size distribution and density and their impact on dust loading [5]. The mismatch sometimes causes filters to load much quicker than expected, resulting in degradated system performance. Figure 3 shows a typical case in this category. The filter plugged in less than one third of its designed service life.

(b)

Fig 2. Typical wear surfaces

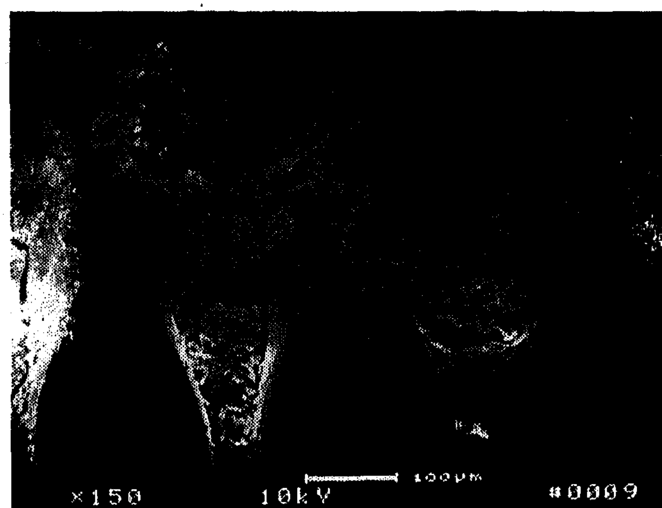

Fig 3. Filter premature loading up

Motion or Functional Failure—There are many different motion or functional failure modes caused by system contamination. While we will not list all these modes, we will list several typical, yet often overlooked motion failure modes in this section. These failure modes include, but are not limited to the following:

- Contaminant Lock
- Agglomeration
- Obliteration
- Hydraulic Lock
- Thermal Lock
- Magnetic Attraction

a. *Contaminant Lock.* Figure 4 shows three typical lock mechanisms caused by moving contaminants in the flow stream. These are known as static force locking, shear force locking, and dynamical force locking. Static force locking refers to the situation where a particle, having nominal size close to the clearance size, comes to the edge of the gap. Due to the sudden changes in pressure upstream and down stream of the particle, it is pushed into the gap causing a jamming effect. Shear force locking

Static Force Locking   Shearing Force Locking

$F = (P_1 - P_2)A_{particle}$ $F = (P_1 - P_2)A_{piston}$

$F \alpha MV^2$

Dynamic Force Locking

Fig 4. Three basic contaminant locking mechanisms

occurs when a moving spool is about to change from one position to another and a particle, having a larger nominal size than the clearance, comes to the middle of the closing gap, keeping the gap from closing because of the particle high shear strength. The dynamic force locking mechanism refers to the phenomenon exhibited by a group of small particles, having a nominal size generally smaller than the clearance, that behave like gas molecules in Brownian motion between the spool and the bore. Here, the pounding force of these small particles causes excessive dragging, which prevents the spool from moving from one direction to another.

b. *Agglomeration.* A very interesting real-world phenomenon is that many filters are designed to have specific nominal cut off sizes, yet contaminants in the passing stream are known to have size distributions below these levels. Intuitively, people think that contaminants or small particles below the cut off size will not be caught by the filter. However, in reality, these filters are often plugged by these fine particles. Why? One answer is agglomeration. Some filter pores are designed in such a way that when the flow stream, carrying the contaminants, passes through the pore, it has to split or splash, changing its flow direction many times before it passes completely through the filter. This repetitive re-direction strengthens the motion behavior of the carried particles in two aspects. First, it makes the dynamic size of the particles become much larger than their physical size. Second, it increases the chances that small particles will collide with larger particles. With the facilitation of some binding agents in the fluid and particle surface properties, many of these particles stick to each other after colliding. As this particle

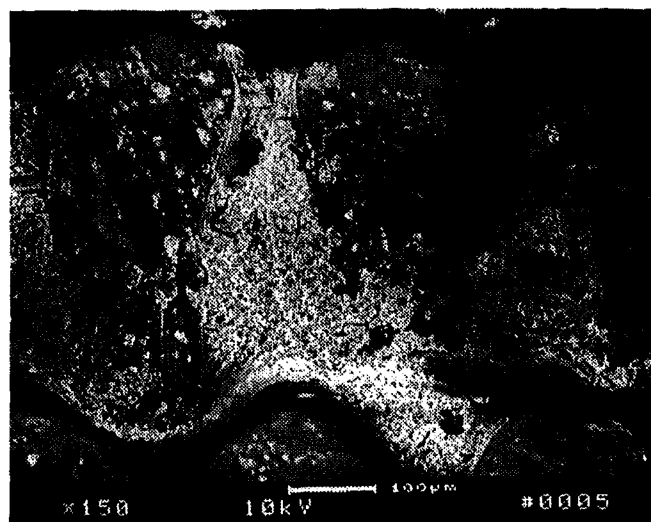

Fig 5. Typical field particle agglomeration pattern

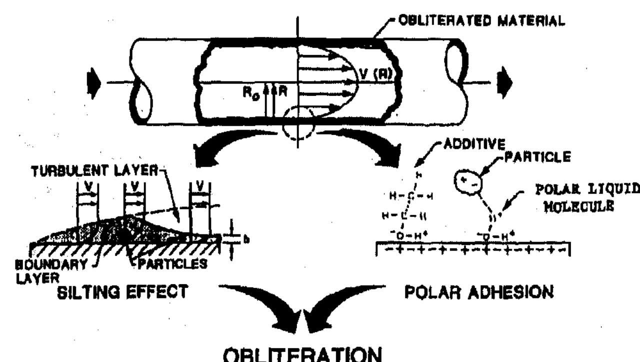
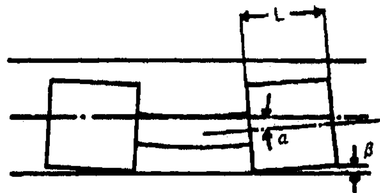
"sticking" process grows, the cluster of particles become larger and larger, finally plugging the openings of the filter. This whole process is called agglomeration. Figure 5 shows a typical agglomeration pattern on a filter removed from field service. In this particular case, the filter had a nominal pore opening size of 70 microns, yet many particles agglomerated on the filter originally had a nominal size of around 5 microns.

c. *Obliteration.* Obliteration is the combined effect of particle silting and polar particle adhesion, as shown in Figure 6. Due to the low boundary layer velocity profile, particles getting to the layer cannot be carried by the flow and start to move towards the tubing surface, creating a silting effect. Some particles parked on the surface may have electrical polarity, which attracts more and more particles from the boundary layer. This leads to a silting surface, with the help of molecular adhesion forces. In some severe situations, obliteration blocks the incoming flow completely, causing system failure.





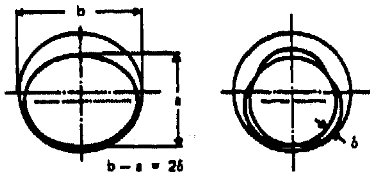


Fig 6. Obliteration working principle

d. *Hydraulic Lock.* Hydraulic moving parts may lock up by unbalanced hydraulic forces. This type of locking has the same apparent look as contaminant locking. Consequently, it often misleads people into using better filters to remove more contaminants (to get the system as clean as possible) at higher cost. However, in practice, even with super clean fluid, the locking phenomenon still occurs. Figure 7 gives the illustration. In virtually any manufacturing process, component dimensions are machined with certain tolerance. It is this tolerance that makes a spool valve have some tapered shape or two adjacent lands not to line up. As flow passes through these tolerance gaps, unbalanced forces create a static locking force or torque which eventually locks up the moving component. Fortunately, this problem often occurs in the product development stage and can be solved with a better design strategy.

(a) Hydraulic Lock from a Curved Axis Spool.

(b) Hydraulic Lock from an Out-Of-Round Spool-Bore Assembly.

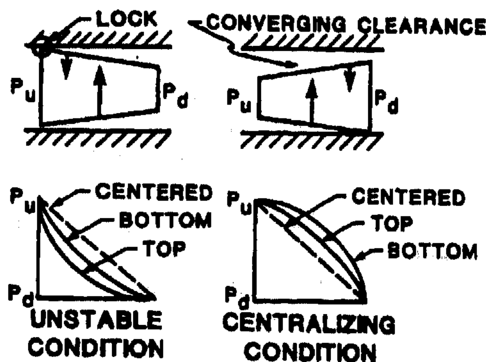

Fig 7. Typical hydraulic locking types

e. *Thermal Lock.* When a system has no or little contamination, moving parts, such as spool valves, work properly even if they experience a thermal cyclic environment. However, when a system is contaminated, particles landed in the gap area will seize the moving parts as clearances are reduced by thermal expansion effects. This phenomenon can become especially severe when two relative moving parts are made from different materials, such as when the bore is made of aluminum and the spool is made of steel. This implies that when a system is known to have to work in a high/low temperature environment, it is important to consider the combined effects of thermal expansion and contamination during the design process.

f. *Magnetic Attraction.* Many hydraulic actuators have electrical or electronic driving devices. These devices generate magnetic fields which will attract ferrous particles, such as iron particles. The attracted particles migrate to the gaps between the moving parts as the electromagnetic devices energize or deenergize. Solenoid valves are typical examples of these types of devices. As particles are attracted into the valves, the armature will seize up.

The above listed failure modes may mutually influence each other. For example, magnetic attraction associated with thermal expansion may produce very serious contamination locking problems. Obliteration and agglomeration may choke system flow, degrading system performance. However, for a particular system, experience shows that one or two key contamination failure modes will typically dominate. As long as these key failure modes are overcome, systems contamination problems will generally be under control.

CONTAMINATION SENSITIVITY ANALYSIS— Contamination sensitivity analysis is a very important step toward achieving total system contamination control and should be considered in all the stages of machine development and usage, i.e. contamination sensitivity analysis should be performed when a machine is

- In the design stage
- In the prototyping stage and
- In operating working condition

With respect to the machine development stage, the corresponding contamination analysis approaches are applicable:

- Preventive design analysis
- Product development analysis
- Contamination diagnostic analysis

Preventive design contamination analysis refers to contamination analysis performed on machines which are undergoing design. For instance, many systems have some components which are likely to have potential

contamination problems. Designers at this stage should select proper filtration systems to protect these components. If possible, designers may build mathematical models to simulate different component arrangements to evaluate the system's anti-contamination performance in virtual reality. In cases where computer modeling and simulations are too complicated, designer may use established databases to assist the analysis.

Product development contamination analysis refers to situations where prototype products have already been manufactured and their contamination sensitivity is to be investigated. At this stage, contamination sensitivity of the prototype products can be evaluated using certain specified or standardized contamination sensitivity test procedures. Although test procedures may differ from each other, they have the following aspects in common:

a. They all vary contamination concentration levels or size distributions from light or small to heavy or large.
b. They all use specific contaminants or standard test dusts such as SAE Fine Test Dust.

Through contamination sensitivity testing, product contamination sensitivity can be defined in terms of contamination concentration levels and particle size distributions. As long as system contamination concentration levels are controlled below the concentration level given by the sensitivity test, and the size distribution is also controlled within the sensitivity test's specified range, the system is not likely to experience contamination problems.

In many cases, knowing the contamination sensitivity of a product is not enough. People want to know how long the product will last under normal working conditions, and whether its real life span will meet the required design life or not. A direct approach to answering these questions is to operate a representative group of the product under its working condition for an extended period until all stop working. However, with today's heavy competition among manufacturers, and with constraints of cost effectiveness, this approach may not be the best among all possibilities. Instead, the accelerated life testing method may be used to investigate longevity problems of a product. In performing accelerated life testing, special attention must be given to both the chemical composition and concentration level of the contaminate so that the failure mode induced during testing will truly represent the field failure mode. Otherwise, accelerated life testing may not produce meaningful results.

Contamination diagnostic analysis refers to the situation where a real system has failed to work properly during field operation due to contamination problems. However, the failure mode is not known. Conducting a diagnostic contamination failure mode analysis on all possible causes, especially on those mentioned in the earlier sections of this paper, will usually show that one or two failure modes dominate. Once these dominant modes are found, the following steps can be used to confirm and remedy them. To confirm a field failure mode in general means to reproduce the failure mode under controlled laboratory conditions. This requires reproduction of the contaminants that caused the field failure and the utilization of these reproduced stimulants in conducting laboratory testing. As soon as the field failure modes are reproduced through laboratory testing , the confirming process is finished. The remaining step is to find a solution which solves the problem.

Figure 8 summarizes contamination sensitivity analysis in a generalized flow chart. As indicated in this chart, in order to achieve targeted longevity, contamination analysis should be conducted alternatively between components and systems in all design, prototyping and field operation stages, utilizing methodologies such as contamination sensitivity testing, accelerated life testing, failure mode analysis and reproducing, and mathematic modeling and computer simulations. In the following section, some case studies are presented.

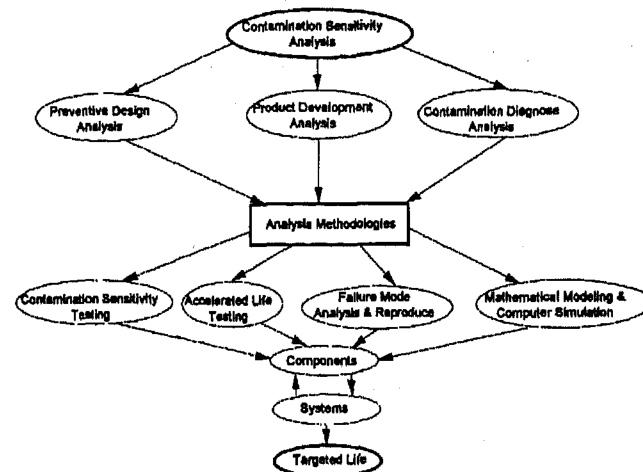

Fig 8. Contamination sensitivity analysis flow chart

CONTAMINATION ANALYSIS CASE STUDY— Contamination sensitivity analysis may best be illustrated through case study examples. In this section, seven specially selected case studies are presented to show the importance and benefit of contamination sensitivity analysis. These cases are listed as follows:

- Dust Ingression Contamination Study
- Lube Oil Additive Sensitivity Study
- Shift Valve Contamination Lock Study
- System Failure Mode Diagnosis
- Contamination Sensitivity Experiment Study
- Accelerated Life Testing
- Contamination Mathematical Modeling and Computer Simulation

Case 1. Dust Ingression Contamination Study. The objective of this study was to investigate contamination sensitivity of engine piston rings upon exposure to two

different dust cuts inhaled through the engine air intake [6]. The engine used in this study was a 5.9 liter, six cylinder, turbocharged industrial-type engine. The engine was operated at 2500 rpm, full load, for about 260 minutes. The first dust cut, a 2-4 µm dust fractionated from AC Fine dust, was then injected into the intake air stream at a concentration of 0.27 mg/ft^3 air, while the engine was operating at the above noted test condition. After 30 minutes dust injection was stopped. When engine operating time reached 350 minutes, a second dust cut, 4-10 µm dust, was injected into the air intake with the same dust concentration level. Again, dust injection was stopped at the end of 30 minutes, while the engine operated under the same profile for another 60 minutes. Ring wear was measured in real-time throughout testing, using two calibrated radioactive isotope tracers, Fe-59 and Cr-51. Figures 9 and 10 show the experimental results. Fig. 9 shows cumulative total ring wear, chrome wear and the chrome to total wear ratio. Places where different dust cuts were turned on and off are also shown. Fig. 10 shows the wear rates for the total ring wear and chrome wear. The curves in Fig. 10 are calculated from the derivatives of the cumulative wear curves shown in Fig. 9. Using formula (3), one may easily calculate the contamination sensitivity values for these two different dust cuts as follows:

Total Wear Sensitivity:

$$S_{T,\ 2\text{-}4\mu} = \frac{\Delta Q_{T,2\text{-}4\mu}}{Q_T} = \frac{25}{13} = 1.92$$

$$S_{T,\ 4\text{-}10\mu} = \frac{\Delta Q_{T,4\text{-}10\mu}}{Q_T} = \frac{52}{13} = 4.00$$

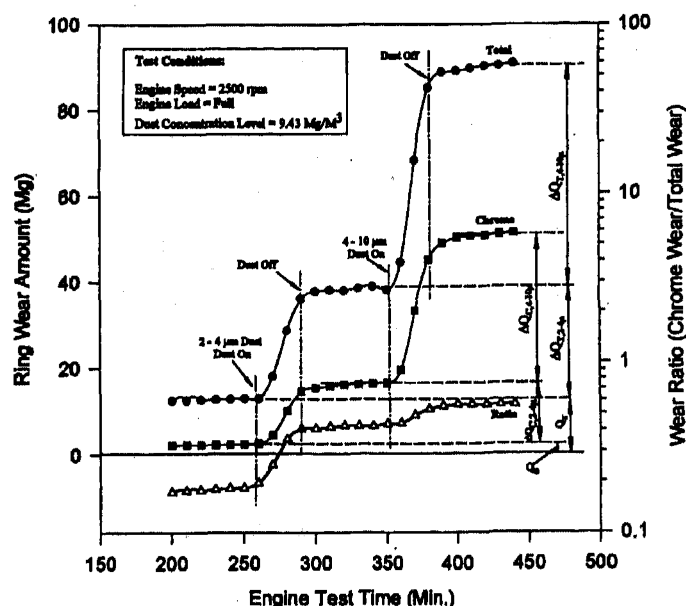

Fig 9. Dust ingression test - cumulative wear & wear ratio

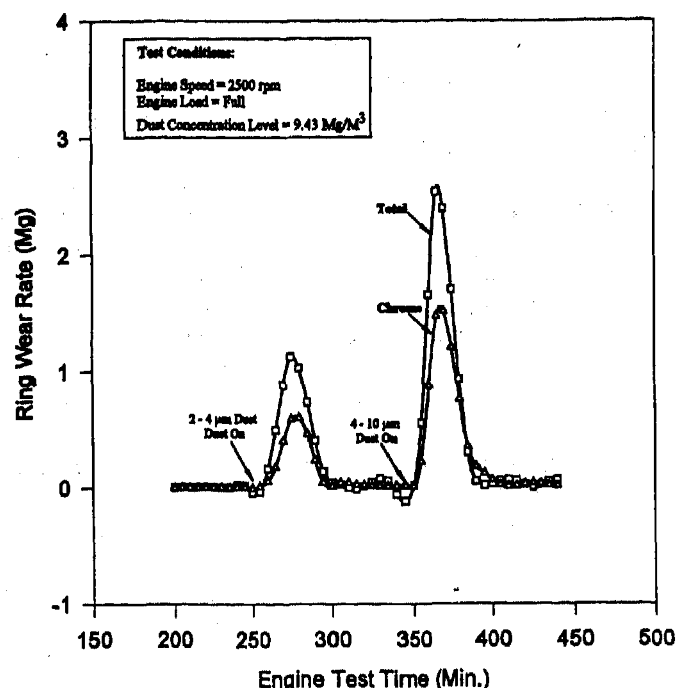

Fig 10. Dust ingression test - ring wear rate

Chrome Wear Sensitivity

$$S_{c,\ 2-4\mu} = 5.96$$

$$S_{c,\ 4-10\mu} = 14.78$$

Examining the results, one may conclude that for this particular engine:

a. Ring wear is more sensitive to the dust cut of 4-10 µm than to a cut of 2-4 µm,
b. The wear ratio increases as the dust cut changes from zero to 2-4 µm and then to 4-10 µm. Since chrome coating is concentrated in the top ring, this ratio increase implies that top ring wear is very sensitive to dust ingression.
c. Ring wear rate changes dramatically as dust turns on and off. The peak wear rate with 4-10 µm dust is more than twice as high as that of the 2-4 µm dust.

This case study shows how important a good air filter is to protect an engine from dust ingression.

Case 2 - Lube Oil Additive Sensitivity Study. Each year chemists from different petrochemical companies develop varieties of different additive packages to improve certain lubricating properties of fuel and lubricants. What is the effectiveness of these packages? People often run bench tests to answer this question. Due to the undefined correlation between bench testing and field operation interpretation of the bench test results can be difficult and

sometimes misleading. However, treating additives as specially formulated contaminants and utilizing radioactive tracer real-time wear measurement techniques, one can perform contamination sensitivity analysis to screen different fuels, lubricants and additive packages and to show their effectiveness with respect to actual engine operation. Figure 11 shows sensitivity analysis results of four different lubricant additives on engine wear. All tests were performed using a four cylinder 2.3 liter engine. The major wear trending curve in this figure is obtained through alternatively testing a reference oil between groups of additives. Each point along this curve represents cumulative wear at the end of an identical four-hour engine test. A representative history of the four-hour test is given in Fig 12. The insert in Fig. 11 shows the sensitivity analysis results calculated using equation (3). Here, one can easily see that additive I is better than additive IV. However, casually comparing the wear data along the wear curve, one may reach the opposite conclusion, since the amount of wear for additive I is higher than that of additive IV. Fig 12 shows the influence of ambient cold start, speed, and load on the wear. In fact, contamination sensitivity analysis can be performed on every point along the histogram curve to examine a variety of properties of additive packages, such as:

- Additive Sensitivity to Cold/Hot Start
- Additive Sensitivity to Speed Change
- Additive Sensitivity to Load Change
- Additive Sensitivity to Steady State/Dynamic Operations (for instance, Urban/Highway Driving Cycles)
- Additive Sensitivity to Lubricant Carry-Over-Effects

These and many other properties are very important to the success of good lubricants. The methodologies given in this case study may offer an effective, time and cost savings approach to the evaluation of fuels, lubricants, and fuel and lubricant additive packages.

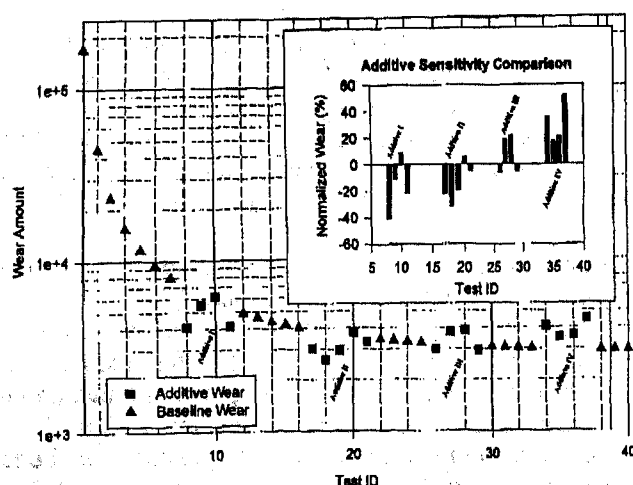

Fig 11. Lube oil additive sensitivity test results

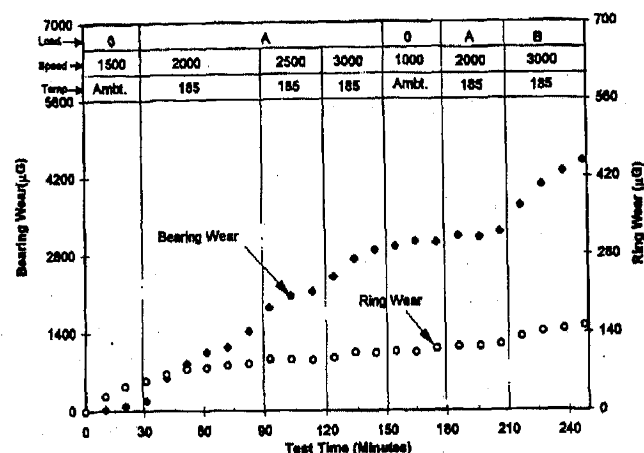

Fig 12. Individual wear measurement histogram

Case 3 - Shift Valve Contamination Lock Study. The objective of this study was to investigate the contamination impact on spool valve shift response time. As shown in Fig. 13, a spring loaded spool shift valve configuration was selected for this study. During the experimental study, two different tolerance groups were used. One group had minimum tolerance, the other had maximum tolerance. The valves were first tested under clean fluid (less than 5 mg/L) conditions, and then with fluid contaminated with 0-200 μm dust at a concentration of 250 mg/L. During each test, the valve spool was pressurized and depressurized, with identical dwell time intervals and the valve response time was measured. Figures 14 and 15 show typical experiment

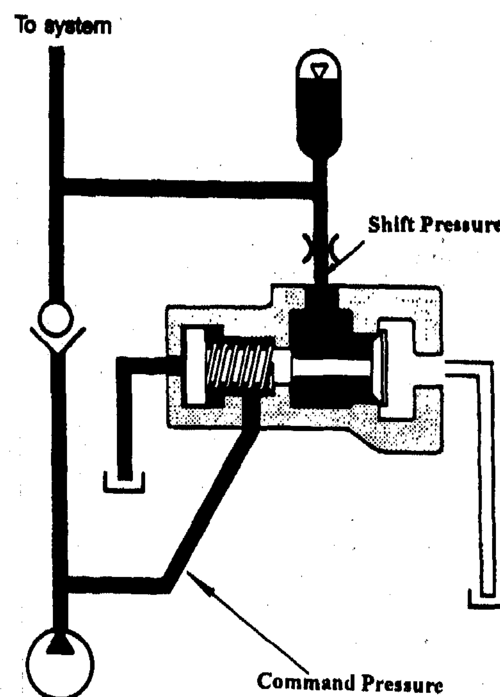

Fig 13. Shift valve contamination lock study

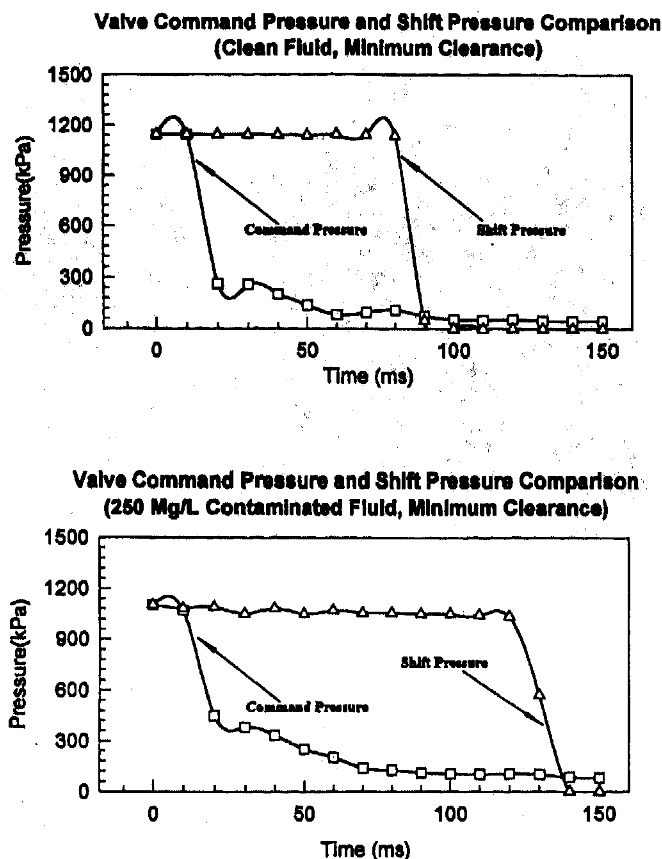

Fig 14. Valve shift pressure signals of minimum clearance

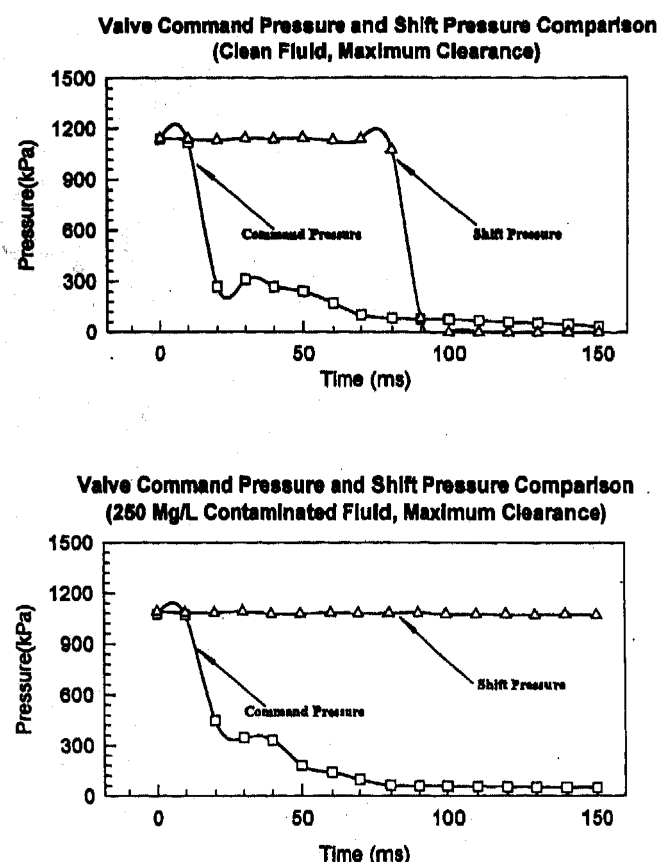

Fig 15. Valve shift pressure signals of maximum clearance

results for valves with minimum and maximum clearance, respectively. For this particular valve assembly, one may conclude that:

a. Under clean fluid conditions, both minimum and maximum clearance valves have similar response time.
b. Under the specified contaminated fluid conditions, both minimum and maximum clearance valves experience some contamination sensitivity, and valves with maximum clearance are more sensitive than valves with minimum clearance.

Valves with minimum clearance shifted within the specified duration time (150 ms) under dirty fluid conditions, while valves with maximum clearance did not shift or "lock up" throughout the specified time duration. In practice, lock-up may not be permanent; the valves may eventually shift, but with a much longer response time. Hydraulic valves, pneumatic valves, and automatic transmission valve bodies will experience similar conditions as shown in this case study. A typical example is that one can definitely feel the "gear jumping phenomenon" when he operates a vehicle with an old or contaminated automatic transmission. Each year there is much transmission warranty repair due to valve sticking has caused by fluid contamination. However, this problem can be solved through contamination sensitivity analysis in the design and prototyping stages.

Case 4 - System Failure Mode Diagnosis. A liquid transfer system was designed to last at least 2000 hours. However, the system stopped working properly at less than one third of its designed life. This system is a two-stage pumping system. The first stage pump has a 30 micron nominal depth media inlet filter and the second stage pump has a 70 micron nominal reversed Dutch weave screen inlet filter. Preliminary investigation indicated that the first stage was normal and that the second stage pump was in good condition. Logic indicated that the second stage inlet filter was the cause of the problems. A SEM photograph of this filter (Fig. 16) confirmed that the screen's filter pores were plugged. This raised an interesting question, namely, why didn't the first stage filter, which has much smaller pores, plug instead of the second stage inlet filter, which has larger nominal pores? It was suspected the particle agglomeration caused the problem. To confirm this as the failure mode, two different experiments were conducted. The first experiment introduced standard Arizona Fine Test Dust directly into the second stage filter. This generated a system malfunction which seemed to mimic that caused in the field. However, further study of SEM photographs of the contaminated filter (see Figure 17) showed that the lab failure did not, in fact, mimic the field failure. A second experiment was conducted using a mix of contaminant simulants which were constituted from field

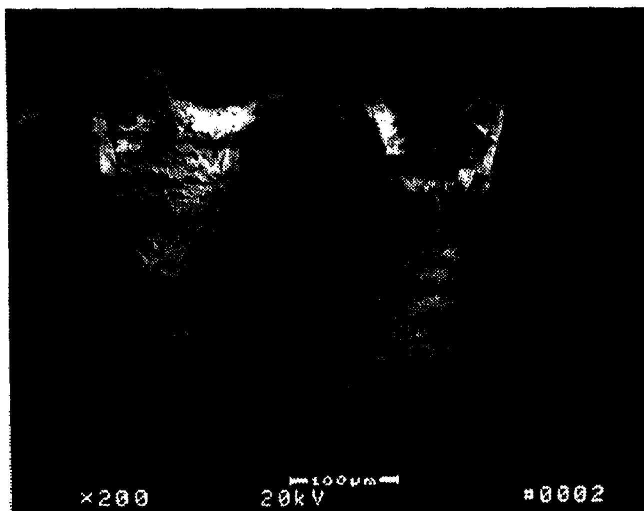

Fig 16. Field failure mode

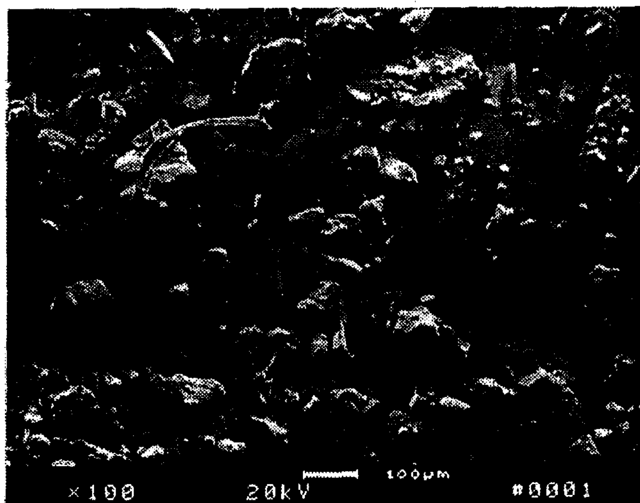

Fig 17. Simulated failure mode usling AC FINE test dust

contaminants. This contaminant mix was introduced to the first stage, with a calculated acceleration dosage to simulate true field operations. This generated a system malfunction which looked like those being experienced in the field. SEM photomicrographs of the second stage inlet filter (see Fig. 18) strongly resembled SEMs of the field filter shown in Fig. 16. These experiments confirmed that agglomeration of the fine particles was the main plugging mechanism, not dust loading.

Case 5 - Contamination Sensitivity Experimental Study. The objective of this study was to investigate the contamination handling ability for a group of turbine pumps. These pumps were installed in a test reservoir, in which the test fluid was circulated with proper speed and agitation to maintain certain level of suspended contaminants that were specifically formulated to simulate field operations.

Fig 18. Simulated failure mode using specially formulated field contaminants

Throughout testing, contamination concentration levels were checked and adjusted at specified time intervals to compensate for particles lost in the test pump assemblies. These pumps were tested for 65 hours and the results are shown in Fig. 19. The predicted data band, estimated average flow rate trend and its predicted band with 95% confidence level are also shown. Using Least Squares Curve fitting technique, one may obtain the flow trending formula:

$$Q = Q_o - Kqt$$

or

$$\frac{Q}{Q_o} = 1 - \frac{Kqt}{Q_o}$$

This formula characterizes contamination caused flow degradation, which is very important for both manufacturers and users. For manufacturers, this formula may be utilized to design pump contamination tolerance. For users, it may be used to evaluate different suppliers and to determine proper pump service intervals.

Case 6 - Accelerated Life Testing. Accelerated Life Testing is a very effective test method to predict system service life in a relatively short period of time. There are three commonly used approaches. The most frequently used is the so called S-N curve approach, which requires several contamination (stress) levels, from high to low, to stress the test articles to failure at each level in order to produce a representative S-N curve, as shown in Fig. 20. Article life is estimated by extending the low stress portions of the S-N curve. A second approach is a two-level contamination stress test to establish a high stress life vs.

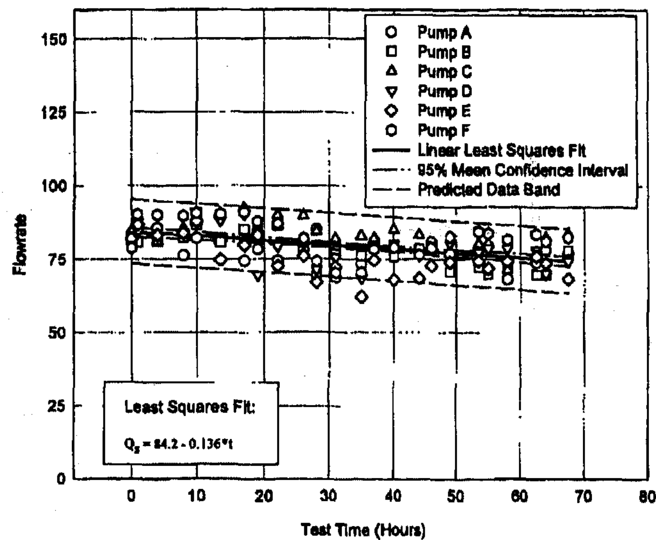

Fig 19. Contamination sensitivity experiment study - test results

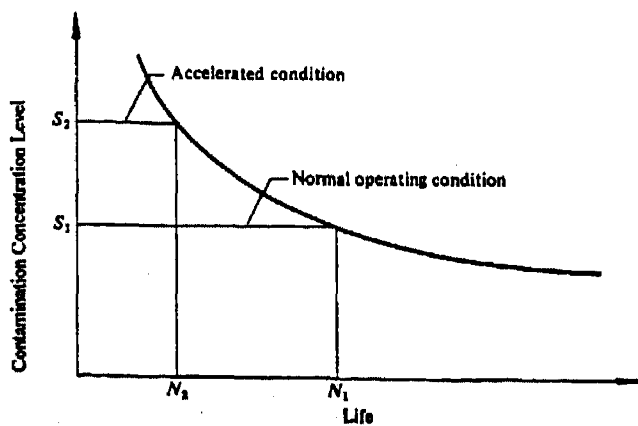

Fig 20. Accelerated life testing - S-N curve approach

low stress life curve. As shown in Fig. 21, the test articles are first tested to failure at a high contamination level to establish point A. Test articles from the same batch are then tested at the high contamination level to about 60-90% of failure. Testing is then continued at low concentration to failure to establish point B in the figure. Connecting points A and B and extending the line to the horizontal axes gives point C, the test article service life.

Sometimes people like to know a component's expected performance history under certain contamination levels in advance. In this situation, the approach of a single acceleration factor is used i.e., the articles are tested only at a specific accelerated concentration level. At the end of testing, test results are converted to predicted life by utilizing some known S-N relationship and mathematical calculations. Fig. 22 shows the accelerated life testing results of this approach. During the test, six pumps of each

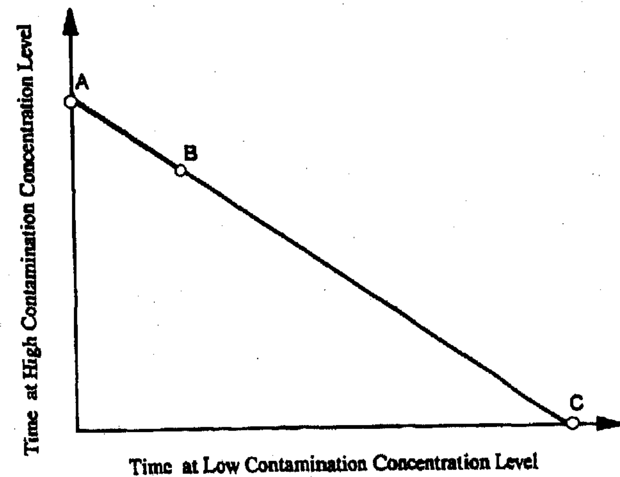

Fig 21. Accelerated life testing - two-point approach

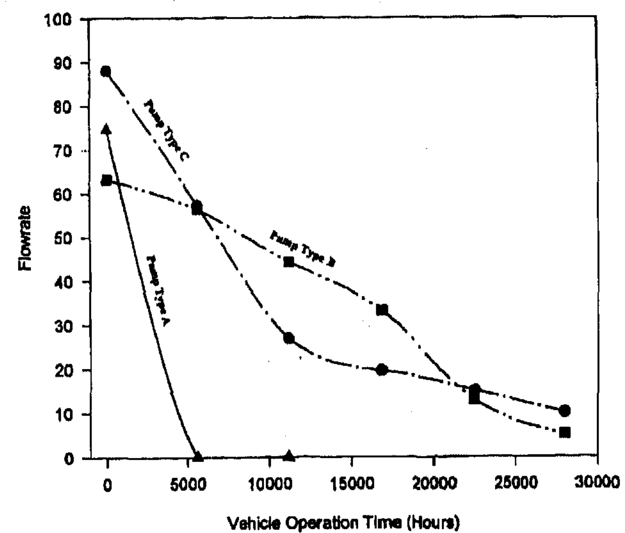

Fig 22. Accelerated life testing results - single level approach

type were tested under the same test conditions, using one specific contamination level, for 1000 hours. Test results were converted to predict service performance history shown in the figure. Examining the curves provides important information:

a. How to select a pump type to meet a targeted service life in a cost effective manner (if pump price is known).
b. How to improve each pump type to maximize its performance and service life.
c. How to utilize pump residual life to optimize total system performance.

Case 7 - Contamination Mathematical Modeling and Computer Simulation. A non-contaminated system, whether linear or nonlinear, may be described by deter-

ministic system governing equations. For example, a motion related system may be described by a second order differential equation in which the spring ratio and damping factors are constant. However, when the system is contaminated, the spring ratio and damping factor are no longer constant. For instance, when a shear force jamming particle comes to the gap between two relative moving components, the spring ratio will dramatically increase, whereas, when the particle leaves the gap, the spring ratio will restore. The same is true for the damping factor. A cluster of small particles, pounding the moving parts, will make the damping factor become a random process. This, in turn, will make the deterministic systems become a stochastic system. To model such a system, stochastic system theories [7] should be used. Fig. 23 shows a turbine motor-pump assembly and its deterministic and stochastic mathematical models. Figure 24 shows the preliminary simulation results. It is obvious that without contamination, pump speed becomes constant once the pump achieves steady state. However, this is not the case for a contaminated system in which the pump speed fluctuates even after stationary average speed has been reached. Additional performance results, such as flow degradations, versus the contamination level, may be obtained through further modeling and simulation effort.

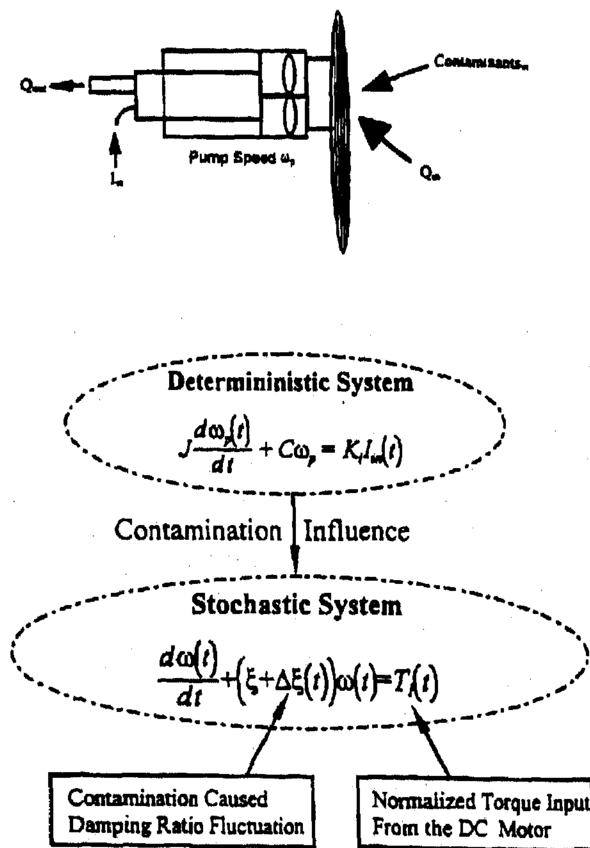

Fig 23. Fundamental mathematical model of contamination systems

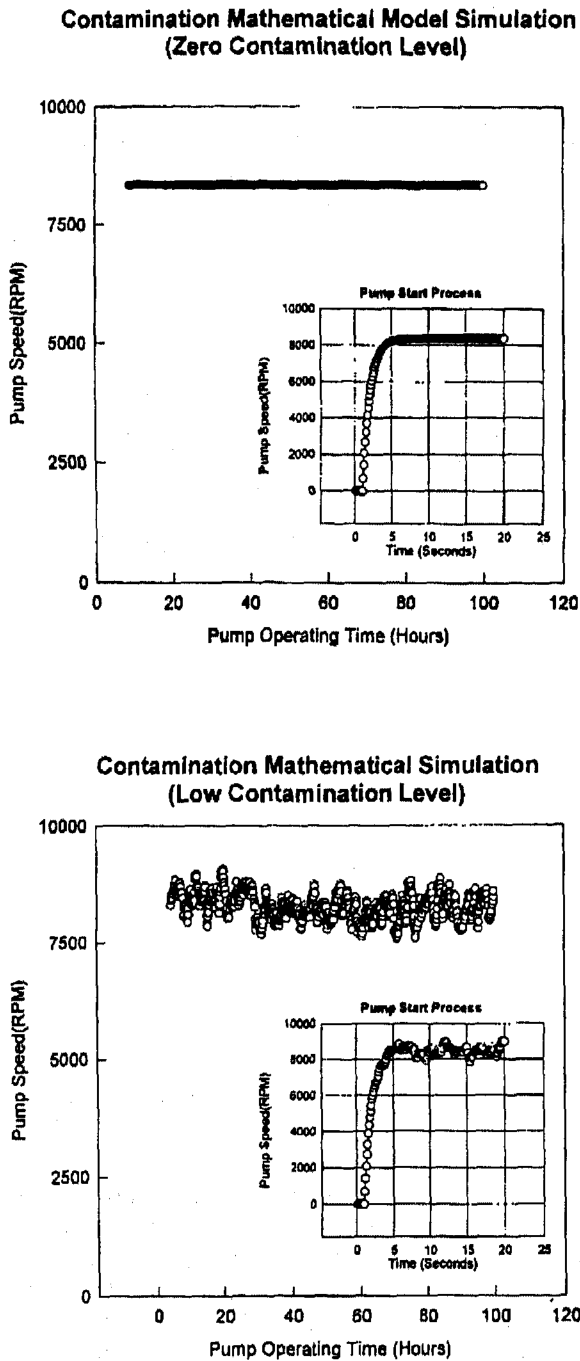

Fig 24. Preliminary contamination mathematical model simulation results

CLOSURE

Contamination sensitivity analysis methodologies, including testing, analysis modeling and simulation technologies presented in this paper, offer a systematic approach towards system contamination control. Failure

modes analysis presented in Section 2.2 may help pinpoint some system failure modes that occurred in field operations, but are often neglected. Case studies presented in Section 2.4 cover several areas of tribology, lubrication, filtration and contamination related issues and interconnections between these disciplines. Dust ingression studies may help to understand the importance of filtration systems and the role of wear resistance surface treatment. Additive sensitivity studies may help lubricant developers investigate lubrication properties of different additives and base stocks or to screen these products in a real-time fashion. Valve lock studies may offer an insight into malfunctioning components. Failure mode case studies may help to understand some filtration phenomenon which look impossible by conventional calculations, but occur during field operations. Contamination sensitivity and accelerated life testing may offer tools to predict machinery service life in a short time frame. Modeling and simulation studies may let designers work in virtual reality to investigate contamination related issues. In summary, proper utilization of contamination control tools will assist simple and complex components and systems to achieve their targeted service life.

Filter Performance Requirements for Engine Air Induction Systems

Neville J. Bugli
Ford Motor Company

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Automotive engine air intake filters are constantly being challenged to deliver higher filtration performances. The need to protect the engine from abrasive contaminants is ever increasing to achieve longer engine life and improved engine performance. This paper discusses some of the key issues affecting engine filter performance.

Currently, the SAE J726 procedure is used to test and evaluate engine air induction filters (AIF). The advantages and limitations of this procedure are discussed. Based on this procedure current engine air filtration technologies are also compared.

Engine protection requirements are also discussed relating to contaminant size and concentrations. To design robust engine air induction filters, the particle size and concentration ingested by the engine should be controlled. In addition to the overall mass (gravimetric) efficiency of the filters, the fractional size efficiency of these filters should also be measured. Fractional size efficiencies would quantify the contaminant size/concentration ingested by the engine which is related to engine wear, oil consumption, power loss etc..

Field evaluations are presented which capture the real time performance of engine air induction filters in dusty environments. Field evaluations should be mandatory to design effective and robust engine air intake filters.

New methods and improvements are briefly recommended for the SAE J726 procedure in quantifying air induction filters. The proposals are to include fractional size efficiencies in addition to the mass efficiency currently measured. Future trends in engine air induction filter systems are also discussed which may benefit from the new test proposals.

INTRODUCTION

Designing robust engine air induction filters is always a challenge. Engine air filters currently designed are required to deliver higher performance levels in smaller package designs. Further, higher filtration performances are required to reduce engine wear and extend engine durability. The engine air induction filter has to survive and perform in a variety of environments and driving conditions. For this paper we will restrict our study and analysis to engine air filtration systems used on passenger cars and light truck applications. Engineers designing air induction filters need to know the different parameters and conditions the air filter is going to be exposed. Packaging constraints also need to be met and satisfied. Packaging is probably a top priority when designing engine air induction systems and in many instances has a dramatic effect on filter performance.

Understanding engine filter performance requirements is mandatory in optimizing air induction system (AIS) designs. The filter system design is especially important to manage flow and flow distribution through the filter. In addition to meeting filtration requirements, the engine AIS filtration also meets and exceeds other requirements. In this paper we briefly

cover some design parameters for engine air induction filters.

We also need to understand the current laboratory evaluation methods to qualify engine AIF. The current SAE J726 method is briefly discussed with its advantages and limitations. Based on the SAE J726, benchmark data are presented on filtration performances for the most popular filter media technologies used today. Performance comparisons include dust holding capacities, initial efficiencies and overall efficiencies.

This paper also discusses engine protection requirements to reduce wear. Typical engine design clearances are reviewed and its impact on engine AIF performances. Studies show that engines need to be protected from abrasive dusts down to 1μm in size (1, 2, 8). Controlling the particle size and concentrations ingested by the engine reduces engine wear and extends engine life/durability.

To design robust engine AIF, we need to understand the field environment as it exists in the real world. The author feels that it should be mandatory for a design engineer to evaluate engine AIF in the field. This paper discusses some field results measured at the Ford proving grounds in Arizona (APG). Efforts are ongoing to evaluate more engine AIF in the field. With majority of the automotive companies being globally oriented, we need to understand what's out there in the rest of the world.

Based on some of the filter performance requirements and expectations, recommendations are being suggested to improve the current SAE J726 standard. The recommendations include;

- Quantifying the dust concentrations ingested by engine
- Identify suitable test aerosol
- Measure fractional size efficiency (by number & mass)
- Simple to use

Future trends and developments in engine AIF are also discussed. The new designs may also benefit from the new recommended test procedures.

ENGINE 'AIF' SYSTEM DESIGN

Over the years, AIS filter designs have dramatically changed to meet and exceed performance parameters. Air induction filtration systems that are designed to protect the engines have to meet and/or contribute to the following key performance requirements:

1. Filtration efficiencies (initial and overall)
2. Dust/contaminant removal capacity
3. Overall sound attenuation;
   - ⇒ In passenger cabin
   - ⇒ Drive by noise requirements
4. Flow management (restriction)
5. Overall Emissions
6. Service requirements

Overall higher design and performance expectations are demanded from engine air induction systems. The design of engine AIF and filtration systems have to meet and satisfy a variety of parameters;

- ♦ packaging environment
- ♦ design compactness
- ♦ higher engine flow rates
- ♦ higher media face velocities
- ♦ higher filtration performances
- ♦ lower head loss (pressure drops)
- ♦ lower costs
- ♦ mass air flow sensor requirements-emissions
- ♦ higher underhood temperatures
- ♦ extended service life & durability
- ♦ generic designs
- ♦ reduce parts complexities
- ♦ recyclability

Excellent related information on engine air induction filters and filtration system designs is provided in references 1, 2 & 19. The engine AIF systems has to be <u>tuned in</u> not only to meet filtration, but other significant requirements. For this paper we will only discuss some filtration performance requirements for engine AIF.

CURRENT FILTRATION PERFORMANCE LEVELS FOR 'AIF'

A variety of air filter media and filter designs are available today to deliver the required filtration performances. Air induction filtration systems should be optimized to provide maximum engine protection from abrasive contaminants. It is widely and well accepted that ***" Engine Air Inlet is the Major Source of Harmful Contaminants"***.

Abrasive contaminants ingested by the engine cause irreversible wear and damage to the engine. Engine wear and protection requirements will be discussed later.

There has always been a debate on the level of AIF performance required to adequately protect the engine. One of the key parameters is the contaminant removal efficiency and how high should it be. Previously

for AIF, the overall gravimetric efficiency would be specified and well accepted by the end user. Today, in addition to the overall efficiency, the end user also specifies a initial efficiency requirement for engine intake filters or AIF. It has been well demonstrated that a clean filter media exhibits a much lower collection efficiency compared to a loaded filter (1,2,31). Even small amounts of contaminant loading dramatically improves the collection efficiency of the filter. Engine designers are increasingly concerned about the amount and type of contaminant that could be ingested by the engine. Nevertheless, the problem of engine wear as it relates to abrasive contaminants (type, size, shape, concentrations etc.) is complex and quantitative analysis is always challenging.

CURRENT TEST METHOD - We currently use the SAE J726 procedure to evaluate engine air induction filters. This test procedure is popular and followed in North and South America. Other standards followed in Japan and Europe are JIS-D-1612 and ISO-5011. All of these standards are very similar and may yield comparable results. There is also an ongoing effort to commonize the SAE J726 with the ISO standard.

Recently, the SAE J726 procedure went through significant and useful revisions. Although not perfect, the SAE J726 has been well accepted as the industry standard for testing and evaluating engine AIF. Some of the key features and advantages of the SAE J726 procedure are;

- Simple
- Standard test dusts used
- Will provide restriction and head loss
- Will measure dust loading/capacity characteristics
- Will measure dust mass/gravimetric efficiency
- Accelerated test
- Provide relative and competitive data
- Covers a wide range of applications

The SAE J726 procedure may have some limitations. Some of them are noted below;

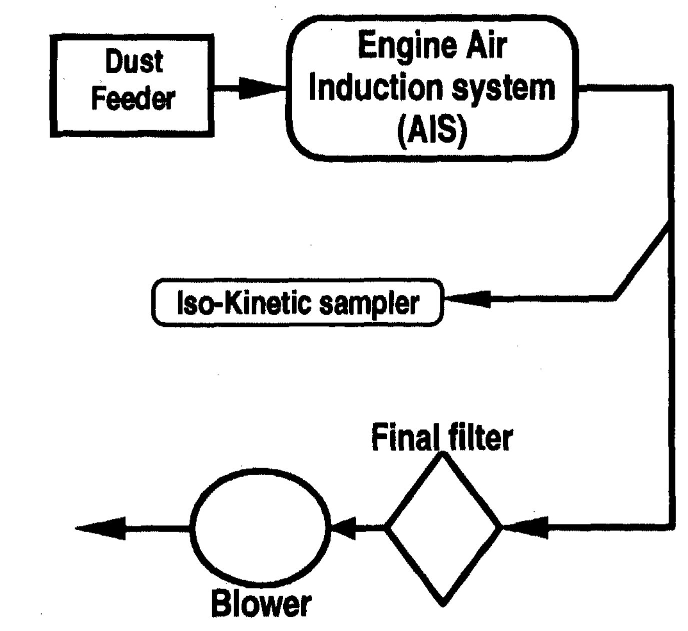
- Static test - The vibration effects are absent.
- Real flow simulation/duty cycle - Although the SAE J726 has a variable flow cycle, it may or may not represent real world driving conditions.
- Standard tests dusts - Real world dusts may be different. Studies have shown that dust/dirt distributions vary depending on geographic locations (1, 34).
- Contaminant size data - There are no provisions for measuring the contaminant size that is presented to the filter and ingested by the engine.
- Contaminant concentrations - There are no requirements or acceptable contaminant concentrations limits for the dust ingested. Ingested air cleanliness is important to protect engines from wear (1, 2, 3).
- Environmental effects absent - Temperature effects are not taken into account. Although temperature cycling may not have a significant effect. On the other hand the humidity may have an effect on the AIF performance depending on the type of filter media used.
- Driving conditions absent - Effect of different driving and ambient conditions are not taken into account. Driving conditions are important and have to be understood before designing engine intake filters (1,2,3,19,31).
- Service life requirements are not addressed.

It is generally agreed that the nature of the above limitations are quite complex and quantitative determinations may not be easy. Nevertheless, they play a very important role in designing engine AIF.

COMPETITIVE EVALUATIONS - For this paper we investigated the filtration performance of various O.E. air induction filters. For simplicity of comparisons the various filtration systems tested are grouped in three categories based on the type of filter media used. The three most common media categories are;

a) Dry paper media
b) Treated paper media
c) Synthetic felt media

The dry paper media evaluated were generally constructed of cellulose fibers. Some dry media used a blend of cellulose/synthetic fibers and some had a phenolic resin applied to the fibers to improve the stiffness and durability of the media.



The treated paper media evaluated had a similar media fiber mix as the dry paper media. The treatment was mainly mineral or synthetic oils.

The synthetic media evaluated was generally a multilayered structure (about 2 to 3 layers). The multilayered media was arranged to give a gradient density effect (coarser to finer fibers) to capture contaminants within the media. The media construction ranged from cellulose/synthetic to 100% synthetic fibers (mostly polyester). Needled felt or spunbonded construction was commonly used. All synthetic media evaluated were dry.

The information on the filtration performances for the above AIF was analyzed from a competitive benchmark database. The competitive benchmark data includes vehicles from model year 1993 to present. The competitive analysis presented in this paper includes some of the latest filtration technologies used for engine AIF.

Complete air induction systems were evaluated using the SAE J726 procedure with one exception. Instead of using the absolute filter downstream we used iso-kinetic sampling method to calculate the gravimetric efficiencies. Figure 1 shows a schematic sketch of the test set up.

Figure 1: Schematic Test Setup

By using iso-kinetic sampling we were able to improve our measurement sensitivity and repeatability. All AIS were evaluated under constant flow conditions. Further, all systems were flowed at their maximum flow rate which was calculated based on engine red line RPM. Both SAE coarse and SAE fine test dusts were used. Initial gravimetric efficiency was calculated after feeding 20 GMs of test dust. The test was terminated at a restriction rise of about 2.5kPa beyond initial restriction. The dust holding capacity and overall gravimetric efficiency was also measured at test termination. Overall, the test data has been compiled for about 70+ vehicles. The competitive comparisons for the three different filtration technologies evaluated are presented below.

For the analysis presented, one-on-one comparisons are difficult as each air induction system was unique. Normalized data have not been presented purposely in order to capture the effect of air cleaner design. The main purpose for the analysis was to relatively distinguish the three technologies used and evaluate general performance levels.

Dust Capacity Comparisons - The dust capacity is a measure of how long the air filter will survive before service is required. As the data will show the overall dust capacities measured were in the range of about 40 GMs to about 450 GMs depending on the type of test dust used. Further, almost all of the air filters evaluated had a recommended service life of 30K miles under normal driving conditions regardless of the type of media used.

The dust capacity measurements are presented in figure 2. The figure shows the average values and the range (minimum & maximum values).

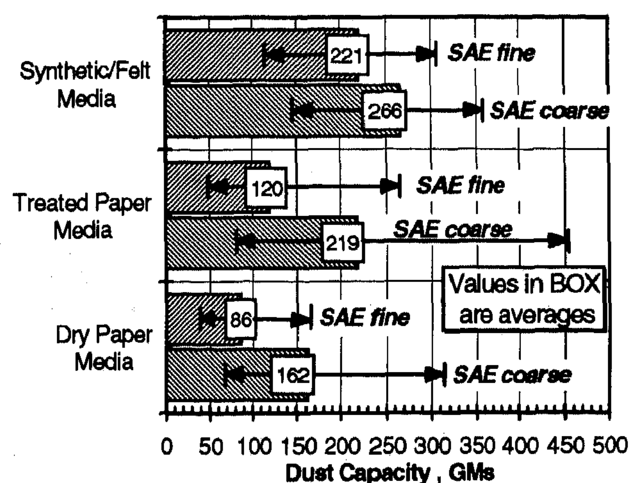


Figure 2:Typical Dust Capacity Performance Levels of AIF. Both Average and Ranges are shown.

On an average for both dry and treated paper media the dust capacity measured using SAE fine test dust was about half the dust capacity measured using when SAE coarse test dust (1,32). The synthetic media on an average showed only a 20% reduction in dust capacity when using SAE fine compared to SAE coarse. The synthetic media due to its depth loading and gradient density characteristics may be less sensitive to dust size distributions. On the other hand the dust loading capacity for the cellulose paper media depends on the formation of a dust cake on its surface. Studies have shown that the dust cake formation is strongly dependent on the face velocity and type of dust size distributions.

The data also shows that on an average the synthetic media when using SAE coarse dust collected about 22% more dust when compared to treated paper

media technology and about 64% more dust when compared to dry media. Similarly, using SAE fine dust the synthetic media collected about 85% more dust compared to treated paper media technology and about 2.5 times more dust when compared to dry media.

Overall, the synthetic media does show a competitive edge in dust holding capacity especially using SAE fine dust when compared to the other two. It could be argued as to which dust (SAE coarse or SAE fine) may be more representative of field conditions. Field evaluations performed by the author and other researchers indicate that SAE fine test dust may be more appropriate to evaluate engine air induction filters.

For normal driving conditions a dust holding capacity of about 100 GMs is generally recommended for a service life of 30K miles. Based on some of the field data the author has analyzed, this may be a very conservative requirement (1). The data shows that the majority of the filters evaluated will meet or significantly exceed this expectation. Field data analysis will be presented at a later date.

Initial Efficiency Comparisons - Initial efficiency is the key filtration performance measure to determine how well the air filter is protecting the engine (1,2). It has been well demonstrated that the initial efficiency of the filter is significantly lower when the filter is new and clean. The efficiency generally builds up after the first 5 - 15% of its useful life (loading) (31,35). Studies have shown that there is a very strong relation between filter removal efficiency and engine wear (2,3,31,35).

The initial efficiency measurements are presented in figure 3. The figure shows the average and the overall range for each media type. The initial efficiencies were measured after feeding 20 GMs of test dust.

When using SAE coarse dust, the treated paper media may show the best initial efficiency when compared to both dry and synthetic media. On an average using SAE coarse dust the treated paper media measured about 4 times lower dust penetration compared to dry paper media and about 2 times lower dust penetration compared to synthetic media. This is significant in terms of protecting the engine. When using SAE fine dust both the treated and synthetic media showed similar performance levels. On an average using SAE fine dust the treated paper and synthetic media measured about 2 times lower dust penetration when compared to dry media.

On an average the dry paper and synthetic media showed little differences in initial efficiency when using SAE coarse or SAE fine test dusts. On the other hand the initial efficiency for the treated paper media shows a strong dependence on the type of test dust used.

The data also shows that a majority of the dry paper media evaluated had significantly lower initial efficiencies. This is a concern as such lower initial efficiencies will induce excessive engine wear. The same was also true for treated media and to a lesser extent for synthetic media. For the dry paper media, efficiencies as low as 91% to 94% were measured using SAE coarse and fine test dust. On the other hand the lowest initial efficiencies measured for the treated and

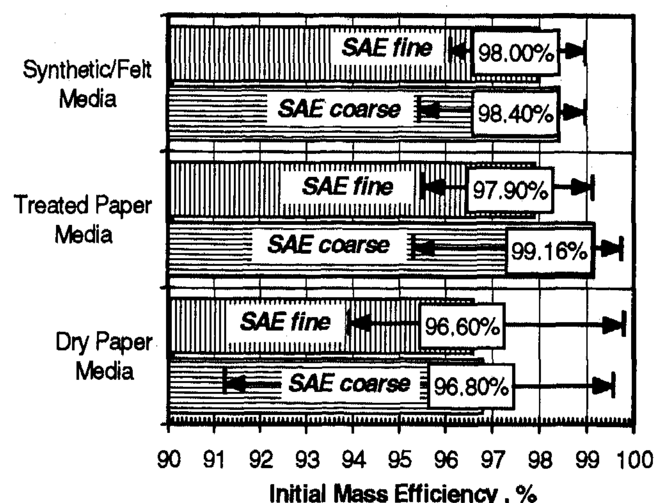

Figure 3: Typical Initial Efficiency Performance Levels of AIF. Both Average and Ranges are shown. Values in box are averages.

synthetic media was in the range of about 95.5% - 96.5% depending on the type of dust.

It is also interesting to note that the dry media when using SAE fine dust showed a higher initial efficiency performance range compared to when using SAE coarse dust. This may happen when the filter media are exposed to high face velocities. At such high face velocities the fine dust builds up relatively compact dust cake compared to coarse dust (35). The build up of the compact dust cake helps in enhancing the filter performance.

For normal driving conditions it is recommended for engine AIF to have a initial gravimetric efficiency in the range of about 98%+ to adequately protect the engine. Based on this requirement (assuming SAE test dust to be field representative) a majority of the filters evaluated did not meet the performance criteria and may not protect the engine. This was true for all three media evaluated. For off- road or dusty environments none of these filters may adequately protect the engine.

Overall, the treated paper media performed better than the dry or synthetic media.

Overall (final) Efficiency Comparisons - The overall efficiency is a measure of how well the air filter will protect the engine throughout its service life. The overall efficiency needs to be high to protect for re-entrainment, bounce, etc. under high dust loading (1,2). Generally the overall efficiency is significantly higher than the initial efficiency and is strongly dependent on dust loading characteristics of the media.

The measured overall efficiencies are shown in figure 4. On an average both the treated paper and synthetic media showed higher overall efficiency levels when compared to the dry paper media. Here also (on an average) the dry paper showed little differences in overall efficiency levels when using SAE coarse or SAE fine test dusts. This was similarly true for the synthetic media.

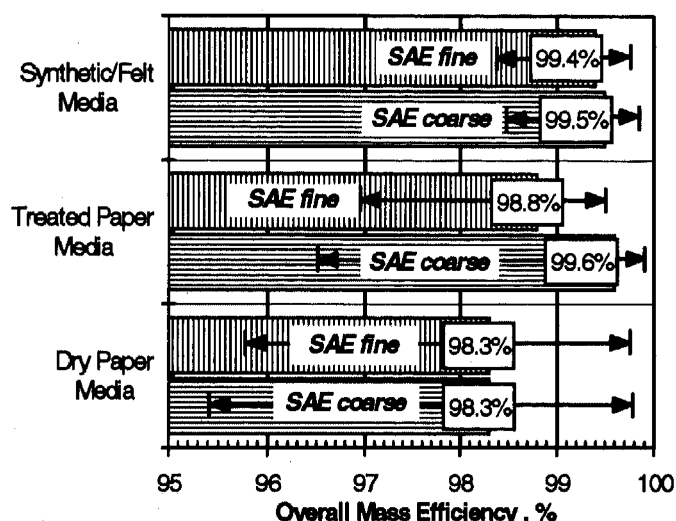

Figure 4: Typical Overall (final) Efficiency Performance Levels of AIF. Both Average and Ranges are shown. Values in box are averages.

For both the dry and treated paper media the overall penetration (1-overall efficiency) values dropped by a factor of ~2 when compared to initial penetration (1-initial efficiency) values. Similarly, for the synthetic media the overall penetration dropped by a factor of ~3.3 when compared to initial penetration.

The spread or the range of data collected also reduces significantly when comparing overall efficiencies to initial efficiencies. This was very prominent for the synthetic media.

The recommended overall efficiency for normal driving conditions is generally 99%+ to adequately protect the engine. Based on this criteria we see that a majority of the filters evaluated may not meet this requirement. This was especially true for the dry and treated paper media.

Overall, the synthetic media seems to perform only slightly better than the treated paper media. On the other hand, both the treated paper and synthetic media performed significantly better than the dry paper media.

Media Face Velocity Comparisons - There is a strong dependence of the media face velocity to its filtration performance. The face velocity of the media affects;

- filtration system restriction
- dust removal efficiency
- dust cake formation
- dust capacity and life

The overall average media face velocities and the corresponding spread (range) are shown in figure 5. The media face velocity was calculated using the following equation;

$$\text{media face velocity} = \frac{\text{total media area}}{\text{rated engine maximum flow}}$$

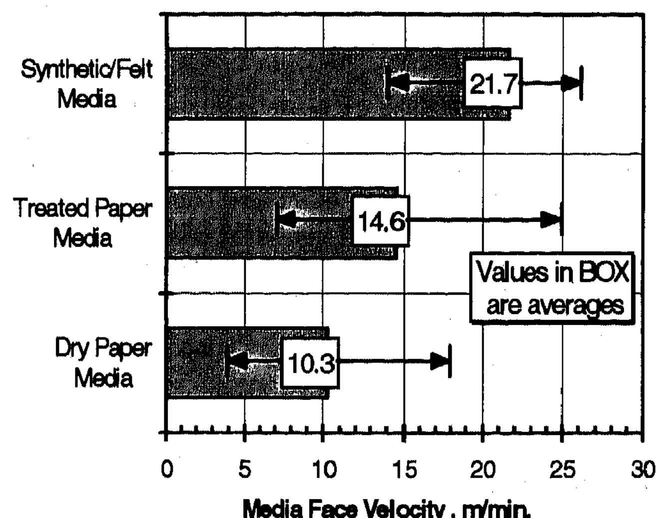

Figure 5: Typical Media Face Velocities Measured For AIF. Both Average and Ranges are shown.

Measurements show that the synthetic media operated at the highest face velocities. By comparison (on an average) the synthetic media operated at about twice the face velocity when compared to dry paper media. Similarly, the synthetic media operated at about 1.5 times higher face velocity when compared to treated paper media.

The average face velocity measured for the dry paper media was about 10.3 m/min. (~34 fpm) and for the treated paper media was about 14.6 m/min. (~48 fpm). The average face velocity measured for the synthetic media was about 21.7 m/min. (~71 fpm). On the other hand the media face velocities for heavy duty applications (medium/heavy duty trucks, trailers, off-road vehicles, agricultural applications etc.) are generally in the range of about 0.9 - 3.0 m/min. (3.0 - 10.0 fpm). By comparison the media face velocities for passenger car/light truck engine AIF about 4 - 16 times higher compared to heavy duty applications. One of the main reasons for this difference is the packaging constraints and environment.

Studies have also shown that filter media are dramatically affected by their face velocity. There is a critical velocity beyond which the filter media should not be used (19). Determining the critical velocity is important in order to effectively design air filters(19).

Discussions - For fibrous filter media the pressure drop rise is directly related to the amount of dust collected within the media and the formation of the dust cake (32). The pressure drop of the media remains low when dust is being collected in the media regime (32). This may be the reason why the synthetic media evaluated showed a relatively high dust loading per unit area for the same terminal conditions. Another way to enhance the dust holding capacity without any pressure drop penalty is to apply a treatment on the media (1).

Typically, we find that the initial and overall filtration efficiency levels for passenger car and light truck air intake systems are significantly lower when compared to heavy duty applications. For heavy duty air intake filters (highway trucks, agricultural vehicles, mining vehicles etc.) the initial efficiencies are in the range of about 99.5% to 99.9%+ and overall efficiencies are in the range of 99.9% to 99.99%+. In addition, majority of the heavy duty air intake filtration systems are also equipped with a pre-separator device. The pre-separator may be stand alone or be an integral part of the filtration system. Such pre-separators may have dust removal efficiencies in the range of about 70%-90% depending on flow rates.

The reasons for these performance differences (efficiency) are not very clear. In our opinion the passenger car/ light truck engine air filtration systems should have the higher efficiency levels to provide better engine protection. One reason for the high efficiency levels of heavy duty filters may be due to their lower media face velocities. Because of the lower face velocities a tighter media (lower permeability) could be used without any appreciable pressure drop penalties. Also the service intervals on heavy duty applications are significantly longer compared to light duty.

ENGINE PROTECTION

Dirt is the most common cause of high metal wear in engines (13). Dirt ingested by the engine eventually ends up in the oil as silica. The recommended maximum amount of silica or dirt in the oil should be less than 5ppm for 4 cylinder engines and less than 10ppm for 6 cylinder engines, when the engine is operated for 50hrs or 2500 miles (13). Efficient combustion and well filtered air are essential to protect engines from wear and also extend oil drain intervals (12).

The key function of a good engine AIF is to provide optimum protection from abrasive contaminants. In real world conditions it could be very challenging for the engine air filter to meet and exceed protection requirements. Selection of proper air and oil filters is very critical for engines designed today (2).

Instead of just focusing only on the engine air filter, engineers and designers should focus more on the overall filtration system to protect the engine. The two key filtration systems for engine protection are the engine intake and the lube oil systems. We may need to look at the interactions of the air and lube filtration systems for optimum engine protection. There is a certain synergy between the design of oil and engine air filters. Because what passes through the engine air filter system also affects the lube oil filter system.

It is beyond the scope of this paper to discuss lube oil filter system or its interaction with the engine intake filtration system. Although occasional references have been made as appropriate. Barris (2) also talks about a 'Total Filtration' approach for heavy duty filters and is an excellent paper.

A well designed air induction filtration system will deliver the following;

- Remove and reduce abrasive contaminants
- Reduce and control the ingested dust concentration levels within acceptable limits
- Control and remove contaminant sizes most harmful to the engine
- Reduce overall engine wear
- Reduce oil contamination
- Reduce blow-by conditions
- Control emissions
- Increase engine life and durability
- Increase lube oil service interval
- Reduce overheating of the engine
- Smooth engine performance

Fodor (3,4) in his study found that about 80% of all engine failures were attributed to engine wear. It is absolutely necessary to have improved filtration for air and oil filters to reduce engine wear (4).

Both, contaminant concentration and size ingested by the engine are important to reduce wear and

improve engine durability and life. It has been demonstrated that by using high efficiency air and oil filters, engine wear can be significantly reduced (16). Studies have also shown that engine life is a function of induction air cleanliness (19). It has also been established that cleanliness of an engine is a pre-requisite for problem free operation (7). Further, the piston ring cleanliness is important to ensure a free piston ring movement in clean ring grooves to ensure proper control of emissions and oil consumption (7).

Unfiltered air can induce significantly wear in an engine generally referred to as dusting out (17). Dirty air intake is the main cause today for wear on piston rings, pistons, cylinder liners, valves, bearings etc. (17).

Engine wear was reduced by about 70% going from a 40 micron to a 15 micron lube oil filter because it reduce the number of abrasive particles by a factor of 2 to 3 (8).

Today, there is a growing trend to deliver engines claiming to have extended service life and durability up to 150K miles or 10 years. In order to achieve this the engines have to be well protected from abrasive contaminants, oil additives etc. and also have better and cleaner manufacturing processes.

CONCENTRATION REQUIREMENTS - Controlling the amount of dust ingested by the engine is very critical for engine protection. In real world (field) conditions, the ambient dust concentrations can vary from < 0.1mg/m^3 to > 1000 mg/m^3 depending on the environment and driving conditions (1,2,5,18). For normal (typical) driving conditions the dust concentrations may be in the range of about 0.1 mg/m^3 to 0.5mg/m^3. In addition, the dust concentrations actually seen by the filtration system may also depend on the inlet tube location and design underhood. Higher dust concentrations also require higher efficiency levels to adequately protect the engine. Often the engine AIF are designed for normal to typical driving conditions. In a dusty environment such filters may not adequately protect the engine. This causes excessive wear and irreversible damage to the engine. Fodor (3) indicated that the air cleanliness ingested by the engine should be < 0.01mg/m^3 to reduce engine wear.

Studies have also indicated that on highways and paved roads diesel engine exhaust or soot is one of the dominant source of airborne particulates (5). Typical average ambient dust concentrations (TSP) can range from 0.03 -0. 3 mg/m^3 (5).

Figure 6 shows a plot of ambient dust concentration levels (mg/ m^3) and the required air filter mass efficiency levels. The required efficiency (initial efficiency) was calculated to meet a minimum downstream dust concentration of 0.01mg/m^3 ingested by the engine. The plot also shows three different ranges;

1. Normal driving conditions (0.1 - 1 mg/ m^3)
2. Dusty Conditions (0.5 - 50 mg/ m^3)
3. Very Dusty Conditions (10 - 1000+ mg/m^3)

For normal driving conditions like rural highways, urban highways, country roads, residential areas etc., in order to meet or exceed the downstream criteria we may require the engine air filter to perform in the range of about <95% to 99.0%+. For an average concentration of about 0.5 mg/ m^3 the required initial efficiency may be ~98%. This is probably a more conservative approach.

Similarly, for dusty conditions like congested urban highways , congested city roads , industrial areas , unpaved roads etc. the required efficiency may

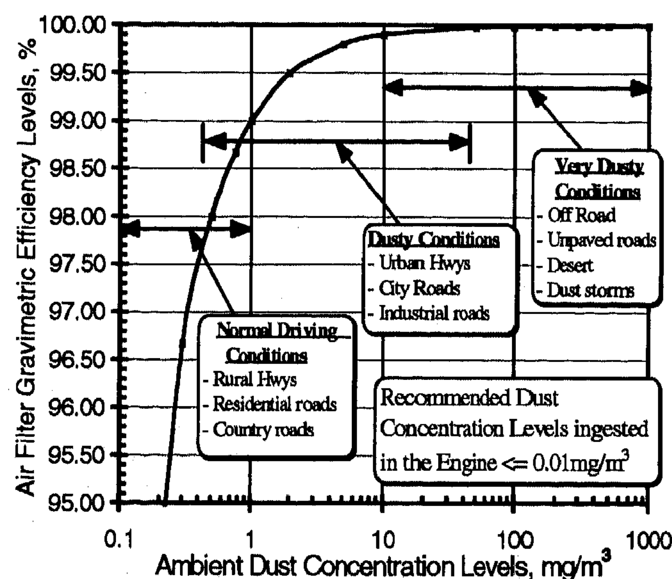

Figure 6: Calculated Engine AIF Gravimetric Efficiencies (initial) based on Ambient Dust Concentration Levels.

be in the range of about 99.0% to 99.98%+. This type of driving would be encountered in congested and busy cities and towns. Assuming an average concentration of about 1.0 mg/ m^3, the initial efficiencies required would be about 99%+.

For very dusty conditions like dust storms, mining operations, agricultural areas etc. the required efficiency levels may be in the range of about 99.98% to 99.999%+.

CONTAMINANT SIZE REQUIREMENTS - It is very critical to remove or control the different contaminant sizes being ingested by the engine. It is also critical to determine the contaminant sizes most harmful to the engine. Many studies have been performed and a variety of technical data is available.

Maximum wear is caused by particles in the size range of about 5 - 15 µm (6, 11). Piston oil ring wear is most sensitive to very small particles (6). It was also determined that dirt and abrasive particles equal to or less than the oil film thickness separating the various sliding or rotating parts will cause excessive wear (13). Even real fine particles (< 1 µm) may cause excessive wear, if their concentrations are high enough to agglomerate (13).

On of the most common wear mechanisms observed on piston ring and cylinder bore is abrasion wear caused by hard particles in the oil film originating from the combustion zone (14). Particles having diameters equal to or larger than the oil film thickness will make contact with the surfaces, initiating wear and excessive friction loads (9). Further, the wear debris adds to the contamination present in the oil causing additional wear on sliding/rotating surfaces (9).

The oil film thickness for any engine may be unique by design and performance requirements. Studies have shown that measuring various oil film thickness may indicate the different sizes of contaminants that may cause excessive wear.

Typical oil film thickness and clearances found in engines are listed in table 1.

The data from table 1 shows that abrasive particles down to 1µm or even smaller can cause engine wear, especially between piston ring and cylinder wall clearances. Investigations have also shown that during the power stroke or high load conditions the piston ring - cylinder wall gap could be reduced to almost zero (10, 30). This tells us that it is important and necessary to control or remove abrasive particles down to very fine sizes. This has also been supported by experimental measurements and investigations (1, 6, 8, 11, 15). The air filters designed for engine AIF may need to remove or reduce fine particles down to 1µm.

Figure 7 shows a typical efficiency curve for a engine AIF. The fraction size efficiency for the air filter was measured using SAE ultrafine test dust. The procedure used was similar to the SAE J1669. The filter media used was a typical cellulose fiber paper media generally used for engine intake filtration. The initial clean efficiencies for the filter have been plotted at three different face velocities of 3.5 m/min., 7.0 m/min. & 10.5 m/min.. The particle size efficiency was also measured after loading the filter using SAE fine test dust (~ 115 GMs loading).

Piston skirt - cylinder wall /liner	~ 25 µm - 100 µm *
oil film thickness between piston ring - cylinder wall	< 1µm - 15 µm **

Table 1: Typical Oil Film Thickness and Clearances Found in Engines.

Data in figure 7 shows that the removal efficiency for 1µm particle was measured in the range of about 40% - 70% depending on the face velocity. The higher face velocities also measured higher removal efficiencies. This is because of higher inertial and interception parameters at higher face velocities. For a 1µm particle size the initial efficiency measured at 10.5m/min. was about 70%. For a 5µm particle size, the

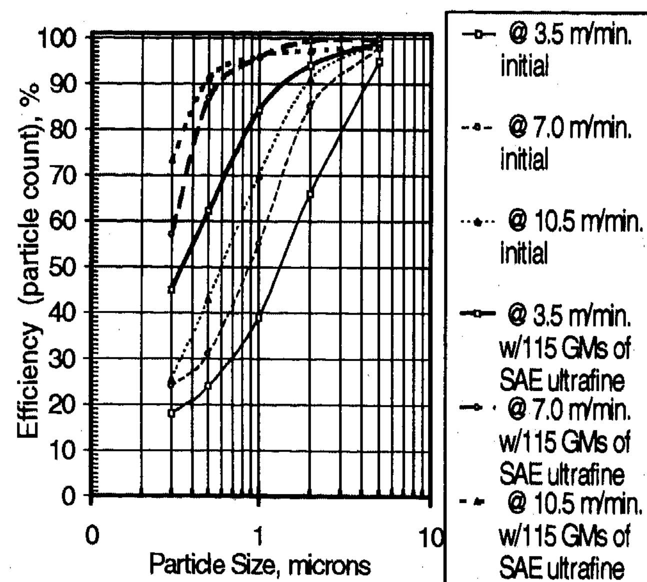

Figure 7: Typical Fractional Efficiency v/s Particle Size for a Dry Paper Media at Various Face Velocities with & without Loading.

the initial collection efficiencies measured were in the range of about 95% - 98% depending on the face

velocity. On the other hand for a 0.3μm particle size the face velocity had little effect on the clean efficiency of the filter.

There is also evidence that at the high face velocity of 10.5m/min., re-entrainment and bounce may be dominant due to a slight drop in efficiencies measured for particles > 1μm.

The filter after being loaded with 115 GMs of SAE ultrafine showed a significant increase in the collection efficiencies. This was especially true for the particle sizes in the range of about 0.3μm to 3.0μm. Beyond 3.0μm size the loading had a marginal effect on the removal efficiency. After loading the filter the particle removal efficiencies measured were in excess of 90%+ for 0.6μm and above. Overall the data shows that the clean filter does allow a significant amount of dust < 5.0μm to penetrate and be ingested by the engine.

Overall after loading , the dust penetration significantly reduces and is lower by a factor of 5 - 10 when compared to initial penetration.

FIELD EVALUATIONS

Field evaluations are mandatory to design and develop robust engine air induction filtration systems. There is definitely a need to understand relationships between laboratory and real world conditions , which is generally a missing link.

Field evaluations are generally complex involving dynamic changes. A variety of driving and environmental conditions will be encountered in field evaluations. Instruments and equipment used in the field need to be robust and should be adaptable to changing conditions. In our opinion such measurements do generate useful data and can be an excellent development tool.

Contaminants generated in the field will vary with the environmental and geographic conditions (34). Contaminants generated in the field will vary in ;

- size distributions
- various shapes
- wide concentration ranges
- material properties
- sources and source generation
- contaminant types

We generally evaluate engine air filters using dry standard test dusts. This may or may not represent field conditions, as contaminants in the field vary. A variety of field contaminants / aerosols potentially ingested by the engine AIF are listed below in table 2 (36, 37);

Types	Typical size ranges
solids - abrasives - dirt - road dust	~0.001 - 100μm +
sooty type aerosols	~0.001 - 1 μm
oils - sticky hydrocarbons	~0.01 - 10 μm
fine metal debris	~0.01 - 10 μm
industrial dusts - generally fine	~0.001 -100 μm
agricultural dusts	< 1.0 - 1000 μm
atmospheric dust	< 0.01 - 20 μm
mining dust	~0.1 - 1000 μm
sand	< 100 - 1000 μm+
water - rain	~50 - 10000 μm
salt crystals	~0.01 - 1.0 μm
snow	large
mud	NA

Table 2: Typical Contaminant Size Distributions

FIELD MEASUREMENTS - Engine air induction filter were evaluated at Arizona Proving Grounds (APG). The main objectives of the field measurements were;

- Capture the real time performance of engine air filters.
- Measure the dust concentrations and size distributions challenged to the engine air filter.
- Measure the dust concentrations and size distributions ingested by the engine.

The tests performed at APG were accelerated tests to evaluate the performance of engine AIF. It is beyond the scope of the paper to discuss details of the measurement techniques used to perform these measurements. Nevertheless some interesting data have been presented on the performance of engine intake air filters.

Test Setup - To capture the real time mass efficiency of the air cleaners, photometers were used upstream and downstream of the filter. By using photometers we were able to improve the sensitivity of measurements. The samplers were designed to be iso-kinetic, but due to the variable engine flow iso-kinetic sampling was not practical. The sampling line losses were kept to a minimum by shortening the lines. Absolute membrane filters were used to collect dust and later analyzed under a electron microscope for

calculating size distributions. All the tests were performed on the dirt track where a lead truck was used to generate a cloud of dust. The test vehicle followed the lead truck always surrounded by a cloud of dust.

Results & Discussions - Figure 8 shows a real time curve of measured mass efficiency as a function of time. Two averaged curves are shown, one measured at APG and the other was generated in the lab using the same photometers. Both curves have been plotted on the same time scale. It is very interesting to observe the low initial efficiencies measured at APG and on the bench. Initial efficiencies as low as about 65 %-70% were measured at APG. The lab measurements measured initial efficiencies in the range of about 50% - 60% . These efficiencies are significantly lower when compared to the initial efficiencies in figure 3.

The air filters were loaded up to a terminal restriction rise of ~2.5kPa. We also see that with loading the mass efficiency quickly builds up as expected. The filter tested in the lab loads up faster compared to APG due to higher dust concentrations used. Further, the filter in the lab was evaluated at maximum engine flow conditions. In comparison the filter tested at APG was exposed to much lower variable flow rates. For both

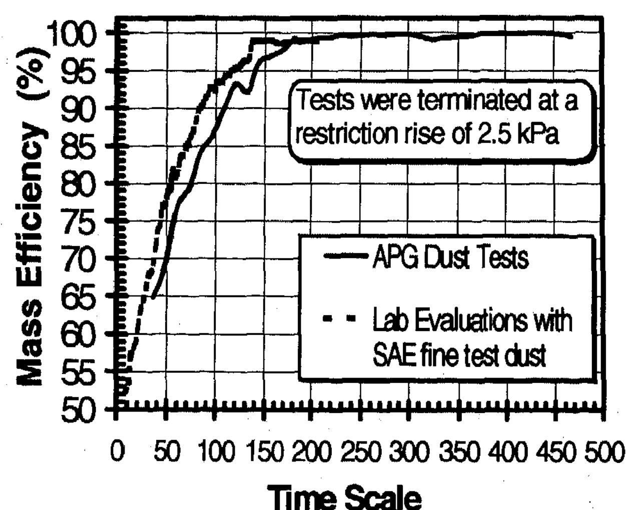

Figure 8: Typical Mass Efficiency of a Dry Paper Filter with Dust Loading at APG (Field Evaluation).

tests, the final efficiencies were measured in the range of about 98% - 99%. The upstream concentration measured during the APG tests were in the range of about 50 - 100 mg/ m^3. The downstream concentrations measured for the APG test was about 11mg/m^3 initially. With loading these dust concentrations significantly reduced to about 0.015 mg/ m^3. These numbers on an average translate to about 85%+ initial mass efficiency and about 99.9%+ final efficiency. APG tests showed that the air filter evaluated had a low initial efficiency and may not adequately protect the engine.

Figure 9 shows the measured upstream dust size distribution (number distribution) that was challenged to the air filter. Majority of the dust particles were measured in the range of about << 1.0µm - 50µm. Dust particles as large as 80µm were also measured. Data also shows that more than 95% of the dust particles were in the range of << 1.0µm - 15µm (particle sizes most harmful to the engine).

Similarly figure 10 shows the downstream dust concentration ingested by the engine. Majority of the particles ingested by the engine were in the range of << 1.0µm - 5.0µm. The filter effectively removed everything above 10µm. On the other hand more than 95% of the dust particles ingested by the engine were in the range of << 1µm - 4µm. Fraction size efficiency measurements in figure 7 also show similar results, correlating to an extent the field and lab results . These particle sizes can potentially cause abrasive wear in the engine.

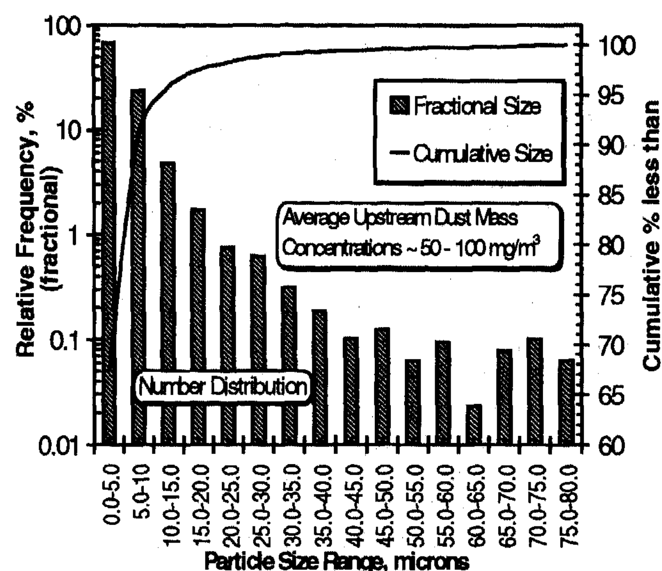

Figure 9: Typical Particle Size Distribution Measured Upstream of the AIF.

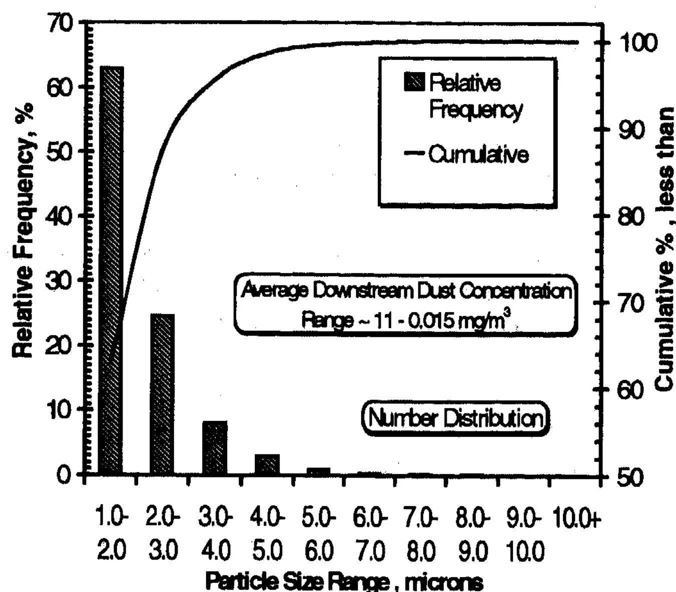

Figure 10: Typical Particle Size Distribution Measured Downstream of the AIF (ingested by the engine).

PROPOSED IMPROVEMENTS AND RECOMMENDATIONS

Studies and field evaluations have clearly established that in order to protect the engines and reduce engine wear, the ingested contaminant concentrations and size distributions need to be controlled. The current SAE J726 procedure does not provide any information on dust concentrations or size distributions. Gravimetric or mass efficiencies currently measured may not be adequate to understand and design effective engine air induction filters.

There is a definite need to quantify downstream conditions by defining acceptable limits on ingested contaminants. Additional studies may be required to selectively quantify what particle sizes are most harmful to the engine. Further, we also need to know the acceptable concentration limits of these harmful particles sizes that may be ingested by the engine. The following improvements are recommend that may add value in designing robust engine air induction filters;

◊ **Identify a Representative Test Aerosol/Dust** - We currently use the SAE coarse, fine, medium and ultrafine tests dusts to evaluate filters. Studies have shown that in real life there may be a distinct BI-modal aerosol distribution present (18, 38). One study showed that the a BI-modal distribution exist with a mass mean radii of about 4μm and 45μm (18).

◊ **Specify Downstream Conditions** - In order to protect the engine, the downstream conditions of the AIF (acceptable ranges) may need to be specified. The downstream conditions may include both concentration requirements and/or size distributions.

◊ **Measure Fractional Size Efficiency** - There is a need to measure how well the engine AIF removes particles that are most harmful to the engine. Fractional efficiency requirements may be specified in terms of number or mass.

◊ **Flow rates** - There may be a need to identify realistic flow rates to evaluate engine air filters for specific engine operations. Many a times the air filters are evaluated at maximum engine rated flows. This may be unrealistic. Using the SAE variable flow cycle to evaluate engine air filters may yield more meaningful data. This may be especially true for filtration systems incorporating inertia separation devices. At low flows (realistic) these separation devices operate with significantly lower efficiency levels.

Some key factors affecting the fractional efficiency of engine air filters are also briefly summarized below;

- type of contaminants - dirt, sand, soot etc.
- contaminant concentration levels
- driving conditions
- contaminant size distributions
- interaction of media with environmental conditions
    - heat
    - humidity
    - water
    - salt
    - snow
    - mud splashes
- type of filter media used
    - paper type - surface loading
    - multilayered - gradient density - depth filtration
    - porous depth media
    - true depth filters
- media face velocity
- pleat design - size and shape
- filter media treatments - oils etc.
- air filter design
- air cleaner housing design - inlet/outlet configurations
- effects of vibrations on filter media
- shelf life requirements

- effect of pre-separation (inertia type) devices
- others

FUTURE TRENDS

Design of current and future engine air induction systems are being driven by customer needs and wants. Engine air intake filtration being an integral part of the air induction system will also need to meet customer requirements. Future air induction filtration designs will be challenged to meet new designs, packaging constraints, new technologies, performances, manufacturing and cost targets. Some future challenges may include;

- Finer filtration may be required. This will apply to both engine air and lube oil filters.
- Extended service life on both engine and lube oil filters. Service life greater than 100K miles may be achievable on engine air induction filters - AIF.
- Packaging constraints are driving designs to be very compact. Compact canister type filter designs may be the way to go.
- Filter media designs may have to handle higher face velocities.
- Higher underhood reliability and robustness to meet temperature and durability requirements.
- Systems integration involving mass air flow sensors, resonators, various other sensors - ACT...., battery cool box, etc..
- Generic designs to save costs
- Overall system cost savings
- Green filters / recyclability
- Provide higher value to the customer.

SUMMARY

- Higher initial collection efficiencies are required to reduce engine wear.
- Lab and field evaluations show that the initial collection efficiencies of engine air filters may be significantly lower than expected. This may cause excessive engine wear. Efficiencies as low as 60% were measured.
- For normal to dusty driving conditions initial gravimetric (by mass) efficiencies in the range of about 98% to 99.5% may be acceptable.
- Higher initial gravimetric efficiencies in excess of 99.9%+ may be required for very dusty environments.
- The overall/final efficiencies should be higher than the initial efficiencies. Lower overall/final efficiencies would indicate re-entrainment problems.
- Quantifying the engine air filter performance by measuring the fractional size efficiency may add value. This may be added as an option in the SAE J726 procedure.
- Based on oil film thickness and bearing clearances abrasive particles in the size range of < 1.0μm to 20μm may cause excessive engine wear.
- Field and lab evaluations show that for a typical engine air filter there is a significant penetration of particles in the range of < 1.0 μm - 5 μm. Such fine particles may be harmful to the engine.
- Understanding ingested contaminant size distributions, mass concentrations and related engine wear is important.
- The dry paper filters that were evaluated may or may not provide adequate engine protection.
- Overall, treated and synthetic media filters may provide better engine protection.
- The standard SAE fine test dust may be more representative of field conditions
- We need to understand the synergy between the engine air and lube oil filters.

ABSTRACT

A Paper-Tire is a virtual product defined as a set of force and moment equations that are entirely determined by well defined and widely recognized tire characteristics (such as cornering stiffness, peak location, and slide/peak ratio). The vehicle dynamicist may use the Paper-Tire concept to study the effects of tires with various hypothetical characteristics on vehicle behavior. If the dynamicist discovers a set of characteristics yielding a desired vehicle response, he could then ask tire manufacturers to attempt to develop a tire specification with the preferred characteristics. (There is, of course, no guarantee that tire manufacturers can develop a practical tire with the preferred characteristics.)

The paper explains the general principles of the Paper-Tire concept with the help of the BNPS model (derived from the 'Magic Formula'). A limited set of examples for tire cornering and braking performance are provided at a single load; further possible developments are indicated.

INTRODUCTION

In his daily modeling work, a vehicle dynamicist is often faced with the problem of optimizing the performance of a vehicle component, for example in the suspension or the steering system. This task is greatly eased if the component's performance equation can be expressed in terms of widely known and accepted parameters.

This paper facilitates the optimization process for tires, specifically their cornering and braking/driving capabilities. The optimization process is based on a model containing only universally recognized tire descriptors, such as cornering stiffness and slide/peak ratio; no additional information is necessary to describe the desired tire performance function. By varying the numerical values of these well defined and generally accepted descriptors rather than the values of some physically unspecified quantities (e.g., the constants of polynomial expressions), the effect of various tire characteristics on vehicle behavior can be mapped out rather quickly.

Since the numerical values of the performance descriptors are constructed 'on paper', the model is called the 'Paper-Tire'. By varying any or all of the independent descriptors the vehicle dynamicist is in a position to study their potential effects on vehicle behavior and select tire characteristics that yield the best vehicle response. The next step would be to ask tire manufacturers to develop tires with characteristics that come as close as possible to the selected values.

THE BASIC EQUATION

Of all the different models describing the cornering or braking/driving behavior of tires (physical models, black-box models, etc.), the Magic Formula seemed to be best suited for our purposes. The Magic Formula was first proposed in 1987 by Bakker, Nyborg, and Pacejka [1] and later altered and expanded in various ways. A thorough discussion was offered by Schuring, Pelz, and Pottinger [2], who also suggested a version of the Magic Formula that is suitable for personal computer processing (the BNPS model).

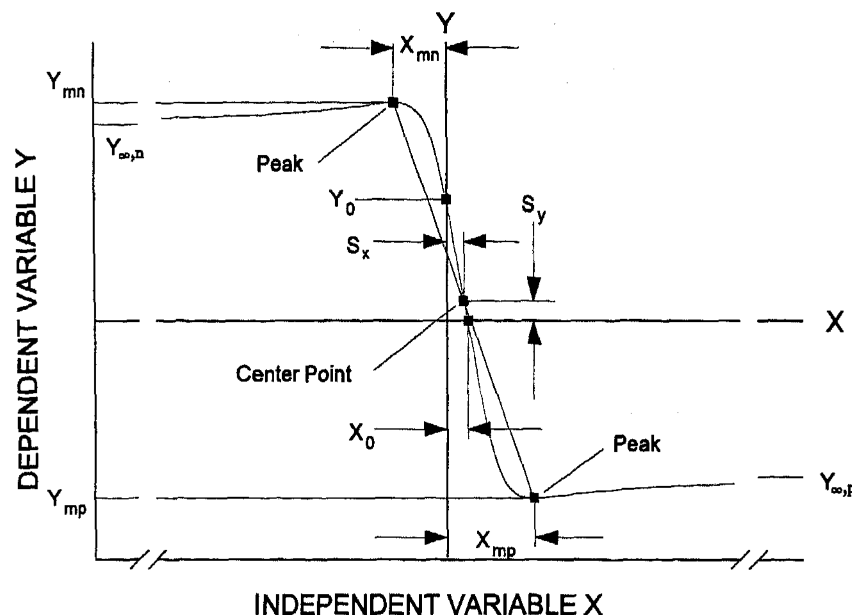

Figure 1. Typical Magic Formula Function, Y,(X)

The Magic Formula makes extensive use of trigonometric functions. Here it is expressed in the following form:

$$Y = S_y + D \sin[C \tan^{-1}\{B(X - S_x)(1-E) + E \tan^{-1} B(X - S_x)\}], \quad (1)$$

where the dependent variable Y represents any quantifiable tire response, such as a force or moment; and the independent variable X is a tire service variable, such as slip angle, inclination angle, or longitudinal slip.

The Magic Formula formula contains six constants -- S_x, S_y, B, C, D, and E (called MF constants in the following).

By varying these constants, a large variety of Y(X) functions with common and uncommon curve shapes can be generated [2]. However, all these curves regardless of their shape are composed of two symmetrical branches spreading from a center point (or center of gravity) toward positive and negative X-values, respectively. The coordinates of the center point are $X = S_x$ and $Y = S_y$ as given in Eq. (1) and indicated in Fig. 1, which shows a typical Y(X) relation between lateral force and slip angle produced by Eq. (1). Symmetry is provided by the fact that a 180 degree rotation of one of the two branches around the center point brings it in congruence with the other branch.

Restrictions- In this paper, the use of Eq. (1) will be restricted to S-shaped curves as shown in Fig. 1 with two peaks, one for the positive branch and a corresponding one for the negative branch. Each is followed by a smooth tail reaching a fixed value at infinite X values, as indicated in Fig 1. Furthermore, the center point of the two branches is situated near the origin of Y(X). These curves suit our purposes because they fully satisfy the formula's intended application to cornering and braking/driving tire forces and moments.

These conditions are realized if two restrictions are satisfied. First we demand that

$$1 < C < 3 \quad (2)$$

The mathematical background leading to this restriction is given in Ref [2].

Second, calling for a smooth S-type path for Y(X), as discussed, we require that

$$1 > E > -(1 + 0.5 \cdot C^2) \quad (3)$$

This relation is also discussed in [2].

Fig. 2 outlines the practical field of C and E given by Eqs. (2) and (3). For instance, for C = 0.9, E may range from 1 to -1.41; for C = 1.5, from 1 to -2.13; for C = 2.4, from 1 to -3.88; etc. Outside this range, Eq. 1 begins to describe rather uncommon shapes ('warp', 'hump', 'saddle') that are of no interest here.

The lower limit given in Eq. (3) can be generously overstepped without causing large errors, however. For instance, if the lower limit of E is selected at $E \approx -1.8(1 + 0.5 \cdot C^2)$ rather than at $E \approx -(1 + 0.5 \cdot C^2)$, a slight irregularity ('warp') of the slope dY/dX in the vicinity of the center point will occur with a maximum error of only 5 %.

CONVERSIONS

None of the six MF constants is a direct part of the commonly accepted nomenclature for tire force and moment performance. Hence the task at hand is to convert the six constants S_x, S_y, B, C, D, and E into six other, well-recognized and graphically demonstrable tire

performance descriptors. These six well-recognized descriptors must not only be independent from each other, their values must also cover the whole range of the performance function Y(X). These requirement are satisfied by :

1. The slope dY/dX ,S_t,at X = 0, also called stiffness (first constant). The stiffness governs the cornering and braking behavior at small slip values.

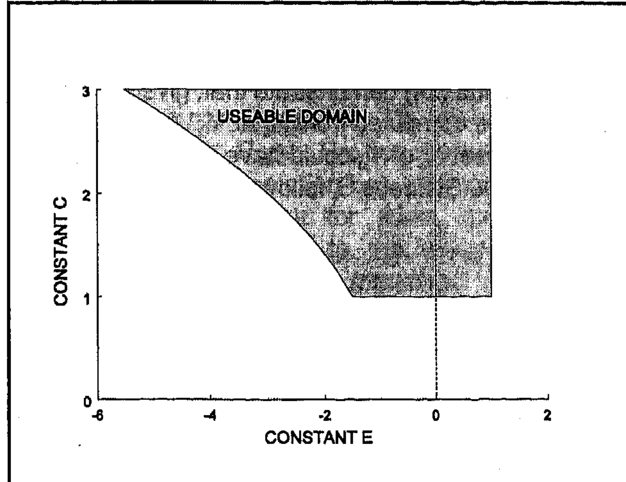

Figure 2. Field of Application for Constants C and E

2. The coordinates of the two peaks (four more constants). The peak values affect the cornering and braking behavior at larger slip values. The four coordinates of the two peaks are Y_{mp} and X_{mp} for the positive branch of X (index p); and Y_{mn} and X_{mn} for the negative branch of X (index n). Index 'm' stands for 'max' or 'min'.

3. The slide/peak (S/P) ratio (the sixth constant); that is the ratio of the ordinate at large X-values and the ordinate of the peak. This ratio is important for both cornering and braking at large slip values. The S/P ratio can be specified for either the positive or the negative branch of X. For the positive branch it is

$$R_p = Y_{\infty,p}/Y_{mp} \quad (4a)$$

for the negative branch it is

$$R_n = Y_{\infty,n}/Y_{mn}. \quad (4b)$$

Index ∞ stands for very large X-values. The S/P ratios of the positive and the negative branch are not independent from each other. Hence only one of the two can be picked arbitrarily.

The task is now to express the six constants of Eq. (1) by the six tire performance descriptors just given.

Center Point - Since the performance curve Y(X) is symmetrical, a straight line between the two peaks intersects the curve at the center point (see Fig. 1).

$$S_x= 0.5(X_{mp}+ X_{mn}) \quad ((5))$$

$$S_y= 0.5(Y_{mp}+ Y_{mn}) \quad ((6))$$

Hence by selecting the maximum and the minimum point of the desired Y(X) function, we have the coordinates of the center point. (Note: Equation numbers in double parentheses (( )) will be used later for final conversions.)

<u>Constant D</u> - Constant D is derived from the max/min values of Y. D is positive for a positive slope (stiffness) and negative for a negative slope (stiffness). The max/min values follow from the fact that the argument of sin [ ] in Eq. (1) cannot be larger than +1 at X > S_x, and -1 for X < S_x.

The max/min values of Y are therefore

$$Y_{mp}= S_y+ D, \quad \text{and} \quad Y_{mn}= S_y -D \quad (7)$$

Consequently,

$$D = 0.5(Y_{mp}- Y_{mn}) \quad ((8))$$

I.e., the constant D is half the vertical distance between the two peaks. Again, by selecting the max/min points of the desired Y(X) function, constant D can be easily computed.

<u>Constant C</u> - Constant C is determined from the S/P ratio, R, defined by Eqs. (4a) and (4b). The desired Y values at very large X-values are derived from Eq. (1) at X → (±)∞. The result is

$$Y_{\infty,p}= S_y+ D\cdot\sin(0.5\cdot\pi\cdot C), \quad \text{and}$$
$$Y_{\infty,n}= S_y- D\cdot\sin(0.5\pi\cdot\cdot C) \quad (9)$$

provided that E < 1, as stipulated in Eq. (3). These relations together with Eqs. (7) substituted into Eqs. (4a) and (4b) yield

$$\sin(0.5\cdot\pi\cdot C)=(1/D)[R_p(S_y+D)-S_y]=-(1/D)[R_n(S_y-D)-S_y] \quad (10)$$

If we abbreviate

$$R^*\equiv (1/D)[R_p(S_y + D)- S_y]= -(1/D)[R_n(S_y - D) - S_y] \quad (11)$$

we have

$$\sin(0.5\cdot\pi\cdot C) = R^* \quad (12)$$

so that as shown in the APPENDIX

$$C = 2[1 - (1/\pi) \sin^{-1}R^*] \quad ((13))$$

From this equation, constant C can be computed as a function of given values of R_p (or R_n), D, and S_y. If, as is mostly the case, S_y<<D, Eq. (11) simplifies to

$$R^*\approx R_p = R_n \equiv R \quad (14)$$

so that

$$C \approx 2[1 - (1/\pi) \sin^{-1}R] \quad (15)$$

Eq. (13) is valid for R*-values (or Eq. (15) for R-values) between +1 and -1, so that C values extend from 1 to 3.

Constant B - Constant B is derived from tire stiffness defined as the slope S_t= dY/dX at X = 0, as noted. To alleviate the differentiation of Eq. (1), we make use of our initial premise that the center point is in close proximity to the origin [X,Y = 0,0] so that, for the purpose of differentiation, $S_x = S_y \approx 0$. The first derivative dY/dX at X=0 then yields the stiffness

$$S_t \approx B \cdot C \cdot D \qquad (16)$$

With a numerical value of stiffness S_t selected, and with C and D computed by Eqs. (13) and (8), respectively, we determine constant B as

$$B = S_t/(C \cdot D) \qquad ((17))$$

Note that stiffness S_t may be positive or negative. It is positive if D is positive; and negative if D is negative. Hence B is always positive (as is C).

Constant E - Constant E is found at dY/dX = 0, as follows. Eq. (1) can be re-written as

$$y = D \cdot \sin(C \cdot z) \qquad (18)$$

with

$$z = \tan^{-1}\{B \cdot x(1 - E) + E \cdot \tan^{-1}(B \cdot x)\} \qquad (19)$$

where, temporarily,

$x = X - Sx$ and $y = Y - S_y$.

To find the max/min values of y, we impose

$$y' = z' \cdot C \cdot D \cdot \cos(C \cdot z) = 0 \qquad (20)$$

This equation is satisfied if either z' =dz/dx= 0 or cos(C·z) = 0 (C = 0 or D = 0 are trivial). A short investigation reveals that only the case of cos(C·z) = 0 need be considered here.

Hence we have (C · z) = (±) π/2 or z = (±) π/(2·C), so that substituting in Eq. (19)

$$(\pm)\pi/(2 \cdot C) = \tan^{-1}\{B \cdot x_m(1-E) + E \cdot \tan^{-1}(B \cdot x_m)\} \qquad (21)$$

The variable $x_m = X_m - S_x$ refers to the X-value of the peak for either the positive or the negative branch of X. From Eq 21 follows that

$$E = \frac{(\pm)\pi \tan[(/(2 \cdot C)] - B(X_m - S_x)}{\tan^{-1}[B(X_m - S_x)] - B(X_m - S_x)} \qquad ((22))$$

The positive sign stands for the positive X branch where $X_m = X_{mp}$; the negative sign, for the negative X branch where $X_m = X_{mn}$. In either case, the numerical value of E is the same.

Offsets X_0 and Y_0 To compute pull forces and pull moments, the offsets of Y at X = 0 and of X at Y = 0 must be known. Fig. 1 shows that the X-offset is (nearly)

$$X_o = S_x - (S_y/S_t) \qquad (23)$$

and the Y-offset

$$Y_o = S_y - (S_x \cdot S_t) \qquad (24)$$

Eqs. (23) and (24) demonstrate that, given S_x and S_y, stiffness S_t can be computed from X_o or Y_o. Hence instead of stiffness S_t, offset X_o or Y_o could have been specified as independent input. Stiffness S_t follows then from S_x, S_y, X_o or Y_o as

$$S_t = (S_y - Y_o)/S_x \qquad (25)$$

or

$$S_t = S_y/(S_x - X_o) \qquad (26)$$

COMPUTATIONS

We begin by choosing numeric values of the coordinates of the two peaks: for the positive branch, they are X_{mp} and Y_{mp}; for the negative branch they are X_{mn} and Y_{mn}. Also, numerical values of both stiffness, S_t, and S/P ratio, R, are selected.

These six performance descriptors are then converted into the six original MF constants in several steps. As a first step, constants S_x, S_y, and D are computed from the four peak coordinates, according to Eqs. (5), (6), and (8), respectively. Also, constant C is calculated from the S/P ratio R by Eq. (13) or (15).

As a next step, constant B is derived from stiffness, S_t, and the previously determined constants C and D by Eq. (17). Lastly, constant E is computed from B, C, S_x, and X_{mp} (or X_{mn}) by Eq. (22).

Constant E must be checked against the permissible range given by Eq. (3). If E exceeds the lower end of the permitted range by more than, say, a factor of 1.8, new values of the six performance descriptors must be chosen that would bring E into compliance. Finally, if needed, offsets X_o and Y_o are computed from S_x, S_y, and S_t, according to Eqs. (23) and (24).

We realize that the choice of these six performance descriptors is somewhat arbitrary; six other independent descriptors could have been selected. For instance, instead of stiffness S_t, offset X_o or Y_o could have been specified. Stiffness S_t would then be calculated from S_x, S_y, and X_o (or Y_o) according to Eqs. (25) or (26), respectively.

All these steps are easily combined into a Paper-Tire program. The program accepts six independent performance descriptors as input (stiffness, four peak coordinates, and S/P ratio), and delivers six MF constants (two center point coordinates; plus B, C, D, and E) as output. From these constants the desired Y(X) function can be computed.

SOME EXAMPLES

The few examples given here are arbitrarily restricted to the relation between lateral force and slip angle at a single load. Following the same Paper-Tire concept, we could evolve similar examples for other performance functions such as the relation between longitudinal force and slip ratio; or between aligning moment and slip angle; or indeed between any two variables whose relation can be represented by the general S-shaped curve described earlier.

Standard Curve - To demonstrate various possibilities of the Paper-Tire concept, we will start with an actually measured relation between lateral force and slip angle and consider it for some reason in need of modification, according to the wishes of the vehicle dynamicist. The actually measured curve, called the standard curve, is depicted in Fig. 3; its physical parameters are

stiffness S_t= - 80,000 N/rad
positive peak values Y_{mp}= -5,500 N; X_{mp}= 0.18 rad
negative peak values Y_{mn}= 5,000 N; X_{mn}= -0.16 rad
S/P ratio R = 0.9

From these six physical parameters, the six MF constants were computed by the Paper-Tire program and the MF function Eq. (1) calculated and drawn Fig. 3. The six MF constants of the standard curve are
S_x= 0.01 rad; S_y= -250 N; B = 11.84 1/rad; C = 1.29; D = -5250 N; E = -0.801

We also find the two offsets as X_o= 0.00687 rad; Y_o=550 N.

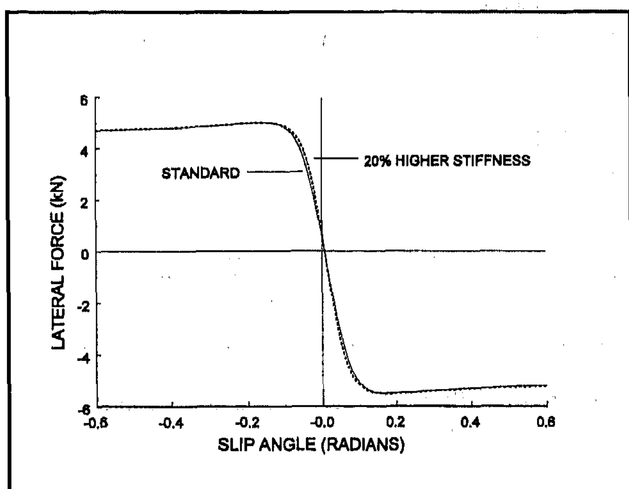

Figure 3. Effect of a 20% Increase in Cornering Stiffness

Change of Stiffness - We will increase the stiffness S_t of the standard curve by 20% from -80,000 N/rad to -96,000 N/rad; the peak coordinates and the S/P ratio are kept the same. How are the MF constants affected by this change?

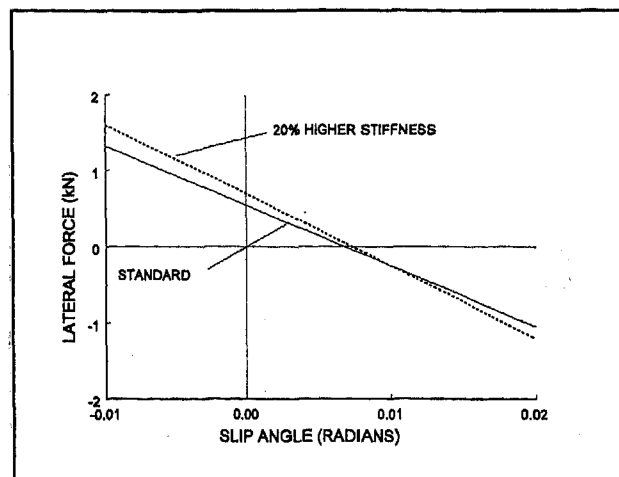

Figure 4. Effect of 20% Increase in Cornering Stiffness at Small Slip Angles

Exercising the Paper-Tire program, we find a new B value of B = 14.21 1/rad; and a new E value of E = -0.261. The latter number is well within the permissible range of E between 1 and $-(1+0.5{\cdot}C^2)$ = -1.83. The other four MF constants remain unchanged. The result is shown and compared with the standard curve in Figs. 3 and 4. We note that the two offsets are increased – X_o by 8% from 0.00687 rad to 0.0074 rad; and Y_0 by 29% from 550 N to 710 N.

Change of Peak Forces - We might find it desirable to increase the peak lateral forces of the standard curve by 10%; i.e., from -5500 N to -6050 N for the positive peak, and from 5000 N to 5500 N for the negative peak. The slip angle location of the peaks should remain unchanged, and so should stiffness and S/P ratio.

The Paper-Tire program shows that the increases in the peak forces entails three modifications to the MF constants: S_y expands by 10% from -250 N to -275 N; B drops by 9% from 11.84 1/rad to 10.76 1/rad; and D grows by 10% from -5250 N to -5775 N. We also note that the two offsets are diminished by 5% – X_o from 0.00687 rad to 0.00656 rad, and Y_o from 550 N to 525 N. The Y(X) function computed from these new MF constants is compared with the standard curve inFig. 5.

Change of Slip Angle at Peak Forces - Instead of changing the magnitude of the peak forces we will change their slip angles, here by 100%. Hence X_{mp} increases from 0.18 rad to 0.36 rad; and X_{mn} from -0.16 rad to -0.32 rad. All other physical parameters are kept the same. Result: S_x grows by 100% from 0.01 rad to 0.02 rad; and E jumps from -0.801 to +0.478. The latter value is safely below the upper limit of 1. Fig. 6 shows an overall comparison of the new curve with the standard curve; Fig. 7 highlights the area around the positive peak.

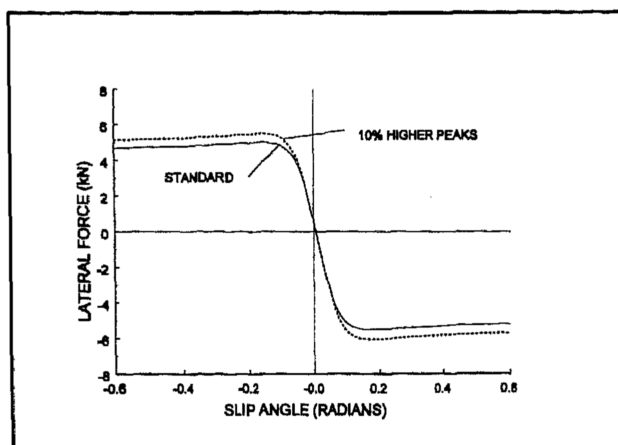

Figure 5. Effect of a 10% Increase in Peak Lateral Force

Changes of the S/P Ratio - We might find it advantageous to modify the S/P ratio of the standard curve downwards by 20% from 0.9 to 0.72; peaks and stiffness remain unchanged. The Paper-Tire program responds withchanges of C by 16 % from 1.29 to 1.49; of B by 14% from 11.84 1/rad to 10.24 1/rad; and of E from -0.801 to -0.036 (well within limits). The resulting new function is compared with the standard function in Fig. 8.

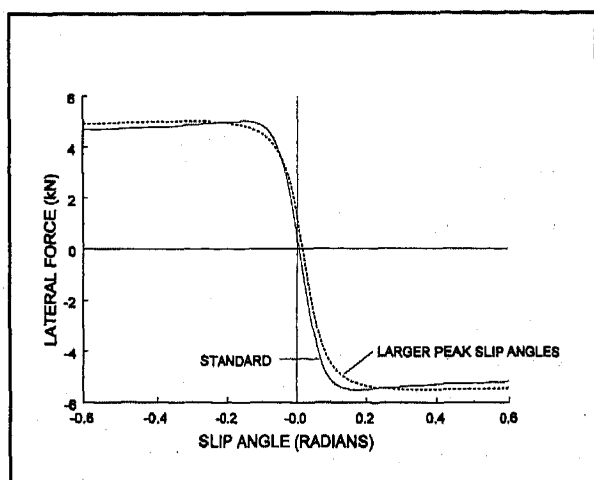

Figure 6. Effect of a 100% Increase in the Slip Angle at Peak Lateral Force

Changes of All Performance Characteristics - As a last example, the effect of simultaneous changes of all physical parameters is demonstrated. We have dropped stiffness S_t by 15% (from -80,000 N/rad to -68,000 N/rad); reduced both the positive and negative peak forces by 10 % (Y_{mp} from -5500 N to -4950 N, and Y_{mn} from 5000 N to 4500 N); increased the two corresponding slip angles by 20% (X_{mp} from 0.18 rad to 0.216 rad, and X_{mn} from -0.16 rad to -0.192 rad); and elevated the S/P ratio R by 5% from 0.90 to 0.95. (Reminder: at R = 1, the peak values recede into the region of very large slip angles.)

As a result, all six MF constants are affected. S_x is increased by 40% from 0.010 to 0.014; S_y dimishes by 10% from -250 N to -225 N; C is reduced by 7% from 1.29 to 1.20; B slightly increased by 1% from 11.84 1/rad to 11.97 1/rad; D reduced by 10% from -5250 N to -4725 N; and E changed a little from -0.801 to -0.965. The resulting new function is compared with the standard function in Fig 9, and, in some detail, in Fig 10.

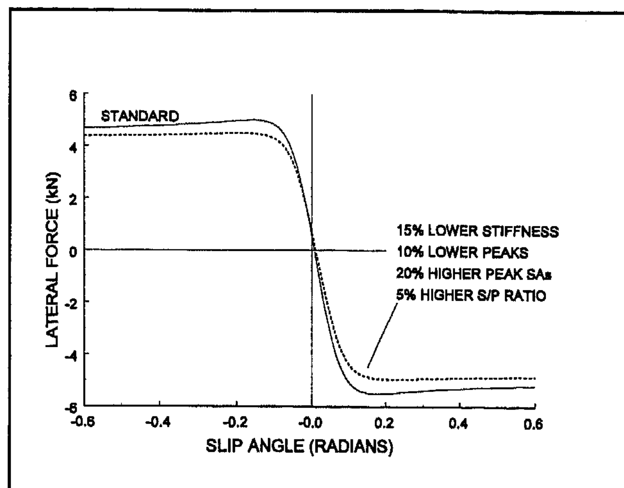

Figure 9 Effect of Making Six Independent Changes at Once

DISCUSSION

The main purpose of the preceding remarks was to demonstrate the principle of the Paper-Tire concept and give some samples of its usefulness and versatility. There appears to be no other tire model presently available that would combine the accuracy of the Magic Formula (accuracy with respect to fitting physical test data) with the convenience and ease offered by the use of generally accepted and physically meaningful performance descriptors.

The Paper-Tire concept is by no means restricted to lateral force/slip angle relations, as exercised here for illustration purposes; any other relation exhibiting the desired features (i.e.,S-shape, and symmetry with respect to a center point located closely to the origin) would be amenable to the Paper-Tire concept. In this general sense, the foregoing must be considered a small part of a potentially much larger body of equations that would include other performance relations such as, the longitudinal force/slip ratio relation; the overturning moment/slip angle relation; and the relation between longitudinal and lateral force for combined braking/driving [3]. For all these and other, similar performance relations, suitable performance descriptors are available that could take the place of the MF constants, so that a total picture of tire performance would evolve based exclusively on conventional performance characteristics, and hence, could be easily modified and optimized.

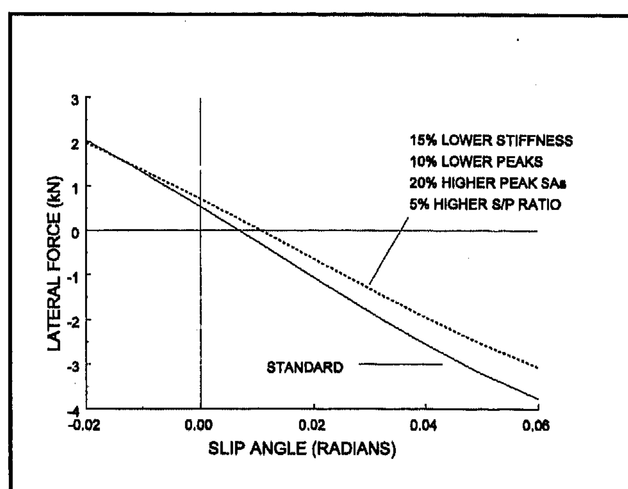

Figure 10 Positive Slip Angle Detail for a Combination of Six Independent Changes

This paper is only the first step toward that goal. Two areas of further development are foreseen: asymmetrical performance curves, and load effects.

Asymmetry - Eq. (1) is not able to directly handle asymmetrical cases where there is no center point and hence imperfect congruence exists between the positive and the negative branches. A case in point is the relation between longitudinal force and slip ratio: the relations for braking (negative slip ratios) and for driving (positive slip ratios) are often different. A proven way out of this is to develop two MF functions -- one for braking and one for driving. The driving function ignores all data for negative slip ratios and covers only data for positive slip ratios; vice versa, the braking function ignores all data for positive slip ratios and covers only data for negative slip ratio. The 'ignored' branches are then dropped and the remaining branches fused together near the origin with identical slopes. Details of this procedure have already been worked out and are available for further processing.

Load Effects - Another problem that must be addressed before universal application of the Paper-Tire Concept becomes feasible is posed by the effect of tire load on pertinent performance descriptors. Vehicle dynamics is inevitably bound up with tire load changes, which in turn influence the numerical values of the descriptors involved. The solution to this problem is rather straightforward. Each of the performance descriptors used in the Paper- Tire Concept, such as cornering stiffness and peak forces, must be expressed as a function of load, so that at any given load a set of numerical descriptor values used as an input to the Paper-Tire program would evolve. The load functions of a given Paper-Tire could be based either on actual data or on hypothetical load-descriptor relations. The latter would provide an additional degree of freedom for determining the 'perfect' tire for the task at hand.

APPENDIX

Eq. (12) in the derivation is repeated as Eq. (A1).

$$\sin(0.5\pi C) = R^* \qquad \text{(A1)}$$

By solving for C, we obtain

$$C = (2/\pi)\sin^{-1}R^* \qquad \text{(A2)}$$

Since the principal values of $\sin^{-1}$ lie in the range$[-\pi/2,\pi/2]$, C satisfies the relation $-1 \leq C \leq 1$. However, Eq. (2) requires that $1 < C < 3$.

We can resolve this discrepancy by considering the portion of the sine curve given below. The value C_1 corresponding to the ordinate value R^* is the principal value as given in Eq. (A2). However there are an infinite number of values of C that satisfy equation A1, including the point C_2. If both C_1 and C_2 satisfy equation A1 for the same value R^* and $-1 < C_1 < 1$, then we have the $1 < C_2 < 3$. Because of the symmetry of the sine curve around the vertical line $C = 1$, we have the $C_1 - 0 = 2 - C_2$. Some elementary algebra produces Eq. (A3) which is also Eq. (13) in the paper.

$$C = 2[1 - (1/\pi)\sin^{-1}R^*] \qquad \text{(A3)}$$

Abstract

The Variable Dynamic Testbed Vehicle (VDTV) concept has been proposed as a tool to evaluate collision avoidance systems and to perform driving-related human factors research. The goal of this study is to analytically investigate to what extent a VDTV with adjustable front and rear anti-roll bar stiffnesses, programmable damping rates, and four-wheel-steering can emulate the lateral dynamics of a broad range of passenger vehicles. Using a selected compact-sized automobile as a baseline, our study indicated this baseline vehicle can be controlled to emulate the lateral response characteristics (including the vehicle's understeer coefficient and the 90% lateral acceleration rise time in a J-turn maneuver) of a fleet of production vehicles, from low to high lateral acceleration conditions. Also, the roll gradient of the baselined vehicle can be altered via changes made to the torsional stiffnesses of the front and/or rear anti-roll bars to emulate the roll stiffnesses of a fleet of production vehicles.

Introduction

To study the correlation between vehicle response characteristics and driver commands relative to crash avoidance, the National Highway Traffic Safety Administration's Office of Crash Avoidance Research (OCAR) has at its disposal a comprehensive set of tools and facilities. These include the Vehicle Research and Test Center, and the (currently being developed) National Advanced Driving Simulator. To augment these tools and facilities, OCAR has defined its concept of a Variable Dynamic Testbed Vehicle (VDTV).[1] This vehicle will be capable of emulating a broad range of automobile dynamic characteristics, allowing it to be used in development of collision avoidance systems, and conducting of driving-related human factors research, among other applications.

Vehicles with "programmable" response characteristics have been proposed and developed in the past. In the 1970's, an experimental vehicle, called Variable Response Vehicle, was developed by the General Motors Corporation for vehicle handling research.[2] It had independent electro-hydraulic controlled front and rear steering actuators and a front steering feel system. These active systems enabled it to emulate a variety of directional control characteristics. In the 1990's, a similar research vehicle, called Simulator Vehicle, was developed by the Nissan Motor Company.[3] Both yaw rate and lateral acceleration response characteristics of this vehicle were varied independently. It was used to study the relation between driver's perception and vehicle handling quality.

To emulate both the lateral and longitudinal response characteristics of a broad range of vehicles, the "mechanical" steering, suspension, and braking sub-systems of a "passive" vehicle must

*To whom all correspondence should be sent.

cles, the "mechanical" steering, suspension, and braking sub-systems of a "passive" vehicle must all be made "programmable". With regard to emulating the lateral response characteristics of vehicles, an earlier study[4] indicated that the VDTV must have the following active sub-systems: (1) steering: steer-by-wire, programmable steering feel as well as four-wheel-steering, and (2) suspension: semi-active suspension as well as variable front and rear anti-roll bar systems. Other active sub-systems considered in Reference 4 (such as the brake-by-wire and throttle-by-wire systems) were not included in this study.

Equipped with the above mentioned actively controlled systems, the lateral response characteristics of the VDTV can be conveniently altered via the governing control algorithms. However, it was not clear what range of production vehicles could be emulated by such a variable dynamic vehicle. One objective of the dynamics analysis was to gain a quantitative understanding on the "emulability" of such a variable dynamic vehicle. The second objective was to generate quantitative information for the functional requirements document[14] that accompanied the VDTV Request for Proposal.

Scope and Approach of Dynamics Analysis

The scope and approach taken in the dynamics analysis are as follows:

1. A vehicle dynamics simulation program, called Vehicle Dynamic Analysis, Nonlinear (VDANL) was selected as the simulation tool to perform all the vehicle dynamic computations.

2. The VDANL program has parameter files for about twenty passenger vehicle models. Only five models were selected to represent a broad range of production passenger vehicles.

3. Three performance metrics were selected to characterize both the steady-state and transient lateral responses of these production vehicle models in "representative" cornering maneuvers.

4. One of the five models studied was selected as the baseline VDTV. However, to account for the added weights of the data acquisition system, four-wheel-steering system, etc., several vehicle and tire parameters of the selected vehicle model were modified accordingly.

5. Two sensitivity analyses were made to assess to what degree vehicle performance metrics selected in step (3) are influenced by the following vehicle parameters: (a) the torsional stiffnessess of the front and rear anti-roll bars, and (b) the damping rates of the suspension shock absorbers.

6. A simulation study was made to assess to what extent the understeer coefficient and speed of lateral response of the five production vehicles selected in step (2) can be emulated by a four-wheel-steered VDTV.

7. The Consumers Union obstacle avoidance course (to be described latter) was used to objectively evaluate the handling qualities of passenger vehicles during emergency double lane change maneuvers. The performance of the baseline VDTV in making double lane change maneuvers using different combinations of tires and four wheel steering control algorithm were compared.

Results obtained from these seven steps are given in the following sub-sections.

Vehicle Dynamics Simulation Program

A vehicle dynamics simulation program, developed by Systems Technology, Incorporated, called "Vehicle Dynamics Analysis, Non-Linear" (VDANL) was used in this research. This program was originally developed to study the performance of vehicle/driver systems in a variety of driving scenarios and conditions, and to study vehicle lateral control and stability.[5]

A signal flow diagram of the program VDANL is depicted in Figure 1 (from Reference 6). The program VDANL has a total of seventeen degrees-of-freedom (DOFs). The block labeled "Vehicle Dynamics" (in Figure 1) has six DOFs

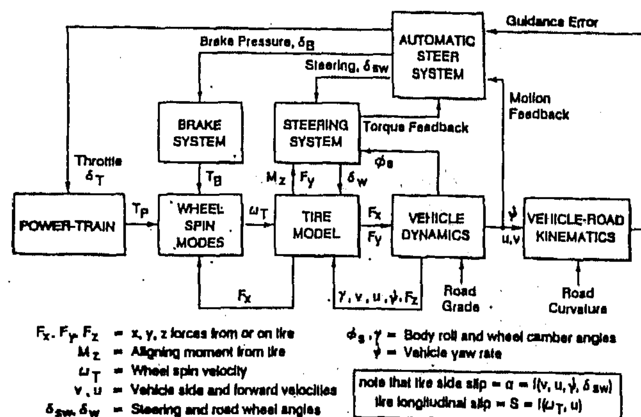

Figure 1: Flow diagram of the VDANL vehicle dynamic simulation program

for the sprung mass and three DOFs each for the front and rear unsprung masses. In the block labeled "Tire Dynamics," four DOFs for the rotational speeds of the four wheels are included. Finally, one degree of freedom each is contained in the blocks labeled "Steering System", "Brake System", and "Power Train." Representative vehicle and tire parameters that must be supplied for a typical simulation run are tabulated in Table 1 for the five passenger vehicle models that were selected in step (2).

The suspension system modeled in VDANL exerts forces on three lumped masses. Two unsprung masses represent the front and rear axles with tires, and one sprung mass represents the vehicle's body. Rather than model each component of the suspension individually, VDANL uses composite characteristics of all components to calculate overall suspension dynamics. This method produces less complicated calculations and a significant reduction in data size. The simulation program VDANL also includes an option of using both front and rear anti-roll bars to provide extra auxillary roll stiffness.

The simulation program VDANL uses a comprehensive tire model that includes the effects of road surface interaction and saturation limit. This assures accurate representations of real driving conditions, from low-g to limit lateral maneuvers, and for combined lateral and longitudinal maneuvers (for example, brake-in-a-turn). The program VDANL uses tire parameters defined by the Calspan Corporation (cf. Table 1) that contain parameters for cornering stiffness, camber stiffness, lateral and circumferential friction, aligning torque, as well as overturning moment.

Besides the above mentioned models, the simulation program VDANL also provides a "closed-loop" driving capability by using the block labeled "Automatic Steer System." This block contains internal algorithms that a human driver uses to generate the required steering, braking, and throttle commands. It can also represent how an autonomous steering system generates the needed steering commands. Furthermore, an "Open" module option provides an interface between a user-supplied "subroutine" and the main program. In this research, we used this option to implement four-wheel-steering control algorithms.

Data predicted by VDANL have been extensively validated via road tests for a wide variety of vehicles and driving conditions.[6–9] Results obtained using the simulation program were found to represent measured vehicle responses quite well for most vehicles and maneuvers.

Selected Production Vehicle Models

Five production passenger vehicle models were selected in this study to represent a fleet of passenger vehicles for the VDTV to "emulate." These represented a wide spectrum in vehicle weight: from "small," "compact," "mid-sized," to "full-sized" passenger vehicles. Additionally, these five vehicle models were selected because they span wide ranges in both wheelbase ratio and track width ratio. The wheelbase ratio, the ratio between the vehicle's wheelbase and its center of gravity (c.g.) height $(L/h_{c.g.})$, is strongly related to the amount of weight transfer between the rear and front wheels during acceleration/deceleration maneuvers. Track width ratio, the ratio between the vehicle's halved track width and c.g. height $(tw/2h_{c.g.})$, is strongly related to the amount of weight transfer between the inside and outside wheels during lateral cornering ma-

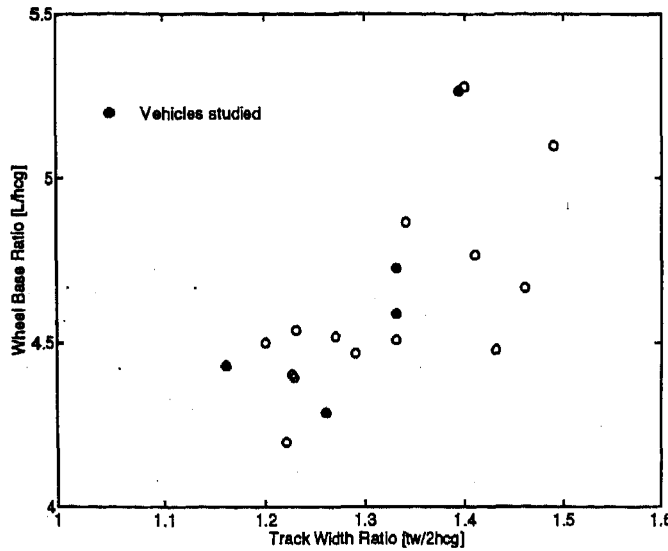

Figure 2: Vehicle's wheelbase ratios versus trackwidth ratios

A plot of wheelbase ratios versus track width ratios for five production vehicles is shown in Figure 2. In that figure, the "o"s denote the wheelbase and track width ratios combinations of production vehicle models with parameter files available from the VDANL program. The "•"s represent the five selected passenger vehicle models. Clearly, the selected vehicles span good ranges in both the wheel base ratios and the track width ratios. Estimated values of other vehicle and tire parameters are tabulated in Table 1. See Appendix E of Reference 10 for the estimated values of vehicle and tire parameters that are not given in Table 1.

Steady-state and Transient Lateral Response Characteristics of Passenger Vehicles

Using the simulation program VDANL, and estimates of vehicle and tire parameters given in Table 1, three steady-state and transient lateral response performance metrics of the five selected passenger vehicles were computed. Results are given in the following sections.

The steady-state handling quality of a vehicle can be characterized by its understeer coefficient (K_u, in deg/g). The understeer coefficient, defined in sub-section 9.4.7 of Reference 11, can be understood using the following steady-state cornering equilibrium equation:

$$\delta_T = \delta_{SW}/N_S = \overbrace{57.3L/R}^{Ackerman\ angle} + K_u a_y\,, \qquad (1)$$

where,

δ_T = tire angle (deg),
δ_{SW} = steering wheel angle (deg),
N_S = steering ratio (-),
L = wheel base (m),
R = turning radius (m),
K_u = understeer coefficient (deg/g),
a_y = lateral acceleration at vehicle's c.g. (g).

From this equation, the understeer coefficient of a vehicle can be determined with a "turn circle" maneuver. In this maneuver, the forward speed of the vehicle is kept constant at, for example, 80 km/h. The steering wheel angle is increased slowly at an uniform rate of about 5 deg/sec until the limit lateral acceleration of the vehicle is reached. A cross plot between the lateral acceleration of the vehicle's c.g. on the X-axis and the steering wheel angle on the Y-axis can then be generated. From this plot, the understeer coefficient is determined as follows:

$$K_u = \frac{1}{N_S}\frac{\partial \delta_{SW}}{\partial a_y} - 57.3\frac{gL}{U^2}\,. \qquad (2)$$

The first term on the right hand side of equation (2) can be derived from the instantaneous slope of the a_y versus δ_{SW} plot at a given lateral acceleration. The variable "U" in the second term represents the forward speed of the vehicle. That term can be easily computed if we know the wheelbase of the vehicle as well as the speed at which that simulation run was performed. Results obtained from these turn circle maneuvers are given in two cross plots: vehicle's lateral acceleration versus the steering wheel angle (Figure 3), and lateral acceleration versus the understeer coefficient (Figure 4), for the five selected passenger vehicles. From Figure 4, we note that the understeer coefficients of these vehicles remain unchanged when the lateral acceleration of the vehicle is lower than about 0.3 g. However, these understeer coefficients increase drastically as their respective limit lateral acceleration levels are approached. These results are fairly representative for most passenger vehicles.

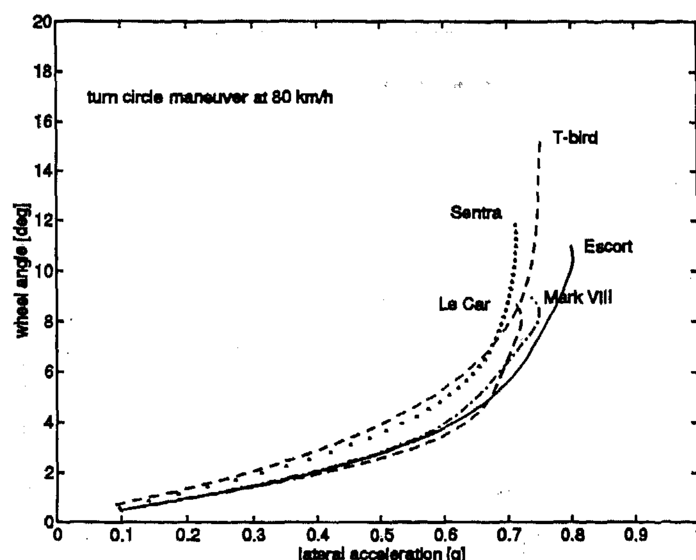

Figure 3: Turn circle maneuver, steering wheel angle versus lateral acceleration

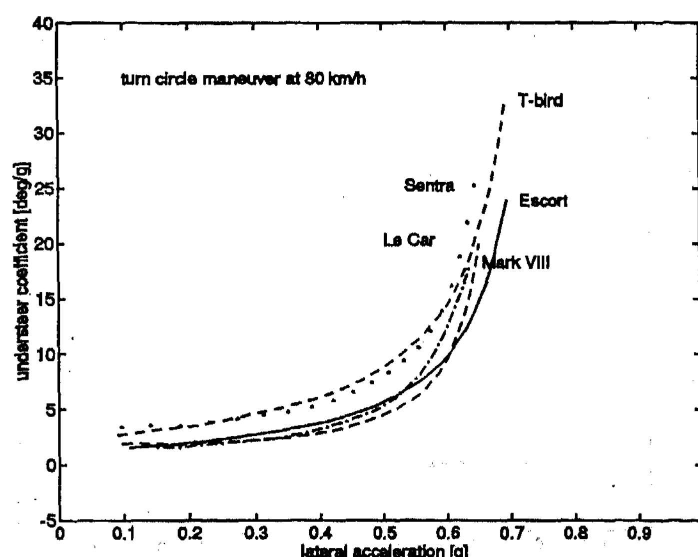

Figure 4: Turn circle maneuver, understeer coefficient versus lateral acceleration

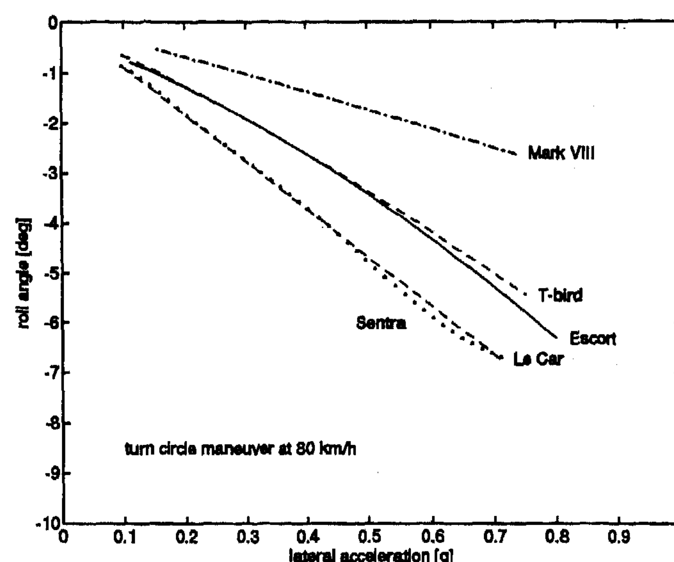

Figure 5: Turn circle maneuver, roll angle versus lateral acceleration

Another performance metric commonly used to characterize the steady-state vehicle handling quality of a vehicle is its control sensitivity (in g/deg). The control sensitivity of a vehicle at a given forward speed is also known as its steering sensitivity or lateral acceleration gain. In equation (1), the vehicle control sensitivity is given by a_y/δ_{SW}. The relation between the vehicle's control sensitivity and its understeer coefficient is given by:

$$\frac{a_y}{\delta_{SW}} = \frac{1}{N_S}[\ K_u + 57.3\frac{gL}{U^2}\ ]^{-1}. \qquad (3)$$

Since the vehicle's control sensitivity can be computed using the understeer coefficient, only the understeer coefficient is used in this study.

The roll gradient of a vehicle can also be determined using data obtained from the turn circle maneuver. A vehicle's roll gradient, defined in sub-section 9.4.19 of Reference 11, can be determined from a cross plot between the lateral acceleration of the vehicle's c.g. and the vehicle's roll angle. Results obtained for the five passenger vehicles are depicted in Figure 5 wherein we note that the roll gradients of full-size vehicles tend to be small, while the reverse is true for small and compact vehicles.

The transient lateral response characteristics of the vehicles are compared using the "90% rise

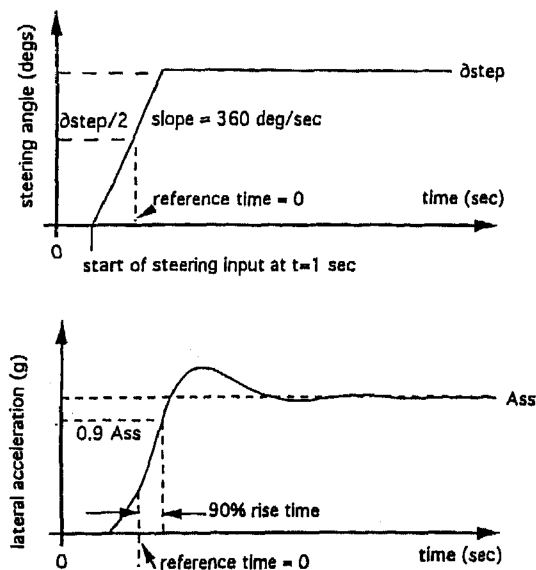

Figure 6: Steering wheel angle and vehicle's lateral acceleration during a J-turn maneuver

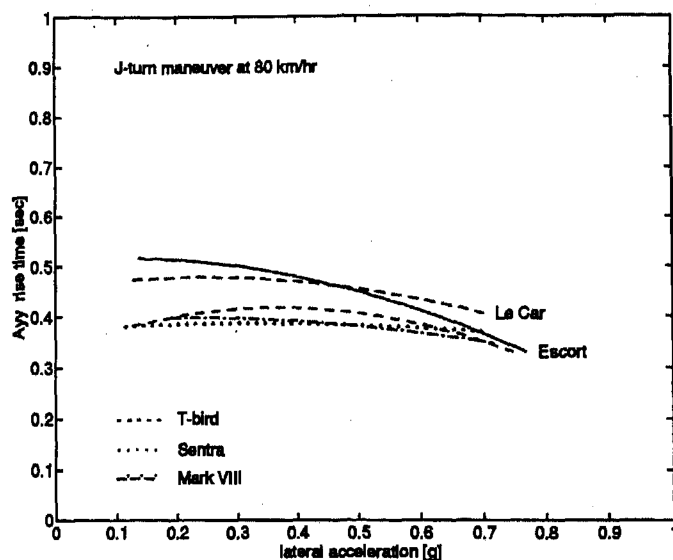

Figure 7: J-turn maneuver, 90% rise time versus lateral acceleration

times" of their lateral acceleration responses. The 90% rise time is a measure of the vehicle's "speed of response" when it is subjected to a "step" steering wheel command. Since a true "step" is physically impossible, the steering command is ramped to its steady-state value at an uniform rate of 360 degrees per second. The resultant maneuver is commonly called a J-turn maneuver. The 90% rise time is defined as the time it takes the vehicle's lateral acceleration to reach 90% of its steady-state value, as measured from the time the steering command reaches 50% of its steady-state value. See Figure 6 and Reference 12 for further details. Plots of the 90% rise time versus the vehicle's lateral acceleration, for the five selected passenger vehicles are depicted in Figure 7.

The speed of lateral response of a vehicle can also be measured using frequency-domain performance metrics such as the vehicle's lateral acceleration -3 dB bandwidth (in Hz). This is the frequency at which the magnitude of the transfer function, from the steering wheel to the vehicle's lateral acceleration, has dropped below 70.7% of its steady-state value. Again, there is a strong correlation between the vehicle's 90% rise time and its lateral acceleration bandwidth. For the 1989 Escort, that correlation is depicted in Figure 8: the larger the bandwidth, the smaller the 90% rise time. A linear approximation between

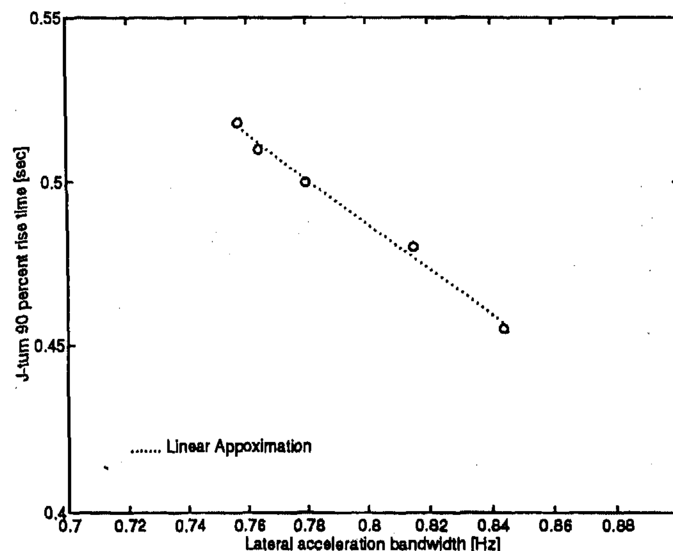

Figure 8: Correlation between vehicle bandwidth and 90% rise time

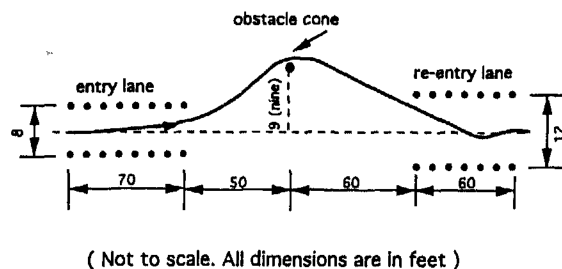

Figure 9: Consumers Union obstacle avoidance course

the bandwidth and rise time is given by:

$$t_{rise} \approx 1.0381 - 0.6888 \times BW\,. \qquad (4)$$

Here, BW is the vehicle's lateral acceleration bandwidth in Hz, and t_{rise} is the vehicle's J-turn 90% rise time in seconds. Since the lateral acceleration bandwidth is closely correlated with the 90% rise time, only the rise time is used in our study.

The Consumers Union obstacle avoidance course, depicted in Figure 9, was used to objectively evaluate the handling quality of passenger vehicles during emergency double lane change maneuvers. Details of this obstacle avoidance course are defined in Reference 13. The maximum speed that a passenger vehicle can successfully complete the double lane change maneuver is denoted by U_{max}. The magnitude of U_{max}, in km/hr, is another lateral response performance metric used in our study.

Selected Baseline Vehicle

For the purpose of dynamics analyses, the 1989 Ford Escort was selected as the baseline variable dynamic testbed vehicle. The following modifications are made to the production model to account for the added weights of the data acquisition system, four wheel steering actuator mechanism, and others:

- Sprung mass and moment of inertia of the production Escort were each increased by 28%. However, these inertia properties were increased without altering the longitudinal, lateral, and vertical positions of the vehicle's overall c.g. location.
- Spring rates and damper rates of the production vehicle's suspension were each increased by 28%. Since the vehicle sprung mass was increased by 28%, there was no change in either the frequency or damping ratio of the vehicle's heave mode.
- Torsional stiffness of the front anti-roll bar of the production Escort was increased by 28% (in magnitude). The production Escort has no rear anti-roll bar.
- "Larger" tires were selected for the modified Escort. The tire model used is P195/75R14.

With these modifications, the weight and moment of inertia of the "compact" Escort were now midway between those of "compact" and "mid-sized" vehicles. It was judged that such a modified Escort could better emulate the lateral response characteristics of both the "small" and "compact" production vehicles, that have higher accident statistics. If a mid-sized vehicle had been selected instead as the baseline vehicle, the added weights would have caused its weight to approach that of a "full-size" vehicle. This heavier baseline vehicle might not have been able to emulate the lateral response characteristics of both the "small" and "compact" vehicles as well.

Sensitivity Analyses

Two types of sensitivity analyses were performed to assess the degree that selected vehicle performance metrics could be influenced by two vehicle parameters: effects of (1) the torsional stiffnessess of the front and rear anti-roll bars on the vehicle's roll gradient, and (2) the damping rates of the suspension shock absorbers on the 90% rise time of the vehicle in J-turn maneuvers.

Five anti-roll bar configurations used in this study are depicted in Figure 10. In that figure,

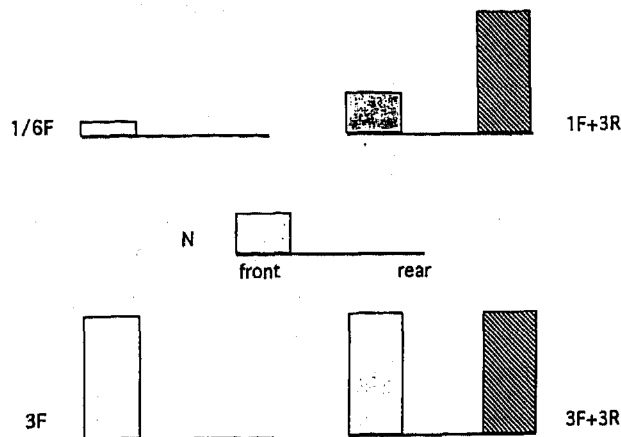

Figure 10: Anti-roll bar stiffness configurations used in a sensitivity analysis

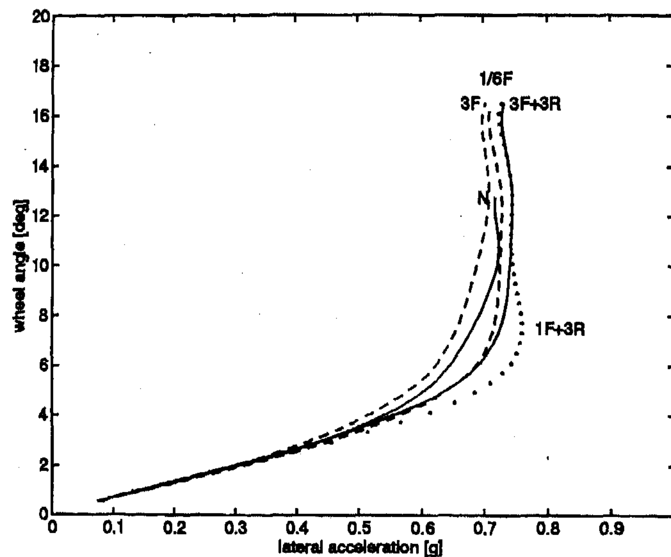

Figure 11: Turn circle maneuver results for five anti-roll bar configurations

"N" denotes for the "nominal" anti-roll bar configuration of the baseline VDTV: stiffnesses of the front and rear anti-roll bars are -288.6 and 0 Nm/deg, respectively (the baseline VDTV does not have a rear anti-roll bar). The stiffnesses of all the other anti-roll bar configuration variants are multiples of the nominal front anti-roll bar stiffness. For example, the front and rear anti-roll bar stiffnesses of the configuration labeled "1F+3R" are -288.6 and -865.8 Nm/deg, respectively.

Plots of steering wheel angle versus the vehicle's lateral acceleration obtained in turn circle maneuvers, for the five anti-roll bar configurations, are compared in Figure 11. Plots that compare the vehicle's understeer coefficient, roll gradient, and 90% rise time in a J-turn maneuver are given in Figures 12, 13, and 14, respectively. From Figure 12, we observe:

- For low-g (below 0.3 g) maneuvers, the anti-roll bars' stiffnesses have very little effect on the vehicle's understeer coefficient.
- At high-g conditions, the anti-roll bars' stiffnesses have the following influences on the vehicle's understeer coefficient:
  - understeer coefficient is increased by an increase in the front anti-roll bar stiffness. See results obtained for the "3F" configuration.

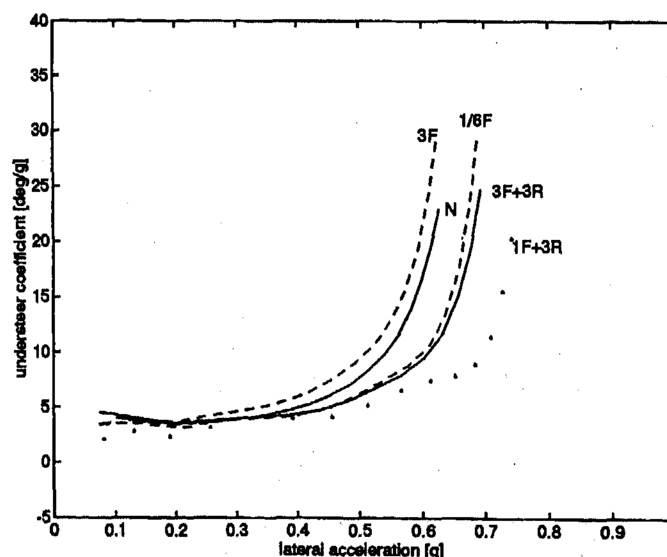

Figure 12: Understeer coefficient results for five anti-roll bar configurations

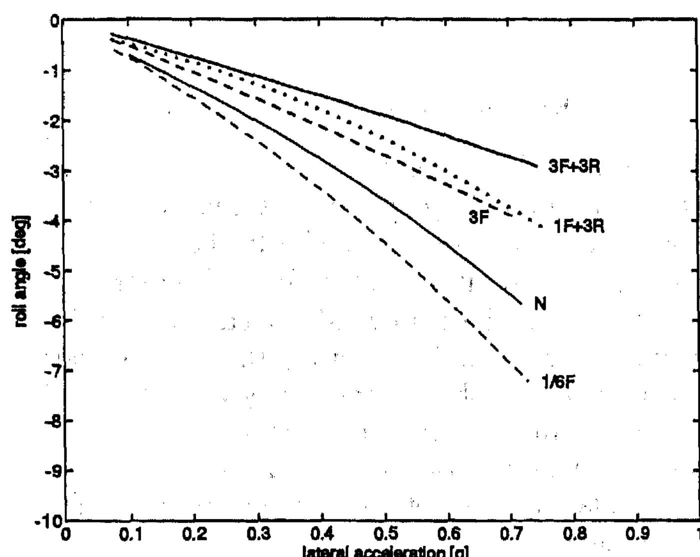

Figure 13: Vehicle roll gradient results for five anti-roll bar configurations

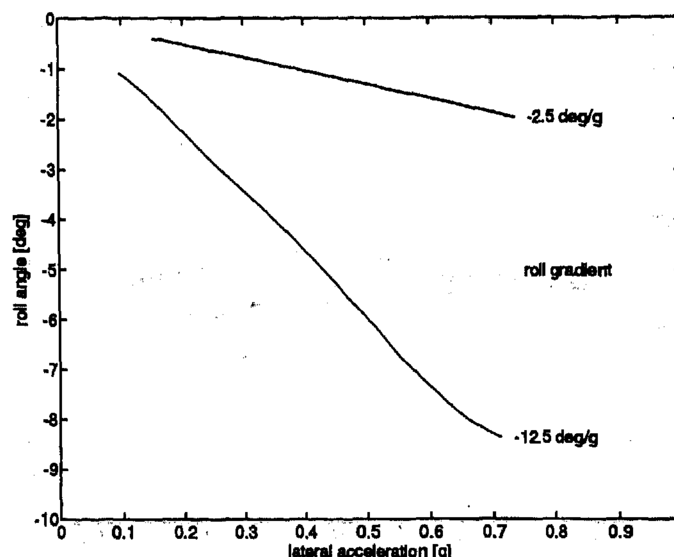

Figure 14: Emulation range of an active anti-roll bar controlled system

- understeer coefficient is decreased by an increase in the rear anti-roll bar stiffness. See results obtained for the "1F+3R" configuration. Alternatively, the vehicle's understeer coefficient can be decreased by decreasing the front anti-roll bar stiffness. See results obtained for the "$\frac{1}{6}$F" configuration.

From Figure 13, we conclude that the stiffnesses of the anti-roll bars have a dominant influence on the vehicle's roll gradient. The larger the magnitude of the total anti-roll bar stiffness (sum of both the front and rear anti-roll bar stiffnesses), the smaller is the vehicle's roll gradient. Hence, the roll gradient for the "3F+3R" configuration is the smallest among the five configurations studied. Hence, changing the stiffnesses of the vehicle's anti-roll bars (either mechanically or by using active anti-roll bar controlled systems) is an effective way to alter the vehicle's roll gradient. The alternative of using a fully active suspension system to control the vehicle roll gradient is likely to be more expensive.

The specified emulation range of the VDTV's roll gradient, depicted in Figure 14, is obtained using results depicted in Figure 13: (a) the lower limit is obtained by reducing 25% from the roll gradient of the "3F+3R" configuration, and (b) the upper limit is obtained by adding 25% to the roll gradient of the "$\frac{1}{6}$F" configuration. This specified emulation range of the vehicle's roll gradient also appeared in Section 7.1.2 of Reference 14. Note also that the upper and lower roll gradient limits depicted in Figure 13 completely envelop the a_y versus roll angle plots of the five passeneger vehicles given in Figure 5.

The effects that anti-roll bar stiffnesses have on the 90% rise time in J-turn maneuvers are less obvious. However, the following trends are observed in Figure 15:

- vehicle becomes more responsive (with a smaller J-turn 90% rise time) if the stiffness of the front anti-roll bar is increased. See results obtained for the "3F" configuration.

- vehicle becomes less responsive (with a larger J-turn 90% rise time) if the stiffness of the front anti-roll bar is decreased. See results obtained for the "$\frac{1}{6}$F" configuration.

- vehicle also becomes less responsive (with a larger J-turn 90% rise time) if the stiffness of the rear anti-roll bar is increased. See results obtained for the "1F+3R" configuration.

The objective of the second set of senstivity analyses was to assess to what degree the damping rates of the vehicle suspension influence the

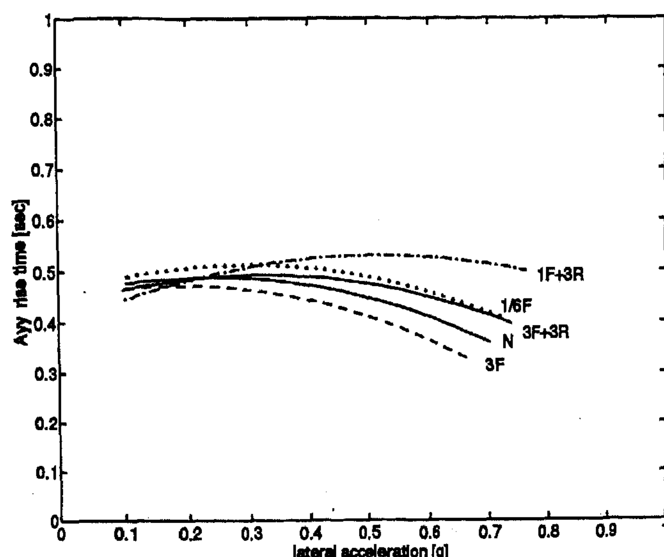

Figure 15: Rise time results for five anti-roll bar configurations

vehicle's J-turn 90% rise time. This analysis was performed for the Jet Propulsion Laboratory by Systems Technology Incorporated. Results obtained are summarized in the following two paragraphs while the details are given in Reference 15.

Three sets of damper rates were used in the sensitivity analyses. The "hardest" damping rates are: at a piston speed of 75 cm/sec, the damping forces are 3400 and 900 Newtons in extension and compression, respectively. The "softest" damping rates are: at a piston speed of 75 cm/sec, the damping forces are 1200 and 670 Newtons in extension and compression, respectively. The nominal damping forces are between those of the "hardest" and "softest" dampers. These damping rates are identical to those specified in sub-section 4.3.8 of Reference 14.

Using the above mentioned damping rates, the 90% rise times of a vehicle in a 80 km/hr 0.22 g J-turn maneuver were determined using VDANL. The 90% rise times obtained were 0.43, 0.51, and 0.49 seconds for the "softest," "nominal," and "hardest" damping rates, respectively. Differences among these rise times are quite small. Considering the accuracy of the VDANL simulation program, we concluded that suspension damping rates do not significantly influence the speed of response of a vehicle in cornering maneuvers.

Four-Wheel-Steering Control Algorithms

The lateral dynamics of a vehicle can be substantially altered by steering its rear wheels in conjunction with the front wheels. For example, the control sensitivity of a four-wheel-steering vehicle at a given forward speed can be increased/decreased by steering the rear wheels out-of-phase/in-phase respectively with the front wheels. Additionally, the transient lateral response characteristics of the vehicle can also be manipulated via carefully designed rear steering algorithms.

Both open-loop and closed-loop 4WS algorithms have been proposed and used in vehicle research.[16–19] Closed-loop 4WS algorithms use selected vehicle measurements (for example, vehicle's yaw rate) as well as the driver's steering command to control the rear steering actuator. On the other hand, open-loop algorithms do not feedback any vehicle measurements. The open-loop and closed-loop control algorithms described in the following sub-section are taken from Reference 19. They are given here to illustrate the flexibility available to alter the lateral response characteristics of a VDTV via four-wheel-steering algorithms.

- 4WSN Algorithm: This is an open-loop algorithm first suggested by Nissan Motor Company. Using a vehicle model, a speed-dependent ratio between the rear and front wheels is computed in order to achieve zero steady-state side velocity:

$$\delta_{rc}/\delta_{fc} = K_N(U)\,. \qquad (5)$$

  Here, δ_{fc} equals the driver steering wheel command divided by the steering ratio. The command to the rear steering actuator is given by δ_{rc}. The variable U is the forward speed of the vehicle. The function K_N is the "Nissan" ratio. At low speeds, the rear wheels are steered out-of-phase with the front wheels (i.e., K_N is negative) to enhance the vehicle maneuverability. At high speeds, the rear wheels are steered in-phase with the front

wheels (i.e., K_N is positive) to enhance the vehicle lateral stability. However, the lateral forces generated by both the front and rear wheels counteract one another, and the response time of the vehicle's yaw rate may deteriorate. To overcome this problem, we delay the steering of the rear wheel by τ_D seconds:[17]

$$\delta_{rc}(t) = K_N(U)\,\delta_{fc}(t - \tau_D)\,. \qquad (6)$$

The delay time τ_D is on the order of 0.1 seconds. The parameters K_N and τ_D in this "delayed" Nissan algorithm can be used to alter the steady-state and transient response characteristics of the vehicle, respectively.[17] Numerous other open-loop 4WS algorithms have also been suggested. See, for example, Reference 18. However, open-loop algorithms were not used in our study.

4WSY Algorithm: This is a simple closed-loop algorithm with feed-forward of the front steering command and feedback of the vehicle's yaw-rate:

$$\delta_{rc} \;=\; K_1(U)\,\delta_{fc} + K_2(U)\,r\,. \qquad (7)$$

Here, the variable δ_{fc} was defined in connection with the 4WSN algorithm. The variable r is the filtered yaw rate of the vehicle. This closed-loop 4WS algorithm, depicted in Figure 16, was the main focus of our study.

In equation (7), the feed-forward gain $K_1(U)$ chiefly alters the vehicle's steady-state responses. On the other hand, the feedback gain $K_2(U)$ affects both the steady-state and transient characteristics of the vehicle. Both parameters must be selected with care. The rear steering angle increases monotonically with the magnitude of K_1. Since the maximum rear steering actuator excursion is typically bounded (say, not more than 10 degrees), the magnitude of K_1 must be selected within this physical constraint. On the other hand, feeding back the vehicle's yaw rate can

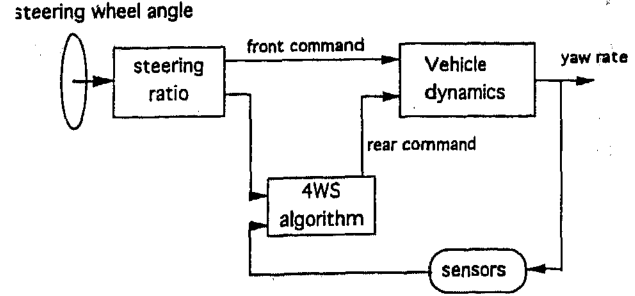

Figure 16: Four wheel steering controlled configuration

degrade the closed-loop stability of a four-wheel-steering vehicle. Care must be exercised to ensure that the damping ratio of the vehicle's yaw mode is always above a preselected minimum level. Appropriately selected, these control parameters allow us to vary the lateral dynamics of the VDTV so that it emulates the response characteristics of a broad range of vehicles.

For simplicity, the control parameters K_1 and K_2 are not made functions of the vehicle's forward speed in our study. In practice, they can be made functions of both the vehicle's forward velocity and other vehicle measurements such as its lateral acceleration. Other closed-loop 4WS algorithms have also been proposed in the literature.[18–19]

Plots of steering wheel angle versus the vehicle's lateral acceleration obtained from turn circle maneuvers, for four combinations of control parameters (K_1, K_2) are compared in Figure 17. In that figure, 4WS control algorithms that steered the front and rear wheels "in-phase" have positive K_1, and are denoted by "I1" and "I2". On the other hand, 4WS control algorithms that steered the front and rear wheels "out-of-phase" have negative K_1, and are denoted by "O1" and "O2". Plots that compare the understeer coefficients of the nominal two-wheel-steering vehicle, and the "I2" and "O2" four-wheel-steering vehicles are

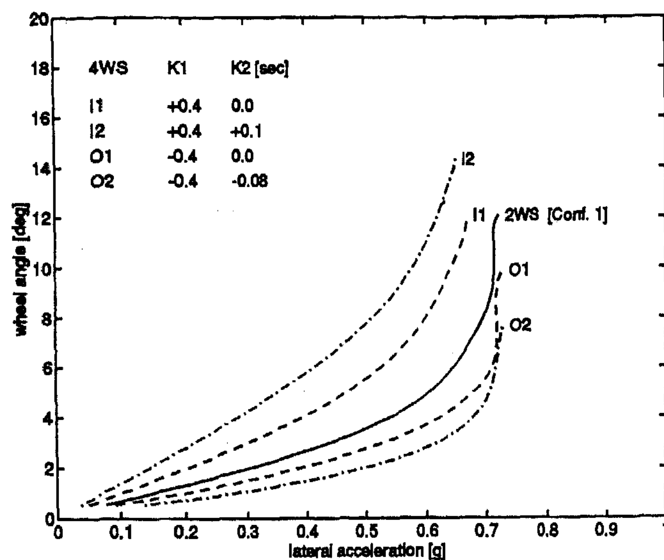

Figure 17: Turn cicrle maneuver results obtained with 4WS VDTV [Configuration I]

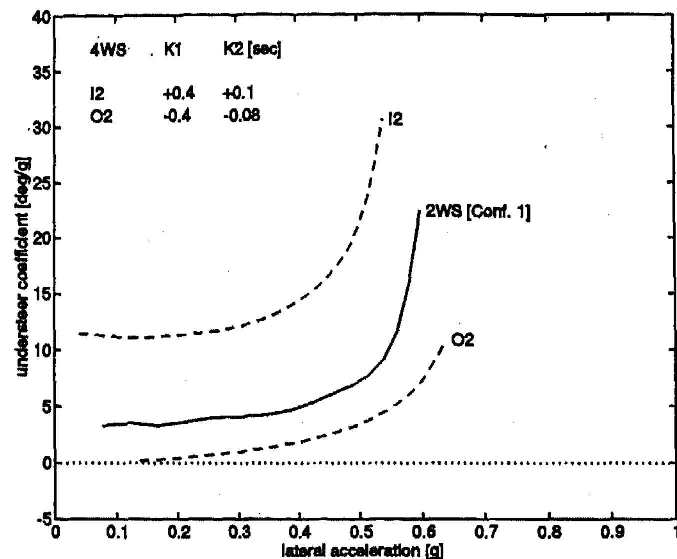

Figure 18: Understeer coefficient results obtained with 4WS VDTV [Configuration I]

shown in Figure 18. For clarity, results obtained for the "I1" and "O1" four-wheel-steering vehicles are omitted in that figure. The following observations can be made from Figure 18:

- the understeer coefficient of the four-wheel-steering vehicle is increased by steering the rear wheels in-phase with the front wheels, and can be further increased by having a negative yaw rate feedback (with positive K_2).
- the understeer coefficient of the four-wheel-steering vehicle is decreased by steering the rear wheels out-of-phase with the front wheels, and can be further decreased by having a positive yaw rate feedback (with negative K_2).

In Figures 17 and 18, the two-wheel-steering vehicle is denoted by "2WS [Configuration I]." Results obtained for a second two-wheel-steering vehicle, denoted by "2WS [Configuration II]" are given in Figures 19 and 20. The main difference between these two configurations is: all four tires used in the "Configuration I" are P195/75R14 tires (that are used by the Toyota Van in Reference 10). For "Configuration II", the two front tires of "Configuration I" are replaced by two P195/75R14 tires (that are used by the Chevrolet S10 in Reference 10).

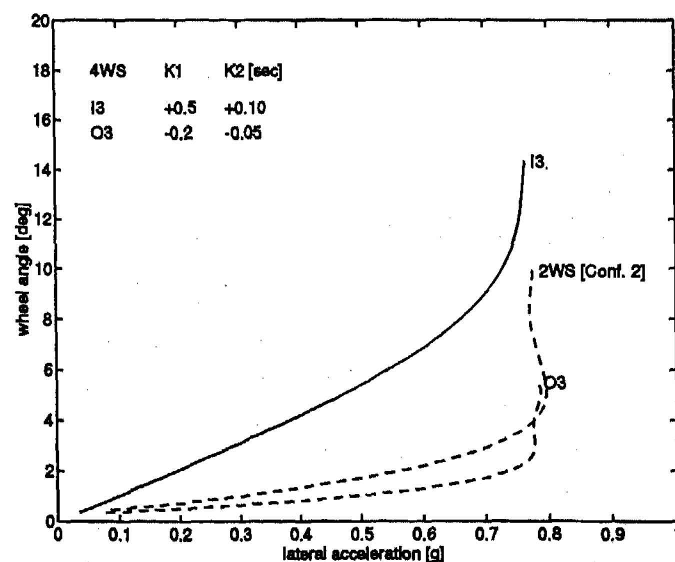

Figure 19: Turn cicrle maneuver results obtained with 4WS VDTV [Configuration II]

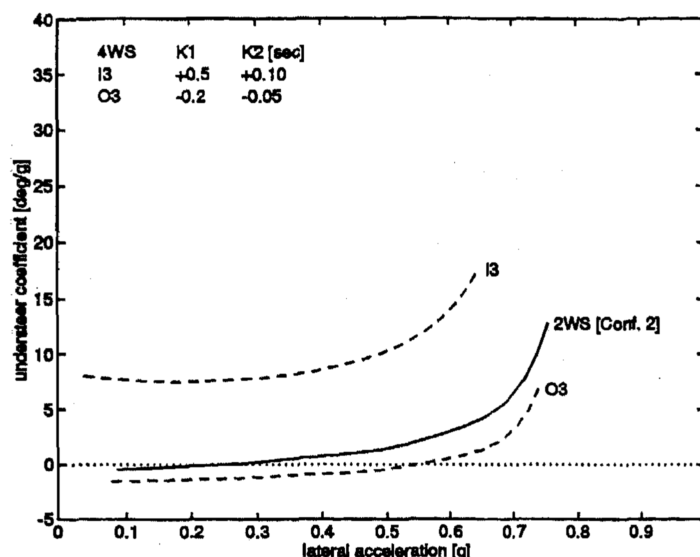

Figure 20: Understeer coefficient results obtained with 4WS VDTV [Configuration II]

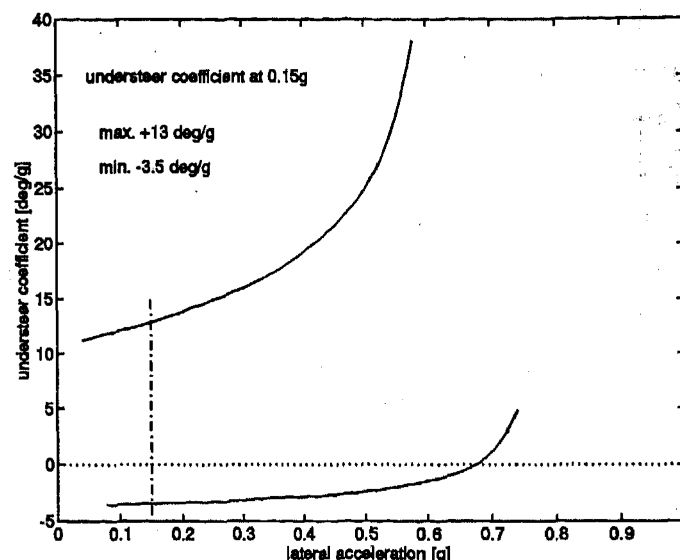

Figure 21: Emulation range of the VDTV understeer coefficient

Turn circle maneuver results obtained with the second two-wheel-steering vehicle and its four-wheel-steering derivatives are given in Figures 19 and 20. In Figure 20, the second two-wheel-steering vehicle controlled by the "O3" 4WS algorithm can generate negative understeer coefficient (i.e., oversteer). The emulation range of the VDTV's understeer coefficient, estimated using results given in Figures 18 and 20, is depicted in Figure 21. The upper bound in that figure was obtained by adding 25% to the result obtained for the "I2" four-wheel-steering vehicle (see Figure 18). The lower bound in that figure was obtained by subtracting 2.5 deg/g from result obtained for the "O3" four-wheel-steering vehicle (see Figure 20).

The effects that 4WS control algorithms have on the vehicle's 90% rise time in J-turn maneuvers are fairly significant. The following observations can be made from Figure 22:

- vehicle becomes more responsive (with a smaller J-turn 90% rise time) if the front and rear tires are steered in-phase and with a negative yaw rate feedback (positive K_2). See results obtained for the "I3" four-wheel-steering vehicle.
- vehicle becomes even more responsive if the stiffness of the front anti-roll bar is increased.

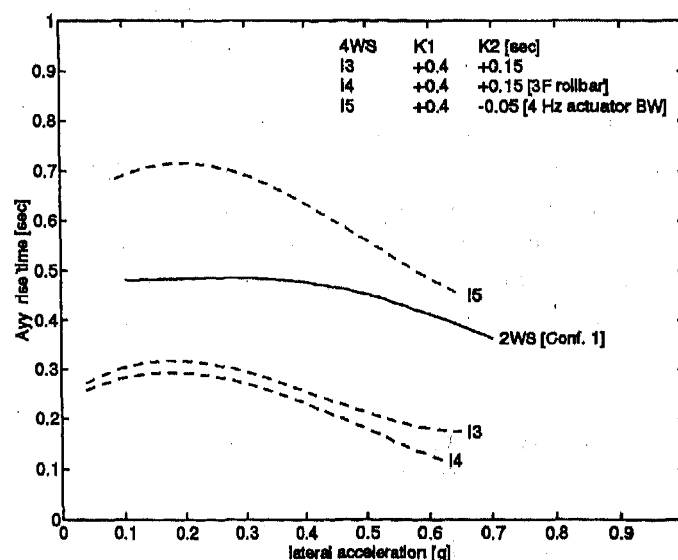

Figure 22: Rise time results obtained with a 4WS VDTV

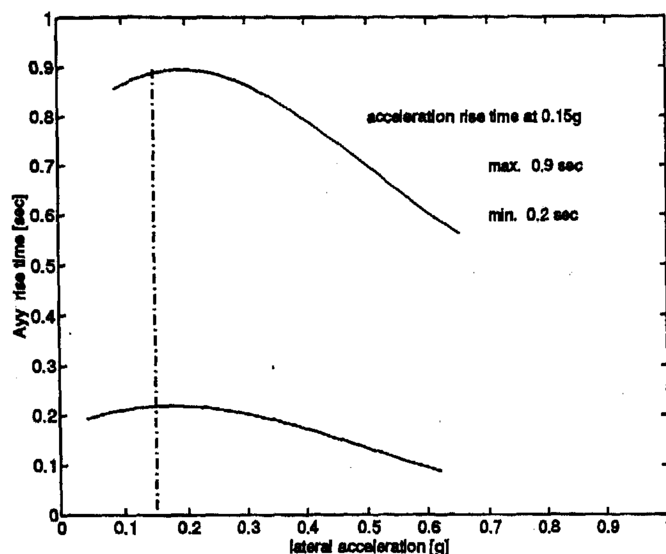

Figure 23: Emulation range of the VDTV J-turn 90% rise time

See results obtained for "I4" four-wheel-steering vehicle.

- vehicle becomes less responsive (with a larger J-turn 90% rise time) if the front and rear tires are steered in-phase and with a positive yaw rate feedback (negative K_2), as well as using a steering actuator with a lower bandwidth of 4 Hertz (the nominal bandwidth of the steering actuator is on the order of 10 Hz). See results obtained for the "I5" four-wheel-steering vehicle.

The emulation range for the VDTV's J-turn 90% rise time is depicted in Figure 23. The upper and lower bounds in that figure are obtained by increasing and decreasing, respectively, 25% of results obtained by the "I5" and "I4" four-wheel-steering vehicles that are depicted in Figure 22.

Results obtained from the Consumers Union Obstacle Course

Consumers Union obstacle avoidance course, depicted in Figure 9, was used to objectively evaluate the handling qualities of passenger vehicles during emergency double lane change maneuvers. Details of this obstacle avoidance course are defined in Reference 13. The VDANL closed-

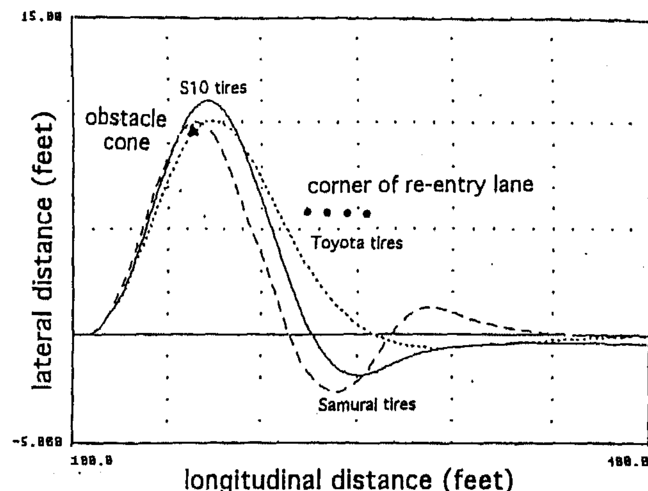

Figure 24: Obstacle avoidance lane change maneuver results

loop crash avoidance option was used to determine the maximum speed at which the baseline VDTV (with P195/75R14 Toyota Van tires) can successfully complete this double lane change maneuver. This analytical simulation was then repeated on two other VDTV variants: the first has P195/75R14 Chevrolet S10 tires and the second has P205/70R15 Samurai tires. The maximum speed was found using the Samurai tires, and was 52.7 km/hr. In Section 3.5.2.3 of Reference 14, we specified that the VDTV shall be able to successfully negotiate the Consumers Union obstacle course at all speeds below 55 km/hr.

Figure 24 displays the lateral versus longitudinal positions for the crash avoidance double lane change maneuver of the three VDTV variants with different tire models. As shown in that figure, all three VDTV variants can clear the corner of the re-entry lane, but only the variants with the S10 and Samurai tires can clear the obstacle cone. The VDTV with the Samurai tires is most "aggressive" because it can get back to the centerline of the re-entry lane in the shortest longitudinal distance. However, the vehicle trajectory beyond that "crossover" point is quite oscillatory. On the other hand, the vehicle trajectory obtained with the S10 tires, both before and after the crossover point is better damped. Time histories of the steering wheel angle, vehicle's lateral acceleration and sideslip angle, as well as tire

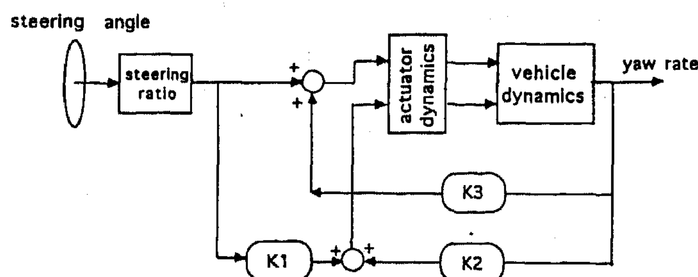

Figure 25: A combined four-wheel-steering and steer-by-wire control architecture

forces are given in Reference 15.

Concluding Remarks

A Variable Dynamic Testbed Vehicle concept has been proposed as a tool to perform driving-related human factors research. The goal of this study was to analytically investigate to what degree a VDTV with four-wheel-steering can emulate the lateral dynamics of a broad range of vehicle models. Using a selected compact-sized automobile as a baseline, our study indicated this vehicle can be controlled to emulate the lateral response characteristics (including the vehicle's understeer coefficient and the 90% lateral acceleration rise time in a J-turn maneuver) of a fleet of production vehicles, from low to high lateral acceleration conditions. Also, the roll gradient of the baselined vehicle can be altered via changes made to the torsional stiffnesses of the front and/or rear anti-roll bars to emulate the roll stiffnesses of a fleet of production vehicles.

The levels of emulation can potentially be improved if the VDTV has both the four-wheel-steering and steer-by-wire features depicted in Figure 25. With this steering configuration, the controller architecture given in (7) becomes:

$$\bar{\delta}_{rc} = K_1(U)\delta_{fc} + K_2(U)r\,, \quad (8)$$
$$\bar{\delta}_{fc} = \delta_{fc} + K_3(U)r. \quad (9)$$

Here, the variables δ_{fc} and r were defined in connection with the 4WSY control algorithm. Front and rear steering commands are given by $\bar{\delta}_{fc}$ and $\bar{\delta}_{rc}$, respectively. The added emulation benefits that one can derive with this controller architecture are not confirmed in this study, but experimental results obtained from a vehicle fitted with a similar steering system have shown promise.[3] The proposed VDTV, with both the steer-by-wire and four-wheel-steering features,[14] will be an ideal testbed to verify results obtained by the Simulator Vehicle of Reference 3.

Acknowledgments

ABSTRACT

This paper presents an overview of work performed by the National Highway Traffic Safety Administration's (NHTSA) Vehicle Research and Test Center (VRTC) to test, validate, and improve the planned National Advanced Driving Simulator's (NADS) vehicle dynamics simulation. This vehicle dynamics simulation, called NADSdyna, was developed by the University of Iowa's Center for Computer-Aided Design (CCAD). NADSdyna is based upon CCAD's general purpose, real-time, multi-body dynamics software, referred to as the Real-Time Recursive Dynamics (RTRD), supplemented by vehicle dynamics specific submodules. VRTC has "beta tested" NADSdyna, making certain that the software both works as computer code and that it correctly models vehicle dynamics. This paper gives an overview of VRTC's beta test work with NADSdyna.

The paper explains the methodology used by VRTC to validate NADSdyna. The techniques used to obtain vehicle parameters are discussed. Repeated experimental runs were performed at each test condition to generate sufficient data for statistical analyses. The processing paths for both experimental test data and simulation predictions are described. The techniques used to compare simulation predictions with experimentally measured data are presented.

The paper continues with an overview of the NADSdyna validation work performed for one vehicle, a 1994 Ford Taurus GL. Due to the complexity of this work, only an overview of this work is presented in this paper. Also included an overview of the simulation evaluation work for two other vehicle dynamics simulations, VDANL and VDM RoAD, that was performed using the Ford Taurus data. VRTC's efforts to improve NADSdyna's predicted steering system feel and to advance the state-of-the-art in steering system modeling are summarized.

INTRODUCTION

This paper presents an overview of the work that has been performed over the last three years by the National Highway Traffic Safety Administration's (NHTSA) Vehicle Research and Test Center (VRTC) to validate and improve the planned vehicle dynamics simulation for the National Advanced Driving Simulator (NADS).

The National Advanced Driving Simulator (NADS) is being developed by NHTSA and will be situated at the University of Iowa. The NADS will, when

completed in 1999, be the most capable driving simulator in the world. It will have advanced computer generated imagery with the capability of displaying 5.5 million pixels over a complete, 360 degree field of view. The use of higher pixel densities directly in front of the vehicle cab will provide close to real-life visual resolution in this critical area.

NADS will also have a motion base capable of generating large displacements, generating highly realistic kinesthetic cues. The motion base will consist of a yaw turntable, used to generate large yaw rotation angles, mounted on a six degree of freedom hexapod. The hexapod will be mounted on an X-Y Carriage that can generate up to 64 feet of movement in both the X and Y directions.

An advanced driving simulator such as the NADS must include a detailed, highly accurate vehicle dynamics simulation to predict the movements of the simulated vehicle in response to both control and disturbance inputs. The planned NADS vehicle dynamics simulation, called NADSdyna [6], was developed by the University of Iowa's Center for Computer-Aided Design (CCAD) with assistance from Iowa State University and the University of Wisconsin. NADSdyna is based upon CCAD's general purpose, real-time, multi-body dynamics software, referred to as the Real-Time Recursive Dynamics (RTRD) [7, 8, 35], supplemented by vehicle dynamics specific sub-modules. A control program (ICON_lite) is designed to support the non-simulator user in preparing a vehicle model at a workstation.

BRIEF DESCRIPTION OF NADSDYNA - The general purpose, multi-body, dynamics program, Real Time Recursive Dynamics (RTRD), was developed by the University of Iowa's Center for Computer-Aided Design and is the core dynamics of NADSdyna. The RTRD is used to precisely model chassis/suspension/steering linkages to capture geometric nonlinearities. It offers great capabilities in terms of rigid-body mechanism modeling, and accounts for all nonlinear kinematic effects, such as, roll steer, roll centers, and squat/lift forces. The RTRD can model either open or closed loop chains. The RTRD is based on a topological analysis of a rigid body mechanism formulated as modified recursive dynamics equations using minimum relative joint coordinates. The constraint library supports the following joints: revolute, spherical, translational, universal, spherical-translational, revolute-spherical, and translational-revolute. More joints can be added if needed. For closed chains, distance constraints, spherical, and revolute-spherical cut-joint types are supported. Springs, dampers, anti-roll bars, leaf springs are modeled as external forces, and nonlinear models can be used.

Five vehicle submodules are included in NADSdyna: power train, tires, brakes, steering and aerodynamics. These submodules provide NADSdyna with a broad range of functional capabilities and allow most production vehicles to be simulated. The following paragraphs contain a brief summary of the main capabilities of each of these submodules.

The power train submodule models the engine, transmission, and drive line. The engine is modeled using a map specifying engine torque as a function of throttle position and engine rpm. A simple, first order, time lag is also included. Both automatic and manual transmission are provided. For the drive line, transfer case, differential, and final drive gear box models are provided that permit most typical vehicles to be simulated. Vehicles may have front wheel drive, rear wheel drive, or four wheel drive.

The tire submodule models each of the vehicle's tires and calculates the spin angular velocity of each wheel. Four empirical tire models are provided for use in the simulation: Calspan's [36], System Technology Inc.'s [12], Gim/Nikravesh's [37], and a table look-up model. The wheel spin dynamics are solved using implicit integration of the first order differential equations for the longitudinal slips as suggested by Bernard [9]. This method allows simulation of the vehicle at low speed (including the singularity configuration, zero longitudinal velocity) and allows the simulated vehicle to stop smoothly on a hill.

The brake submodule includes models of the three main types of brakes: manual hydraulic brakes, power-assisted hydraulic brakes, and pneumatic brakes. Each type of brake can be modeled either with and without an antilock brake system.

The steering submodule can be modeled either kinematically or using a power assisted dynamic model. Vehicles with either rack and pinion or Pitman arm steering systems can be simulated.

The aerodynamic submodule calculates the aerodynamic forces acting on the vehicle. SAE J1594 is used to determine the quasi-steady state forces.

NADSdyna includes a number of pre-processors, which assist in the input of RTRD and submodule data, and initial vehicle parameter verification. The following pre-processors are provided: vehicle rigid-body, power train, tires, brakes, steering, and aerodynamics. Another pre-processor is used to run NADSdyna for non-real-time applications. The pre-processors are all OSF/Motif applications.

Two post-processors are provided with NADSdyna. One of these is used to perform "sanity" checks on NADSdyna data sets [38]. This post-processor has NADSdyna make a variety of standardized runs and checks that the resulting is sensible. The second post-processor assists users in examining and manipulating NADSdyna output. This tool is a Graphical User Interface built on top of Xmath, that allows users to easily examine NADSdyna output. It also includes an easy interface to Xmath and C that allows the user to manipulate NADSdyna output by creating custom functions and data reduction procedures.

OTHER COMMON U.S. DEPARTMENT OF TRANSPORTATION VEHICLE SIMULATIONS - While NADSdyna is an extremely capable vehicle dynamics simulation that is well suited for use with the NADS, it does have some drawbacks that make it less useful as a general purpose vehicle dynamics simulation. Specifically, NADSdyna requires an immense amount of vehicle parameter data, is relatively complicated to run, and only operates on UNIX workstations, not on typical personal computers. As a result, the U.S. Department of Transportation uses other, less complex, vehicle dynamics simulations for much of its vehicle simulation work. Two frequently used vehicle dynamics simulations are "Vehicle Dynamics Analysis, Non-Linear" (VDANL) and "Vehicle Dynamics Models for Roadway Analysis and Design" (VDM RoAD).

As is explained below, NHTSA decided to perform a complete validation of NADSdyna. Much of the difficulty and expense of performing vehicle dynamics simulation validation is in the vehicle parameter measurement and vehicle testing. Due to the high level of complexity of NADSdyna, researchers realized that no additional vehicle parameters measurements or vehicle testing would have to be performed to evaluate both VDANL and VDM RoAD at the same time. Therefore, the NADSdyna validation project also worked with VDANL and VDM RoAD.

BRIEF DESCRIPTION OF VDANL - The VDANL simulation used in this research is the latest version of the VDANL simulation being developed by Systems Technology, Inc. (STI) for the Federal Highway Administration (FHWA) as part of its "Interactive Highway System Design Model" (IHSDM). The original VDANL simulation was developed in the mid 1980's by STI for NHTSA as documented in [12, 14, 15].

STI has made numerous improvements to VDANL since the original version. Version 2 of VDANL, was developed by STI in 1989-1990 for NHTSA [10]. Versions 3 and 4 were developed during 1990 to 1995 when STI made VDANL a commercial product. Version 5.03 of VDANL, used for this research, contains basically the same vehicle and tire model as version 2. However, version 5.03 adds capabilities for trailer towing, simulation of tractor/semi-trailers, off-road tire operation, and complex terrain definitions (among other modifications/improvements). VDANL has been extensively evaluated by VRTC [17, 18, 32] and Iowa State University [21, 22]. The results of these evaluations have shown that VDANL is, in general, able to correctly predict vehicle directional responses, including transient behavior, up to moderately high g levels.

VDANL is a personal computer based program that runs under the DOS® operating system. Four degrees-of-freedom are used to model the vehicle sprung mass: pitch rotation, roll rotation, lateral translation, and vertical translation. Two additional degrees-of-freedom are used to model the total vehicle mass: yaw rotation and longitudinal translation. The front and rear unsprung masses are each modeled with three degrees-of-freedom: vertical translation, lateral translation, and roll rotation. Each wheel has a single spin degree-of-freedom, and the steering system has a single rotational degree-of-freedom. This gives a total of seventeen degrees-of-freedom for a passenger car (adding a two-axle trailer can add ten additional degrees-of-freedom).

The suspension model allows modeling both solid and independent suspension systems. Quasi-static compliance models of wheel camber and steer angle change due to tire lateral and longitudinal forces and aligning moments are included. VDANL contains a sophisticated tire model that predicts tire lateral and longitudinal forces and aligning moments over the complete range of slip angle, longitudinal slip, normal load, and camber angle. Open-loop control inputs of steering angle, throttle pedal position, and brake pedal force are allowed, along with a closed-loop speed controller that modulates the throttle to follow a user specified speed profile. The tire lateral forces are lagged using two first order lags to simulate tire dynamic characteristics.

BRIEF DESCRIPTION OF VDM RoAD - The VDM RoAD simulation from the University of Michigan Transportation Research Institute [16] is an eighteen degree-of-freedom model (UMTRI also developed a simpler fourteen degree-of-freedom simulation for the FHWA). There are no known previously published evaluations of VDM RoAD.

The VDM RoAD "package" consists of a "Simulation Graphical User Interface" (SGUI) [33], the simulation program executable (18DOF.EXE), and the UMTRI "Engineering Plotter" program. All user interaction is done through the SGUI, which allows vehicle parametric information to be entered, and simulation runs to be specified. The SGUI is a graphical front end to a database of vehicle parametric and simulation input/output files. Sample screens from the SGUI are shown in [25] and [33]. The VDM RoAD package evaluated in this report was run on a personal computer under the Microsoft Windows NT™ 3.51 operating system. Versions of VDM RoAD are also available to run on Macintosh and UNIX systems.

The vehicle simulation program has been developed by UMTRI using the AUTOSIM [34] multi-body code generator. A multi-body description of the vehicle model is input to AUTOSIM, and AUTOSIM symbolically derives the multi-body equations, and writes FORTRAN code. The compiled version of the FORTRAN code is called 18DOF.EXE. A description of the passenger car model can be found in the May/June 1995 progress report from UMTRI to FHWA. A more

complete description will be contained in UMTRI's final report.

18DOF.EXE models all six degrees-of-freedom for the vehicle chassis. Only independent suspension systems are modeled, and each wheel contains a vertical degree-of-freedom. The suspension models use tables to define spring and damper forces along with wheel toe and camber angles as a function of suspension motion. The four tire slip angles are modeled as first order differential equations producing tire lateral force and aligning moment lag. A fixed roll center model is used, and anti-pitch/dive forces are modeled. Wheel steer compliance to tire lateral and longitudinal force and aligning moment is modeled. The steering system model allows front Ackerman effects through table lookup as well as mechanical four wheel steering. Brake torque at each wheel is specified by a table as a function of brake pedal force. The six aerodynamic coefficients are specified as functions of aerodynamic side slip angle. Tire forces and moments can be specified using either tables or the STI tire model from version 1.00 of VDANL.

STEERING SYSTEM FEEL - One major area of concern for the NADS vehicle dynamics is the correct prediction of the "feel" of the steering system, i.e., the forces and moments that are fed back to the driver through the steering handwheel. However, steering system feel is also subjective as well as objective issue. When a subject is "driving" a simulated passenger car in the NADS, the subject should think that the steering system is that of an automobile as compared to that of, for example, a heavy truck. The subjectivity of driver impressions of steering system feel make correct prediction extremely difficult, because even small errors in the predicted forces and moments can spoil the subjective feel. As a result of this concern about steering system feel, a portion of this research has focused on this topic.

OBJECTIVES

NHTSA's Vehicle Research and Test Center is approximately halfway through a multi-year research project to test, validate, and improve the planned vehicle dynamics simulation for the NADS. The primary objectives of this project are:

1. To "beta test" the NADSdyna software originally developed by the University of Iowa's Center for Computer-Aided Design. NHTSA must be certain that this software works as computer code.
2. To demonstrate that NADSdyna correctly simulates the dynamics of a broad range of vehicles. Detailed validation work is being performed for two vehicles, a passenger automobile (a 1994 Ford Taurus) and a tractor-semi-trailer (a 1992 Volvo tractor with a Fruehauf van semi-trailer).
3. To develop four data sets that contain the parameters used to describe a vehicle to NADSdyna. The data sets to be developed will be for two passenger automobiles (a 1994 Ford Taurus; the second make/model is to be decided later), a sport utility vehicle (make/model to be decided later), and a tractor-semi-trailer (a 1992 Volvo tractor with a Fruehauf van semi-trailer).
4. To improve the functionality of NADSdyna beyond that originally included by CCAD. Examples of planned improvements include improving the prediction of steering system feel, adding failed vehicle subsystem models, adding interactions with roadway features (bumps and slippery patches), and adding the ability to model wind gusts.

The secondary objective of this project is evaluate two other vehicle dynamics simulations that are used by the U.S. Department of Transportation, VDANL and VDM RoAD. This work was performed because much of the difficulty and expense of performing vehicle dynamics simulation validation is in the vehicle parameter measurement and vehicle testing. Due to the high level of complexity of NADSdyna, no additional vehicle parameters measurements or vehicle testing had to be performed to evaluate both VDANL and VDM RoAD at the same time.

The primary objective of this paper is to present an overview of the research that has been performed by the Vehicle Research and Test Center on this project to date. The companion papers [1, 2, 3, 4, and 5] present additional details of this work. Several reports describing this research [20, 23, 24, 25, 26, 27, and 28] are either being written or have been completed. The current paper attempts tie these papers and reports together.

The major focus of this project's work, to date, has been validating NADSdyna for one vehicle, a 1994 Ford Taurus. The methodology used to perform this validation work is explained below. As this methodology explains, there are three major phases in simulation validation:

1. Experimental data collection. The work performed during this phase for the Ford Taurus is described in greater detail in the companion paper [1] and in the report [20].
2. Vehicle parameter measurement. The work performed during this phase for the Ford Taurus is described in greater detail in the companion paper [2] and in the report [24].
3. Comparison of simulation predictions with experimental data. The work performed during this phase for the Ford Taurus is described in greater detail in the companion paper [3] and in the report [23].

The Ford Taurus data was also used to perform simulation evaluation work for two other vehicle dynamics simulations, VDANL and VDM RoAD. This work is discussed in greater detail in the companion paper [4] and in the report [25].

VRTC's efforts to increase NADSdyna's functionality have, to date, focused on improving NADSdyna's predicted steering system feel. While VRTC plans to improve a number of other areas of NADSdyna, work has not yet begun in these other areas. More details about VRTC steering system research are presented in the companion paper [5] and in the reports [26, 27, and 28].

VALIDATION METHODOLOGY

The simulation validation methodology used in this project is an improved version of the methodology that was described in [18]. This methodology consists of three main phases, experimental data collection, vehicle parameter measurement, and comparison of simulation predictions with experimental data. This section of the paper begins with a definition of simulation validation followed by a detailed description of each of the main validation phases.

DEFINITION OF SIMULATION VALIDATION - A computerized, mathematical model of a physical system, such as a handling and control vehicle dynamics simulation, will be considered to be valid if, within some specified operating range of the physical system, a simulation's predictions of the system's responses of interest to specified input(s) agree with the actual physical system's responses to the same input(s) to within some specified level of accuracy. This definition is compelling and sound, but measuring the actual physical responses is not an error-free exercise due to the inability to control the systematic and random errors within the system. Therefore, the validation confidence will be improved if more than one vehicle are used. Analytical diagnostics, or sanity checks, should be applied along with this definition so that the simulation predictions match the desired model behavior.

The above definition contains several points that need to be explained in greater detail.

First, a simulation's predictions will, in general, only be correct within some portion of the physical system's operating range. An obvious example of this is that a vehicle dynamics simulation's predictions may be correct for low lateral acceleration maneuvers but become progressively worse as lateral acceleration increases and non-linear effects become more important. A second example is that, due to an incorrect modeling of the effects of steering system compliance, a simulation's predictions might get worse as steer angle increases.

Similarly, a simulation's predictions may only be correct for control inputs that predominantly contain frequencies within some specified range. For example, some vehicle dynamics simulations are valid for steady state and relatively slowly varying input conditions but have problems with fast transients that contain high frequencies.

Therefore, simulation validation should be performed in both the time and frequency domains. Validation in the time domain is good for demonstrating that the simulation can correctly predict steady state conditions and that non-linear effects are properly modeled. High frequency transient phenomena, however, are very difficult to study in the time domain. The effects of increasing input frequency on the correctness of a simulation's predictions are best determined through frequency domain studies.

A second significant point contained in the definition of simulation validation is that it is valid only for specified inputs/outputs groups. For example, for a handling and control simulation, simply because the simulation has been shown to be valid for braking and steering control inputs does not imply that the response to a road disturbance (such as a bump in the road) will be correctly predicted. Similarly, a simulation that successfully predicts lateral sprung mass acceleration might fail to predict vertical sprung mass acceleration.

The third significant point in the simulation validation definition is that whether or not a simulation can be considered to be valid depends upon how much the simulation's predictions can acceptably vary from the actual test results at a given operating point. The level of accuracy required to classify a simulation as valid depends on the intended uses of the simulation and the accuracy believed to be attainable. If only the trends of the response of a physical system are to be simulated, with little interest in predicting values, much less accuracy is required than when trying to predict exact values.

EXPERIMENTAL DATA COLLECTION PHASE - Vehicle dynamics simulation validation involves comparing a simulation's predictions of a vehicle's responses to control inputs (steering, braking, throttle) and disturbance inputs (wind, road features) to the actual vehicle's responses to the same inputs. While information on the actual vehicle's responses to inputs (the validation data) may be determined in any of several ways, in general, the best way is through experimental testing of the actual vehicle. This allows direct comparison between a simulation's predictions and the actual vehicle's responses.

The maneuvers performed during experimental testing should cover a broad range of vehicle operating conditions. The maneuvers performed for this research can be divided into six major categories. These are:

1. Steady state lateral performance — These primary validation maneuvers are low frequency turns. They are used to determine the vehicle's steady state lateral gains and understeer.
2. Transient lateral performance — These primary validation maneuvers input a broad range of frequencies at the steering handwheel. They are used to measure the vehicle's frequency response functions and thereby characterize the vehicle's

lateral response to transient inputs. Experience has shown that comparisons in the frequency domain between simulation predictions and actual vehicle responses are usually the best way to validate the transient portions of a simulation.

3. Longitudinal acceleration maneuvers — These primary validation maneuvers are performed either in a fixed gear or with the transmission allowed to change gears. They are used to measure the vehicle's response to throttle inputs.
4. Longitudinal deceleration maneuvers — These primary validation maneuvers are performed to measure the vehicle's response to braking inputs.
5. Road disturbance input maneuvers — These primary validation maneuvers are performed to determine the vehicle's to selected road disturbance inputs.
6. Other driving maneuvers — These maneuvers are not the primary maneuvers used for simulation validation. Instead, they are used to build confidence that validation results from the primary maneuvers can be generalized to other maneuvers including maneuvers in with multiple inputs.

The first five types of maneuvers are characterized as primary validation maneuvers. These are the minimum set of maneuvers needed for validation.

The first and second types of maneuvers characterize both the steady state and transient lateral performance of the vehicle, respectively. Unfortunately, braking and throttle maneuvers always contain both steady state and transient portions. Therefore, for the vehicle's braking and throttle responses, both steady state and transient characteristics must be determined from the same maneuvers.

Repetitive experimental testing of the actual vehicle allows statistical methods to be used to determine the random uncertainty present in the experimental testing and measurement process. Every experimental measurement contains random error superimposed onto the signal. Random errors are defined here as transducer measurement noise, errors due to unaccounted for variations disturbing the vehicle, and random minor changes in the vehicle. For vehicle testing, random error includes, for example, the effects of wind gusts, road roughness, tire non-uniformity, and changes in the brakes from test to test. Note that there are other sources of experimental non-repeatability including, for example, variability in the inputs.

Some of the disagreement between a simulation's predictions and experimental measurements will be due to this random error and errors in parameter measurements for the simulation. Since simulations cannot predict random error, if a simulation's predictions agree with experimental measurements to within the experimental random error level, the simulation should be considered to be valid.

Conversely, while simulations whose predictions are less accurate than the experimental random error level are useable for many tasks, the "best" simulation (for a specified operating regime and input/output set) of a vehicle is one whose predictions agree with experimental measurements to within the random error level.

The easiest way to determine the experimental random error level present in data is to repeat all experiments that are performed for the purpose of simulation validation multiple times. Given data from several tests, statistical procedures can be used to calculate the random error levels.

VEHICLE PARAMETER MEASUREMENT PHASE - A vehicle dynamics simulation is based on a set of equations derived from a model of the vehicle being simulated. Adjustable values, known as vehicle parameters, in these equations describe the particular vehicle or vehicle configuration being studied to the simulation.

During development of a simulation, each vehicle parameter should be unambiguously defined and methods developed to measure or obtain each value that is input to the simulation. Parameters that cannot be clearly defined or for which there is no means of measuring/obtaining are not acceptable in a simulation. Parameter definitions and techniques for measuring/obtaining parameter values should be included in a simulation's documentation.

During validation, vehicle parameters should be measured/obtained independently from the simulation validation data. If the vehicle parameters are not obtained independently, or if their values are adjusted during the validation process not due to improvements in the parameter determination process, but solely to improve the match between a simulation's predictions and the validation data, then the validation process becomes, at least in part, an exercise in curve fitting. While the ability to adjust the vehicle parameters to make a simulation's predictions match validation data is a strong argument for the correctness of a model, it is preferable to match simulation predictions made with independently measured, non-adjusted, vehicle parameters to validation data.

Simulation validation should be performed using several different vehicles. Using only one set of parameters (vehicle) could allow a problem to escape notice. The different vehicle parameter sets used should be for vehicles that differ substantially from each other. For the current work, validation is being performed for two very different vehicle, a medium-sized passenger automobile and a large tractor-semi-trailer.

COMPARISON OF SIMULATION PREDICTIONS WITH VALIDATION DATA - After the vehicle parameters have been measured, a simulation data set prepared, and the validation data collected and reduced, comparisons can be made between the simulation's predictions and the validation data. The simulation's predictions are calculated by feeding the

control inputs that were measured during the collection of the validation data into the simulation. The resulting simulation output is graphically compared to the experimental means and 95 percent confidence limits of the validation data.

FORD TAURUS EXPERIMENTAL DATA COLLECTION

This section briefly describes the data collection system, and data analysis used for the test program. Table 1 lists the data channels, the types of sensors used, and the units in which the data is stored. A more detailed description of the experimental setup and data storage system can be found in Reference [20].

DATA ORGANIZATION - Because of the size and scope of this vehicle testing project (more than 40 transducers, 75 maneuver types and conditions, and nearly 600 individual test runs), data organization is very critical. Therefore, guidelines were written for data file naming conventions, data file storage locations, transducer mnemonic naming conventions, and data units.

Because of the size of the testing program, record keeping is a major concern. For example, when simulating a particular test, the measured vehicle weight from the day of the test is necessary (during the course of this testing program, the total vehicle mass varied more than 70 kilograms, which is approximately 4 percent of the total mass). Daily test information is stored directly with the data. Some of this information is used by the data analysis programs, while some is simply for archival purposes.

DATA ACQUISITION EQUIPMENT - All on-board measurements are made using an Optim Megadac 2210C data recorder, that can digitize up to 128 analog channels with a maximum overall sample rate of 20,000 samples per second. All analog channels are sampled using a 16-bit analog-to-digital converter. The Megadac also has four 16-bit digital counters that may be cascaded.

Data Channel	**Sensor (units)**
Vehicle accelerations in X, Y, and Z-axes	Accelerometers (m/s^2)
Vehicle angular rates about X, Y, and Z-axes	Rate sensors (rad/s)
Power steering rack pressures	Pressure transducers (kPa)
Optical event	Optical trigger (V)
Chassis height	Ultrasonic distance sensors (m)
Brake line pressures	Pressure transducers (kPa)
Tie rod forces	Strain gages (N)
Vehicle speed	Tachometer generator (m/s)
Distance traveled	Fifth wheel (m)
Brake pedal force	Force transducer (N)
Transmission gearshift selector	Engine control module (V)
Engine speed	Engine control module (rad/s)
Gear transmission is in	Engine control module (V)
Wheel rotational velocities	ABS wheel sensors (rad/s)
Handwheel angle	Potentiometer (rad)
Handwheel rotational velocity	Tachometer generator (rad/s)
Handwheel torque	Strain gages (N-m)
Throttle position	Engine control module (%)
Strut accelerations along strut axis	Accelerometers (m/s^2)
Strut lengths	Potentiometers (m)

Table 1. Data Channels

At VRTC, the Megadac is controlled using a Grid model Gridcase 1500-series laptop computer that runs custom software to allow the system to be set up for each specific test. The test driver's primary interaction is through the laptop interface.

For the majority of the maneuvers run for this program, open-loop control inputs are desired. To make the control inputs as "open-loop as possible", three devices are used. Steering wheel angle inputs are constrained by a mechanical steering stop, a pneumatic ram is used to actuate the brake pedal, and a mechanical throttle pedal actuator is used during drive train testing.

TEST MANEUVERS - For many of the maneuvers, approximately 2 seconds of pre-trigger data are collected. This data is used to characterize the pre-maneuver state of the test vehicle. The pre-trigger data collection is a feature of the Megadac. After the Megadac is armed, data is collected and stored in a user definable size circular memory buffer. When the Megadac is triggered, the content of the buffer is written to the tape followed by the post-event data.

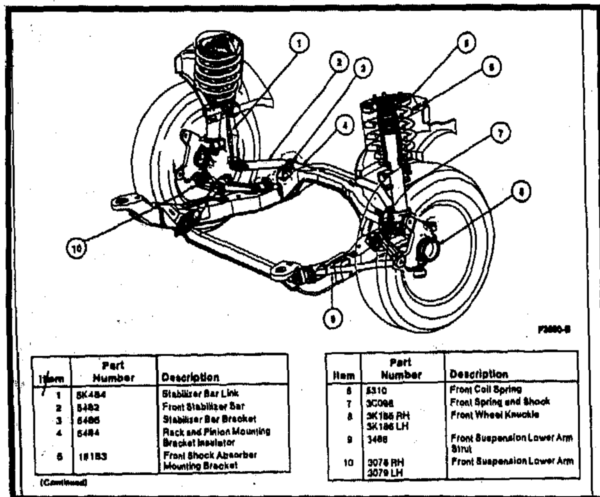
For maneuvers where repeatable open-loop inputs can be achieved, each test is repeated up to 10 times. The data from these repeat tests is then ensemble averaged in the time domain to obtain statistical measures of test repeatability. The maneuvers are summarized in [20].

DATA REDUCTION - Raw vehicle data must be converted into a form suitable for simulation evaluation. The process may involve (depending on the test) removing offsets, digital filtering, computing derived channels from measured channels, ensemble averaging in the time domain, and/or conversion of the time-domain data into the frequency domain. All data processing is done using the software program MATLAB, version 4.2c [3]. Some of the analysis also uses MATLAB Signal Processing Toolbox version 3.0b.

The first step in the processing of all raw data files is to remove channel offsets, digitally filter the data, and compute the derived channels. The MATLAB function BUTTER is used to design a two-pass phaseless Butterworth low-pass digital filter for all channels except longitudinal velocity, with a 3-dB down cutoff frequency of 10 hertz and a total of 12 poles. Because of significant cyclic noise in the longitudinal velocity channel (at the frequency of the fifth wheel rotational speed), a second filter is designed for the longitudinal velocity channel with a 3-dB down cutoff frequency of 2 hertz and a total of 6 poles. This additional filtering of longitudinal velocity was necessary to get "reasonable" wheel slip estimates.

A number of "derived" channels are also computed and included in the output file. Derived channels are channels computed by combining other channels, for example chassis roll angle, which is computed from the difference between the two ultrasonic ride height measurements. The derived channels are front and rear strut lengths, average steering wheel torque, steering rack position, power steering assist force, transmission gear number, chassis roll and pitch angles, and longitudinal wheel slip ratios.

TEST REPEATABILITY - When running repeat testing, one source of test-to-test variation that can be controlled is the repeatability of the vehicle control inputs. For this testing program, the control inputs are steering wheel angle, brake pedal force, throttle position, and for the constant speed runs, cruise control speed setting. Using the 33 meters/second, 6 meters/second^2 J-Turn tests, the repeatability of the steering wheel inputs and the vehicle longitudinal velocity are demonstrated. All of the filtered steering wheel angle data falls within approximately a 1-degree window, demonstrating that very good steering angle repeatability is achieved using the VRTC steering stop. Also, the average vehicle velocity from all 10 tests falls within a window of approximately 0.5 meters/second.



The throttle position repeatability is demonstrated by the 50-percent throttle, straight-line acceleration runs. Excellent repeatability is achieved using VRTC's mechanical throttle pedal actuator, with all of the data falling within a window of approximately 1 percent of throttle position. The brake pedal force repeatability is from the 5 meters/second^2 straight-line braking tests. The brake pedal force from all nine runs falls within a 6-Newton window, demonstrating good repeatability using the pneumatic brake ram.

FORD TAURUS VEHICLE PARAMETER MEASUREMENT

A passenger vehicle is a mechanical system consisting of a finite number of constrained rigid bodies. It depends on the vehicle type and the dynamic problem under consideration what type of constraints, how many bodies, and which degrees of freedom have to be assigned. The vehicle is assumed to be symmetric, and all the joints forming the suspensions are assumed to be frictionless. The front suspension is a MacPherson strut type as shown in Figure 1. The multi-body dynamics model shown in Figure 2 provides the front suspension with two degrees of freedom with respect to the chassis; vertical movements, and rotations about the king pin axis. The rear suspension is a MacPherson strut type with two parallel control arms as shown in Figure 3. The multi-body model shown in Figure 4 gives the rear wheel one degree of freedom about the chassis, a circular vertical movement around the tension strut link. In the actual vehicle, due to bushing compliance, the wheel moves in an "elliptical" circular direction as forced by the control arms and the tension strut. The RTRD's recursive formulation requires rigid bodies to be connected in an open loop structure, or a spanning tree.

The Taurus model contains ten closed loops, a joint on each loop is "cut" to get a spanning tree and the constraint equations associated with Lagrange multipliers are imposed on these cut joints to represent kinematically admissible motion. Graph theory is used to identify the topological structure of multi-body dynamic systems, and weighting factors of some general kinematic joints are used for the purpose of minimizing the chain length and maximizing efficiency in parallel computation [6].

The Inertia and center of gravity height were measured using the IPMD (Inertial Parameter Measurement Device) [39], located at VRTC. The location of all the suspension attachment points on the chassis, center of gravity, mass, and inertia of each component were measured. Bi-filar and tri-filar torsional pendulum's are used to measure the mass moments of inertia of small components. Nonlinear models of the spring, bump stop, and shock absorber are used, and the measurements were performed by Heitz Automotive Testing, Inc. The tire used during all field testing were General Ameritech P205/65R15 belted radials. The tests were performed at Smithers Scientific Services, Inc. on their MTS Flat-Track II flat-belt tire force and moment measuring machine. A complete description of the experiments can be found in [29]. The STI tire model is used , and the parameters were obtained using a preprocessor [40]. A quasi-static model of the compliances is used to avoid the inclusion of stiff elements, and the measurements were performed at Heitz Automotive Testing, Inc. [41]. The anti-roll bar stiffness was measured at VRTC and a quasi-static model is used. The aerodynamic coefficients were measured at the Lockheed Aeronautical Systems Company's Low Speed Wind Tunnel. The brake model with a dynamic lag is used (pneumatic model of NADSdyna), and the parameters were measured at VRTC. A detailed explanation of the measurements and NADSdyna data set can be found in [2, 23, 24, 30]. The power train and a speed dependent power steering system will be added in a later version of the simulation.

NADSdyna VALIDATION FOR THE FORD TAURUS

The utility of the analysis of the aforementioned NADSdyna model depends on the extent to which it has

been evaluated. NADSdyna simulation results compared with experiments are shown in [3, 9, 31]. The following maneuvers are studied:

SLOWLY INCREASING STEER - The slowly increasing steer maneuver involved supplying the simulation with a slowly increasing handwheel angle, while maintaining a constant vehicle speed, until maximum vehicle lateral acceleration, rollover, or a spinout is achieved. A handwheel angle rate about *10 deg/sec* is used to eliminate dynamic effect and maintain steady state properties. The results of this maneuver indicated that the vehicle model has the appropriate non-linear suspension properties, as well as the tire model is appropriate to model severe cornering.

STEP STEER INPUT - This maneuver (J-turn) is a pseudo-step input of handwheel angle. The J-turn maneuvers are simulated to determine steady-state as well as transient responses. A physically realistic input rate on the order of *500 deg/sec* is used. The transient response comparisons between field test and computer model show good agreement in terms of timing of the transient events and peak levels of the variables that indicate limit performance conditions.

DIRECTIONAL DYNAMICS FREQUENCY RESPONSE (PULSE STEER) - Linear frequency responses can be developed for linear, time invariant systems, or approximated for a nonlinear system about some linearized operating condition. For vehicle handling dynamics, frequency responses are derived only for constant speed maneuvers, since handling responses are speed dependent. Additionally linearity is assumed applicable below lateral acceleration levels of *0.3-0.4* g's. The directional dynamic properties of the simulation are reasonable as indicated by the yaw rate and lateral acceleration frequency responses, which give some credibility to the composite lateral/directional dynamics. The roll angle measurements have a high noise to signal ratio, and the dynamics trends are reasonably predicted.

LANE CHANGE MANEUVERS - Once the steady state, transient, and frequency response predictions of the simulation have been evaluated, the simulation is checked against more complex maneuvers designed to simulate real world driving conditions, like lane change maneuvers. In this maneuver the steering input represents the driver/vehicle closed loop following performance. Figure 5 shows that the simulation predicted well the lateral acceleration, and the yaw rate.

BRAKING - The braking maneuvers are performed at different levels of severity from low g up to the limit. Despite uncertainty in road friction and other parameters, the simulation predictions are reasonable. A combined braking and steering maneuver is not necessarily valid since the tire forces are extremely non-linear. Predictions for this maneuver require accurate tire force model for the particular tire/surface used. The tire model does not fit well the experimental data at composite slip conditions [23, 28], which will be improved in a later version of the simulation software.

RIDE ANALYSIS - A simplistic approach is applied where road roughness is considered to be the input of vehicle vibration response. The transfer function of vehicle vertical acceleration at the chassis center of gravity to road acceleration input shows that the natural frequency of the chassis, and wheels, as well as the amplitude attenuation at higher frequencies are reasonably predicted by the simulation.

The evaluation of the 1994 Ford Taurus NADSdyna model have shown that the simulation predicted the fundamental mechanics of vehicle handling responses in general. The results show promise that NADSdyna will provide the fidelity required for the NADS vehicle dynamics simulation. This evaluation effort is being extended to include acceleration maneuvers, a complete dynamic steering system, as well as other vehicles including a tractor semi-trailer.

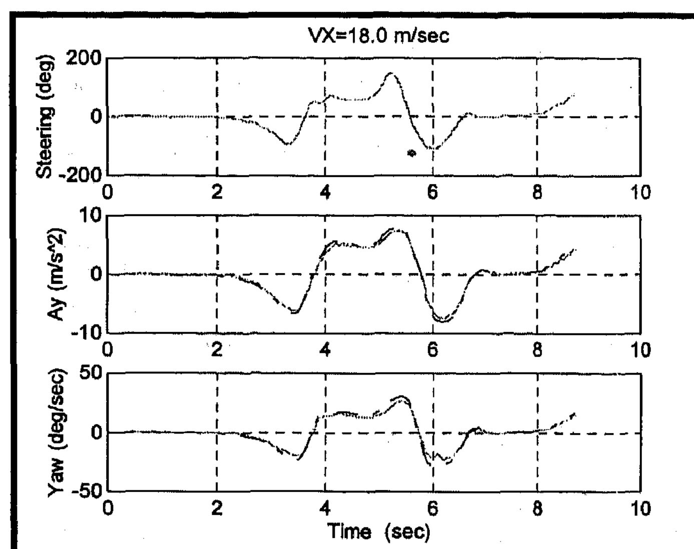

Figure 5. Lane Change Maneuver

VDANL AND VDM RoAD EVALUATION FOR THE FORD TAURUS

REASONS FOR INTEREST IN VDANL AND VDM RoAD - As part of the IHSDM research program, the Federal Highway Administration is using two vehicle dynamics simulations. These simulations are VDANL and VDM RoAD. The Federal Highway Administration's IHSDM program is a comprehensive project that is being developed to aid highway designers and traffic engineers in designing and implementing safe highway arteries and peripheries including, on-off ramps, interchanges, roadsides, medians, etc. The two simulations are an

integral part of the overall IHSDM program. Working in cooperation with the Federal Highway Administration, VRTC has evaluated these vehicle dynamics simulations.

The evaluations of VDANL and VDM RoAD are presented in two documents, the companion SAE paper [4] and a NHTSA report [25]. The SAE paper [4] evaluates the simulations' predictions in the linear range via comparison with analytical models. Consistency checks are made and lateral load transfer, roll gradient, and understeer predictions are evaluated. Linear range contributions of roll steer, roll camber, lateral force compliance, and aligning moment compliance to simulated overall vehicle understeer are computed and compared to the those computed using the analytical model. Both simulations do a good job of predicting expected vehicle responses in the linear range. Also in the linear range, the VDANL and VDM RoAD predictions of yaw rate frequency response are computed and shown to compare well with measured results from the 1994 Ford Taurus. Finally, to evaluate the nonlinear range of vehicle response, understeer gradient plots are generated up to the limit of lateral acceleration, and the results compared with experimental results. Both simulations are shown to predict the trends in the nonlinear understeer plots.

The NHTSA report [25] provides a thorough comparison of the VDANL and VDM RoAD predictions with experimental results from a 1994 Ford Taurus. Many types and severities of steering maneuvers and braking maneuvers are evaluated; and both qualitative and quantitative measures of the simulations' performance are presented. The report concludes that both simulations contain an appropriate order of model dynamics in the linear range of vehicle operation, that they both correctly predict gains and trends into the nonlinear range, and that they correctly predict longitudinal dynamics.

IMPROVING STEERING SYSTEM MODELING

VRTC's efforts to evaluate simulator performance and efforts to further develop steering system models are closely related. Several projects have been completed in support of the development of the steering system model and efforts are currently underway to develop a final steering system model and to properly evaluate its performance.

One project deals with the analytical modeling of the steering system. This project involves modeling the necessary steering system components (inertias, stiffnesses, damping, lash, power assistance, etc.) to fully capture the essence of steering feel via torque feedback through the steering wheel. The steering system model evaluations were done by implementing them in a VDANL-like vehicle dynamics computer simulation and studying the results for soundness using criteria such as: are the torques fed forward and backward through the steering system reasonable, are the time lags and hysteresis correct as modeled, etc. Two models have been developed and are currently being evaluated and refined.

Another project was the implementation of a steering system control hardware in VRTC's fixed-based driving simulator. This task included installing the steering torque feedback servo-motor, torque sensor, and steering angle and rate sensors in the vehicle used in VRTC's simulator. Once installed, these components were evaluated to characterize the performance measures (gain, bandwidth, and phase) of the torque feedback system.

The next step in VRTC's effort to develop tools for evaluating simulator performance is to implement and coordinate the analytical steering system models with the steering system control hardware on the simulator. With knowledge of the performance of the steering system hardware, suitable control logic can be implemented into the steering system model to compensate for the response of the hardware and generate the desired steering feedback torques to the driver.

Once implemented in VRTC's driving simulator, the entire system will be evaluated both objectively and subjectively. Objective measures, such as feedback torque gains and phase shifts, will be measured on the simulator and compared with similar measurements taken from an actual vehicle. Similarly, subjective performance measures of the simulator and an actual vehicle will be made to appraise the fidelity of the simulator's steering system.

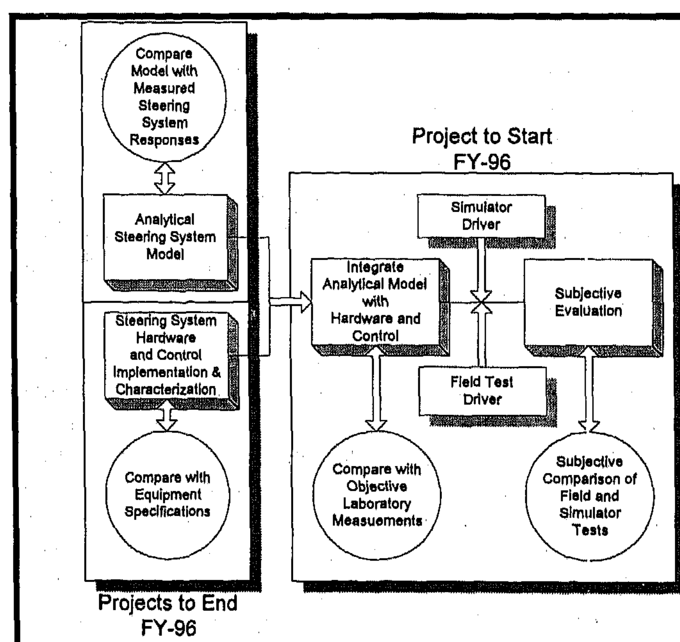

Figure 6. Schematic of Methodology to Develop Simulator Steering System Models/Hardware and Simulator Evaluation Tools

CONCLUSIONS

This project has shown that the current version of NADSdyna does a good job of predicting the performance of the 1994 Ford Taurus over a broad range of maneuvers. The results show promise that NADSdyna will provide the fidelity required for the NADS vehicle dynamics simulation. This validation effort is currently being extended to include acceleration maneuvers. Additionally, NADSdyna validation work is currently being performed for a Volvo-Fruehauf tractor-semitrailer. In work to date, a complete set of vehicle parameters has been measured for this vehicle and a large amount of experimental testing has been performed. The process of comparing NADSdyna predictions to this validation data for the Volvo-Fruehauf has just begun. This work will be reported upon in greater detail in future papers.

This project has also shown that the current versions of VDANL and VDM RoAD do good jobs of predicting the performance of the Taurus.

VRTC will continue to work to achieve the remaining goals of this project. The principle future activities will be:

1. Comprehensive testing of NADSdyna. NHTSA must be certain that all of the parts of this work before the code is placed in service with the NADS.
2. Development of two additional NADSdyna data sets. These will be for a sport utility vehicle and a passenger automobile. The precise make/models for which these data sets will be developed has not yet been decided.
3. Improvement of the functionality of NADSdyna beyond that originally developed by CCAD. Examples of planned improvements including the prediction of steering feel, adding failed vehicle subsystem models, adding interactions with roadway features (bumps and slippery patches), and adding the ability to model wind gusts.

ABSTRACT

As part of the National Advanced Driving Simulator (NADS) program, the Vehicle Research and Test Center (VRTC) in East Liberty, Ohio is evaluating the NADS vehicle dynamics software. As part of VRTC's effort, an extensive vehicle testing program to provide data for the simulation evaluation was performed. This paper describes VRTC's testing of a 1994 Ford Taurus GL passenger car. Each of the test maneuvers run by the Taurus are described, along with instrumentation setup, control actuation, test conditions, and driver procedures. The test data reduction and processing are detailed. Sample results of the testing and an analysis of test repeatablility and measurement noise are also presented.

INTRODUCTION

Starting in 1989, the National Highway Traffic Safety Administration (NHTSA) began researching the use and construction of a new state-of-the-art driving simulator, the National Advanced Driving Simulator (NADS) [1]. A site selection competition among United States universities was conducted, and in 1992, the University of Iowa was selected. As part of the University of Iowa's cost sharing, they contributed the core vehicle dynamics software for the NADS. This software program, called the Real Time Recursive Dynamics (RTRD) [2], is a minimum coordinate set, multi-body dynamics program that breaks the vehicle chassis and suspension system into a tree topology by cutting closed kinematic loops. This tree topology allows the multi-body system to be solved on parallel computers in real time.

After winning the NADS site selection competition, the University of Iowa supplemented the core vehicle dynamics (RTRD) with a collection of sub-modules that model portions of the vehicle such as the powertrain, tires, brakes, steering system, and aerodynamics that cannot be modeled using multi-body dynamics. The RTRD program containing these sub-modules is called NADSdyna [3].

NHTSA's Vehicle Research and Test Center (VRTC) in East Liberty, Ohio, is evaluating the NADSdyna vehicle dynamics software, developing vehicle parameter sets for NADSdyna, and enhancing various aspects of NADSdyna. As part of VRTC's effort, an extensive vehicle testing program to provide "benchmark" data for the simulation evaluation was performed. This paper describes VRTC's testing of a 1994 Ford Taurus GL passenger car. A similar testing program for an articulated tractor-semitrailer will be described in a later report from VRTC.

NADS is intended to be the most advanced driving simulator in the world when it is operational in the late 1990's. It is designed to be a research facility that will allow crash avoidance maneuvers and other high severity or dangerous driving situations to be safely studied. The broad scope of the NADS intended uses requires that the vehicle simulation be able to simulate vehicle ride, cornering, driving acceleration, and braking with a high degree of realism. VRTC's task of evaluating this simulation, therefore, requires a broad testing program covering both mild and severe vehicle ride, cornering, driving acceleration, and braking. The simulation evaluation methodology used is based on past simulation programs at VRTC [4, 5].

VRTC performed this testing program to provide the data needed to evaluate the NADSdyna software. However, there is very little publicly available instrumented vehicle handling and braking test data. One of the purposes of this paper therefore is to make this test data available to other researchers. Electronic versions of the test data described in this paper can be obtained be contacting W. Riley Garrott at VRTC, P. O. Box 37, East Liberty, Ohio, 43319, or via telephone at (937) 666-4511.

The test vehicle used for this project is a 1994 Ford Taurus GL. The Taurus VIN number is 1FALP5249RA164396. The Taurus has a 3.8-liter V6 engine, four-speed automatic transmission, speed sensitive power rack and pinion steering,

and four wheel anti-lock brakes. General Ameri-tech 205/65R15 tires with a cold inflation pressure of 35 psi are used for all testing. The tires were purchased together, and are from the same production batch. Force and moment test data for these tires (from the same batch) can be found in reference [6].

INSTRUMENTATION AND DATA RECORDING

This section briefly describes the transducers and data system used for the test program. Table 1 lists the data channels, the types of sensors used, and the units in which the data is stored. A more detailed description of the experimental setup and data storage system can be found in Reference [7].

DATA ORGANIZATION - Because of the size and scope of this vehicle testing project (more than 40 transducers, 75 maneuver types and conditions, and nearly 600 individual test runs), data organization is very critical. Therefore, guidelines were written for data file naming conventions, data file storage locations, transducer mnemonic naming conventions, and data units.

All data acquired for this project is stored in SI units. To avoid confusion, the decision was made to "build" all units out of the basic SI units. For example, the rotational speed of the engine is given in rad/s rather than in RPM. The axis system used is the SAE standard (from J670e) with X forward, Y to the driver's right, and Z down. The data is stored in engineering units in VRTC's DX file format. This file format allows test information (in ASCII) to be stored with the data (in floating-point numbers). For the purposes of data analysis, the test files are converted from the DX format into MATLAB binary format.

Because of the size of the testing program, record keeping is a major concern. For example, when simulating a particular test, the measured vehicle weight from the day of the test is necessary (during the course of this testing program, the total vehicle mass varied more than 70 kilograms, which is approximately 4 percent of the total mass). Keywords are a feature of VRTC's DX file format that allow information to be stored in the file header, and retrieved by using an associated keyword. This feature is used to store daily test information directly with the data. Some of this information is used by the data analysis programs, while some is simply for archival purposes. While Keywords are a feature of the DX file format, Keywords containing numerical information are also included in the raw data MATLAB files.

Data Acquisition Equipment - All on-board measurements are made using an Optim Megadac 2210C (Megadac) data recorder [8]. The Megadac can digitize up to 128 analog channels with a maximum overall sample rate of 20,000 samples per second. All analog channels are sampled using a 16-bit analog-to-digital converter. The Megadac also has four 16-bit digital counters that may be cascaded. All recorded data is stored on a 60-megabyte, quarter-inch tape cartridge.

At VRTC, the Megadac is controlled using a Grid model Gridcase 1500-series laptop computer. The laptop is connected to the Megadac using a IEEE-488 port. The laptop runs custom software written by VRTC that allows the system to be set up for each specific test (i.e. what channels to record, trigger mode, number and duration of test runs, etc.). The laptop software also keeps data specific to each test that is used when data is transferred from the data cartridge and converted to DX

Table 1. Data Channels

Data Channel	Sensor (units)
Vehicle accelerations in X, Y, and Z-axes	Accelerometers (m/s^2)
Vehicle angular rates about X, Y, and Z-axes	Rate sensors (rad/s)
Power steering rack pressures	Pressure transducers (kPa)
Optical event	Optical trigger (V)
Chassis height	Ultrasonic distance sensors (m)
Brake line pressures	Pressure transducers (kPa)
Tie rod forces	Strain gages (N)
Vehicle speed	Tachometer generator (m/s)
Distance traveled	Fifth wheel (m)
Brake pedal force	Force transducer (N)
Transmission gearshift selector	Engine control module (V)
Engine speed	Engine control module (rad/s)
Gear transmission is in	Engine control module (V)
Wheel rotational velocities	ABS wheel sensors (rad/s)
Handwheel angle	Potentiometer (rad)
Handwheel rotational velocity	Tachometer generator (rad/s)
Handwheel torque	Strain gages (N-m)
Throttle position	Engine control module (%)
Strut accelerations along strut axis	Accelerometers (m/s^2)
Strut lengths	Potentiometers (m)

files. The test driver's primary interaction with the data system is through the laptop interface.

STEER, BRAKE, AND THROTTLE CONTROLS - For the majority of the maneuvers run for this program, open-loop control inputs are desired. To make the control inputs as "open-loop as possible", three devices are used and are described below. Steering wheel angle inputs are constrained by a mechanical steering stop, a pneumatic ram is used to actuate the brake pedal, and a mechanical throttle pedal actuator is used during drivetrain testing.

The steering stop is based on a design from General Motors, and can be used to constrain the motion of the steering wheel and measure steering wheel angle and torque. In this program, it is only used to constrain the steering wheel motion. The steering stop hardware, shown in Figure 1, replaces the existing steering wheel. A torsional load cell is installed between the existing steering wheel mount and the steering stop's steering wheel. To the steering stop's steering wheel is attached a 20-centimeter diameter "Degree" wheel with tapped holes every 10 degrees that allow two adjustable steering stops to be installed. An adjustable length bar is mounted between the two A-pillars, just above the dashboard to provide a rigid base. To this bar is mounted an aluminum plate that has an engagement lever that the adjustable steering stops contact to stop steering wheel rotation. During this testing program, the repeatability of the steering wheel angle using the steering stop is approximately ±1 degree.

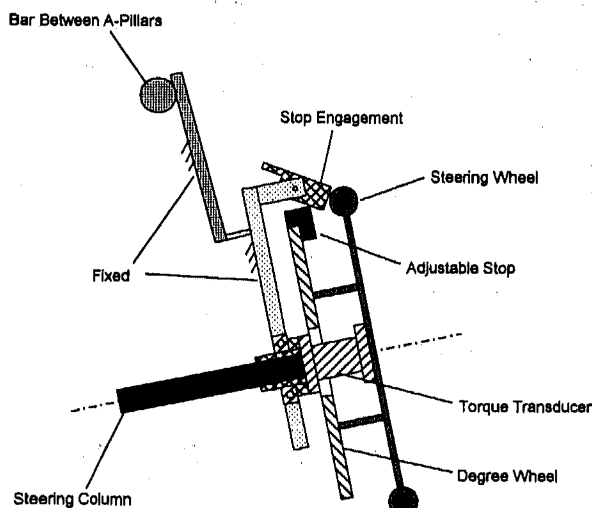

Figure 1. Diagram of steer stop

Repeatable brake pedal force actuation is achieved using a pneumatic ram. The ram, shown in Figure 2, is bolted to the vehicle floor, and oriented to act approximately perpendicular to the brake pedal force transducer. Two compressed air tanks are installed in the trunk for use with the ram. A pressure regulator is used to adjust brake ram force. The test driver uses a U-tube manometer to measure vehicle deceleration during a few test runs, and adjusts the regulated air pressure to the ram to achieve the desired deceleration. An electrically actuated solenoid valve is used to release the air to the ram from either a driver or Megadac command. During this testing program, the repeatability of the brake pedal force using the ram is approximately ±6 newtons.

The third control actuator that is used in this program is a throttle pedal actuator, shown in Figure 3. This actuator is simply an adjustable length strut that is hinged in the middle. The hinge is constrained to move in only one direction, and when the driver pushes down on the handle, the strut locks in its straight position (angle between the legs is 180 degrees). One end of the strut is hinged to the vehicle floor pan, while the other end of the strut engages the throttle pedal. During this testing program, the repeatability of the throttle position using the actuator is approximately ±1 percent of full throttle.

PRE-TEST CALIBRATION RUNS - Each time the Taurus is taken out to the test track, a pre-test calibration procedure is run. The pre-test calibration procedure begins with the car being driven onto the VRTC vehicle weigh station (four low profile Winslow force plates, mounted on the shop floor, that are used by VRTC to measure the four wheel loads simultaneously). The vehicle weight and tire tread depth is noted at each wheel. The Megadac is autobalanced and these values are saved by the Megadac, to be reloaded after the vehicle reaches the test area. Once the vehicle reaches the skid pad, a standing calibration is performed. This is a record of what the transducers are reading with the engine running, but no other inputs. After the standing calibration, the autobalanced values are restored. The next test is the 1000-ft (304.8-m) calibration run. It is designed to check the accuracy of the fifth wheel. The vehicle is driven the length of a 1000-ft course with the data collection system active. Data collected during this run is post-

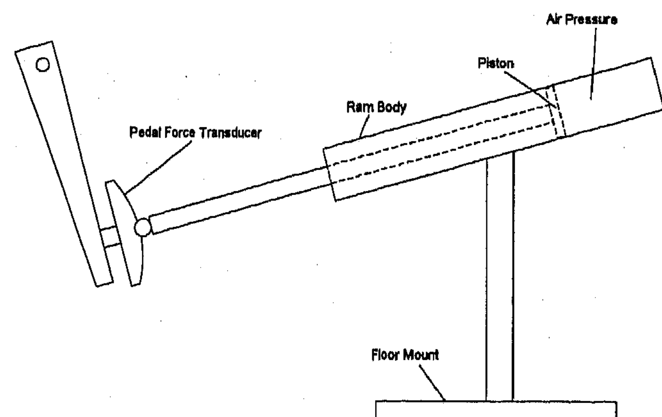

Figure 2. Pneumatic brake ram

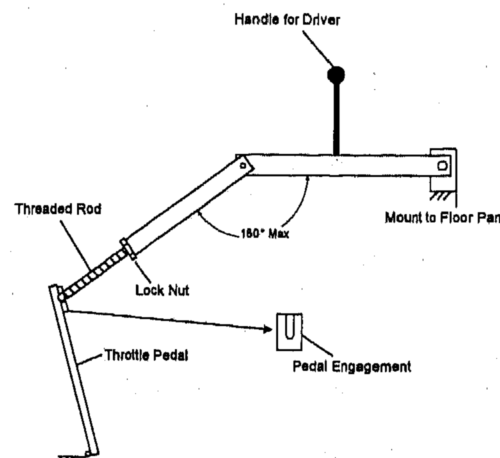

Figure 3. Throttle position actuator

processed to determine the average front ride height and the handwheel position offset can be found during post-test processing. The last calibration procedure is the 18 to 9 meters/second (40 to 20 miles per hour) run (the vehicle is driven in a straight line, and the speed is held constant at 18 and 9 meters/second for approximately 5 seconds each). This test is designed to check the accuracy of the vehicle speed sensor at two test speeds. Data from this run are used during post-test processing to determine the four tire rolling radii.

TEST MANEUVERS

This section describes the test maneuvers run for this project. Each basic maneuver type will be described in detail, and the actual test cases presented in tabular form. All testing was performed at the Transportation Research Center, in East Liberty, Ohio. Detailed descriptions of the TRC facilities used can be found in reference [9]. Basic descriptions of the facilities used are:

•**Vehicle Dynamics Area (VDA):** a 550 by 450-meter flat asphalt test surface with loops on two sides. The VDA is used for all handling type testing.

•**Skid Pad:** an 8-lane, 1200-meter long concrete test area with loops at each end. The skid pad is used for straight-line maneuvers such as driveline and brake testing.

•**Brake Slope:** 12-percent and 15-percent slope concrete test surfaces built to test vehicle parking brakes.

For many of the maneuvers, approximately 2 seconds of pre-trigger data are collected. This data is used to characterize the pre-maneuver state of the test vehicle. The pre-trigger data collection is a feature of the Megadac. After the Megadac is armed, data is collected and stored in a user definable size circular memory buffer. When the Megadac is triggered, the content of the buffer is written to the tape followed by the post event data.

For maneuvers where repeatable open-loop inputs can be achieved, each test is repeated up to 10 times. The data from these repeat tests is then ensemble averaged in the time domain to obtain statistical measures of test repeatability. The time-domain ensemble averaging is described later in this paper.

Each maneuver is designated by a two-character maneuver code. The first letter of the code shows the major maneuver type (e.g. "A" indicates a straight-line acceleration test). The second character designates a unique set of driver inputs (i.e. steering, throttle, and braking) for the test. This second character is referred to as the minor maneuver code and the major maneuver determines its meaning.

STRAIGHT-LINE ACCELERATION MANEUVERS - Straight-line acceleration maneuvers (maneuver code A) are run to provide data for characterizing the test vehicle's drivetrain performance. Table 2 shows details of the 10 test conditions run. All of the tests are run on TRC's skid pad. The throttle position is controlled using the mechanical throttle actuator described earlier. The test driver controls the steering wheel and attempts to keep the vehicle traveling in a straight line using the lane markings on the skid pad as an aid.

Minor maneuver codes A, B, and C are designed to test the overall drivetrain characteristics. For these runs, the gear selector is put in the drive ("D") position, and the transmission allowed to shift in its normal mode. Each run is started with the running vehicle stopped with no throttle input, in its test lane, with the driver's foot on the brake pedal. The data acquisition system is set to trigger on approximately 5-percent throttle input. When the data acquisition system is armed, the driver removes his foot from the brake pedal, and simultaneously pushes the throttle actuator into position. Minor maneuver codes A, B, and C correspond to fixed throttle inputs of approximately 10, 30, and 75 percent. Data recording for each test is continued for either 50 seconds or until the vehicle speed reaches 33 meters/second.0

Minor maneuver codes D, E, F, G, H, and I are designed to test the engine characteristics. For these runs, the gear selector is put in the first gear ("1") position so the transmission is not allowed to shift. Each run is started with the running vehicle stopped with no throttle input, in its test lane, with the driver's foot on the brake pedal. The data acquisition system is set to trigger on approximately 5-percent throttle input. When the data acquisition system is armed, the driver removes his foot from the brake pedal, and simultaneously pushes the throttle actuator into position. Run codes D, E, F, G, H, and I correspond to fixed throttle inputs of approximately 10, 20, 30, 50, 75, and 100 percent. Data recording for each test is continued until the vehicle speed reaches 15 meters/second, which corresponds to the maximum safe engine speed in first gear.

The next straight-line acceleration run is minor maneuver code J, which is designed to test the transmission down-shifting characteristics. For these runs, the gear selector is put in the drive ("D") position, and the transmission is allowed to shift in its normal mode. For this test, the vehicle is driven in a straight line at a constant 22 meters/second, utilizing the cruise control. The data system is set to trigger at 60-percent throttle, and the throttle actuator is set for 85-percent throttle. With the vehicle traveling at a constant 22 meters/second and the data system armed, the driver pushes the throttle actuator into position. This causes the transmission to downshift from fourth to third gear. The data system is set to keep approximately 2 seconds of pre-trigger data, and to record for approximately 8 seconds after the throttle application.

Table 2. Straight-Line Acceleration Maneuvers

Code	# Runs	Vx (m/s)	% Throttle	Gear Pos.
AA	9	0 -> 33	10	D
AB	9	0 -> 33	30	D
AC	11	0 -> 33	75	D
AD	5	0 -> 15	10	1
AE	5	0 -> 15	20	1
AF	5	0 -> 15	30	1
AG	5	0 -> 15	50	1
AH	5	0 -> 15	75	1
AI	5	0 -> 15	100	1
AJ	4	22 -> 33	85	D
AK	11	0 -> 33	10 -> 100	D

The final set of straight-line acceleration runs are found in maneuver code K, which are used to determine the shifting characteristics at various throttle positions. For these runs, the gear selector is put in the drive ("D") position, and the transmission is allowed to shift in its normal mode. Each run is started with the running vehicle stopped with no throttle input, in its test lane, with the driver's foot on the brake pedal. The data acquisition system is set to trigger on approximately 5-percent throttle input. When the data acquisition system is armed, the driver removes his foot from the brake pedal, and simultaneously pushes the throttle actuator into position. One run was performed at each throttle position, starting at 10 percent and ending at 100 percent with a 10 percent increase in throttle between each run. Data recording for each test continued until the vehicle reached either 33 meters/second or a constant speed below 33 meters/second.

BRAKE-IN-A-TURN MANEUVERS - Brake-in-a-turn maneuvers (maneuver code B) are run to provide data for characterizing the interaction of the lateral and longitudinal handling modes of the test vehicle. Table 3 shows the test specifications for the six brake-in-a-turn maneuvers, showing two test speeds, 22 and 33 meters/second, each with a low severity and a high severity brake-in-a-turn maneuver. The first four maneuvers were performed with the anti-lock brake system active; the last two were performed with it turned off. All of these maneuvers are run on the VDA.

Table 3. Brake-in-a-Turn Maneuvers

Code	# Runs	Vx (m/s)	Ax (m/s^2)	Ay (m/s^2)
BA	7	22.4	-2.5	-2.2
BB	10	22.4	-4.8	-6.5
BC	8	33.4	-3.7	2.1
BD	11	33.4	-4.7	5.7
BE	11	22.1	-4.0	-4.9
BF	12	33.3	-4.3	6.1

The steering wheel stop is installed, and the stops set at straight ahead and at the desired steering wheel angle for the test. The data system is set to trigger off the steering wheel angle, and is set up to save approximately 2 seconds of pre-trigger data. The data system is used to fire the pneumatic brake pedal ram when the steering wheel trigger level is reached. This means that except for propagation delays (approximately 0.1 seconds), the steering and braking inputs are applied at the same time. Data is recorded until the vehicle comes to a stop.

The brake-in-a-turn maneuver starts with the brake ram air pressure and steering stop position set to give the desired decelerations. The test driver uses the cruise control to attain the initial test speed and the data system is armed. The steering wheel is initially held against the zero (straight ahead) stop. The driver triggers the test by rapidly turning the steering wheel against the other stop and holding it there until the test is complete. As the test triggers, the brake ram fires and the vehicle slows to a stop. Each repeat test is run in approximately the same location on the VDA. Because of heat buildup in the brakes, especially with the 33 meters/second runs, the vehicle is driven for a few minutes between test runs to allow the brakes to cool.

CONSTANT SPEED J-TURN MANEUVERS - Constant speed J-turn maneuvers (maneuver code C) are run to provide data for characterizing the lateral handling mode of the test vehicle. Table 4 shows the test specifications for the twelve J-turn maneuvers, run at three test speeds of 11, 22 and 33 meters/second, each with four severity levels ranging from lateral accelerations of 2 meters/second^2 to 8 meters/second^2. All of these maneuvers are run on the VDA.

Table 4. Constant Speed J-Turn Maneuvers

Code	# Runs	Vx (m/s)	Ay (m/s^2)
CA	10	11.2	2.0
CB	9	11.3	-4.0
CC	10	11.5	6.0
CD	6	11.3	-8.0
CN	8	22.7	-2.0
CP	10	22.4	4.0
CQ	9	22.6	-6.0
CR	7	22.0	6.5
CV	8	33.0	2.0
CW	6	33.5	-4.0
CX	10	33.2	6.0
CY	5	33.2	-7.0

The steering wheel stop is installed, and the stops set at straight ahead and at the desired steering wheel angle for the test. The data system is set to trigger off the steering wheel angle. Approximately 2 seconds of pre-trigger data are saved, and data is recorded for approximately 5 seconds after the steering input to allow the vehicle to reach steady-state.

The J-turn maneuver starts with the steering stop position set to give the desired lateral acceleration. The test driver uses the cruise control to attain the initial test speed and arms the data system. The steering wheel is initially held against the zero (straight ahead) stop. The driver rapidly turns the steering wheel (which triggers data collection) until it hits the other stop and holds it there until the test is complete. Each repeat test is run in approximately the same location on the VDA.

SPECIAL MANEUVERS - Several special maneuvers were performed. Two of these maneuvers provide additional information about the steering system and the third about low-speed vehicle trajectory. The three maneuvers are the flick test, the J-turn and release test, and turning at an intersection.

The flick maneuvers (maneuver code F) are run to test the vehicle's steering stability. Table 5 shows the test specifications for the four maneuvers, run at test speeds of 11 and 22 meters/second. Lateral acceleration levels ranged from 3.6 meters/second^2 to 8.8 meters/second^2.

Table 5. Special Maneuvers

Code	# Runs	Vx (m/s)	Ay (m/s²)
FA	10	11	3.6
FB	7	11	-6.6
FC	7	22	-5.0
FD	8	22	8.8
GA	13	11	2.0
GB	13	11	-4.0
GC	12	11	6.0
GN	12	22	-2.0
GP	13	22	4.0
GQ	12	22	-6.0
TA	1	0 to 4	0 to -1.5
TB	1	0 to 4	0 to 1.4

The steering wheel stop is installed, and the stops set at straight ahead and at steering wheel angles of 90 degrees for maneuvers FA and FC and 180 degrees for maneuvers FB and FD. The data system is set to trigger off the steering wheel angle. Approximately 2 seconds of pre-trigger data are saved, and data is recorded for approximately 3 seconds after the steering input to allow the vehicle to reach steady-state.

The flick maneuver starts with the steering stop position set to give the desired steering input. The test driver uses the cruise control to attain the initial test speed and arms the data system. The steering wheel is initially held against the zero (straight ahead) stop. The driver rapidly turns the steering wheel (which triggers data collection) until it lightly contacts the other stop and then immediately releases the wheel. The vehicle is then permitted to resume its original path on its own. Each repeat test is run in approximately the same location on the VDA.

Constant speed J-turn and release maneuvers (maneuver code G) are run to provide data for characterizing the steering system of the test vehicle. Table 5 shows the test specifications for the six J-turn and release maneuvers, run at two test speeds of 11 and 22 meters/second, each with three severity levels ranging from lateral accelerations of 2 meters/second^2 to 6 meters/second^2. All of these maneuvers are run on the VDA.

The steering wheel stop is installed, and the stops set at straight ahead and at the desired steering wheel angle for the test. The data system is set to trigger off the steering wheel angle. Approximately 2 seconds of pre-trigger data are saved, and data is recorded for approximately 5 seconds after the steering input to allow the vehicle to reach steady-state.

The J-turn and release maneuver starts with the steering stop position set to give the desired lateral acceleration. The test driver uses the cruise control to attain the initial test speed and arms the data system. The steering wheel is initially held against the zero (straight ahead) stop. The driver rapidly turns the steering wheel (which triggers data collection) against the other stop and holds it there for 3 seconds. He then takes his hands off the steering wheel and allows the vehicle to return to a straight course. Each repeat test is run in approximately the same location on the VDA. These repeat tests are not used by the ensemble averaging routines (described later), but are run to better characterize the steering system.

Turning-at-an-intersectionmaneuvers(maneuver code T) are run to provide data for validating vehicle trajectory calculations. Table 5 shows the test specifications for the two turns, one left and the other right, run at low speed. These maneuvers are run on an area of asphalt delineated by two perpendicular lines and each turn is performed once.

The vehicle is positioned at the intersection of two perpendicular lines. Data collection is started and stopped by the driver. No pre-trigger data is collected. In addition to the on-board instrumentation, tire path data is collected. The tires are chalked and as the turn is performed, the chalk from the tires is transferred to the asphalt surface. The x and y-coordinates for multiple points on the path are determined by measuring the distances from the two perpendicular reference lines to the center of the chalk path. The vehicle paths for the left and right turns are shown in Figures 4 and 5, respectively. The lateral acceleration was approximately 1.5 meters/second^2.

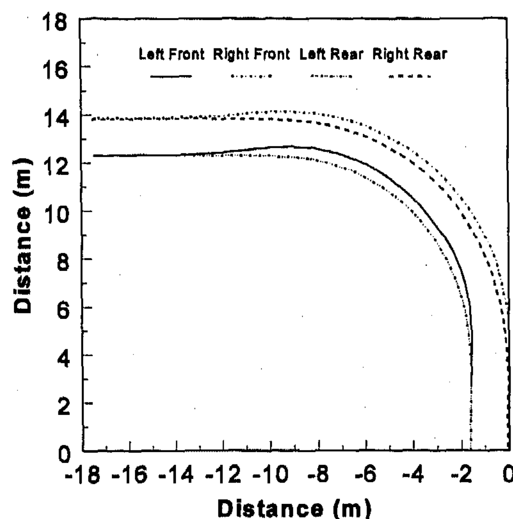

Figure 4. Left turn at an intersection (maneuver code TA)

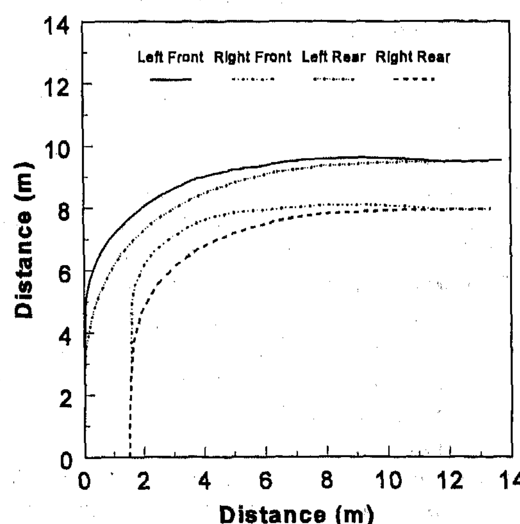

Figure 5. Right turn at an intersection (maneuver code TB)

In Figures 4 and 5, the front axle track appears to be narrower than the back axle track. This is because the front wheels are turned and the front axle is not perpendicular to the vehicle path but is skewed. This effect is more noticeable in the right turn (Figure 5) because that turn is sharper than the left.

Pulse Steer Maneuvers - Constant speed pulse steer maneuvers (maneuver code P) are run to provide data for characterizing the lateral handling mode of the test vehicle in the frequency domain. Table 6 shows the test specifications for the six pulse steer maneuvers (minor maneuver codes B through F) run at three test speeds of 11, 22 and 33 meters/sec, each with positive and negative steering pulses having magnitudes sufficient to achieve lateral accelerations of approximately 3 meters/second^2 (minor maneuver code A was run to debug the test procedure, and is not at one of the standard test speeds). All of these maneuvers are run on the VDA.

Table 6. Pulse Steer Maneuvers

Code	# Runs	Vx (m/s)	Steer Amplitude (rad)
PA	9	20.2	0.75
PB	6	11.4	1.2
PC	7	11.5	-1.1
PD	8	22.8	0.57
PE	10	22.9	-0.55
PF	8	33.7	0.35
PG	9	33.5	-0.38

The steering wheel stop is installed, and the stops set at straight ahead and at the desired maximum steering wheel angle for the test. The data system is set to trigger off the steering wheel angle. Approximately 2 seconds of pre-trigger data are saved, and data is recorded for approximately 5 seconds after the steering input to allow the vehicle to reach steady-state.

The pulse steer maneuver starts with the steering stop position set to achieve a maximum lateral acceleration of approximately 3 meters/second^2. The test driver uses the cruise control to attain the initial test speed, and arms the data system. The steering wheel is initially held against the zero (straight ahead) stop. The driver triggers the test by rapidly turning the steering wheel to the other stop, then immediately returning it to the zero stop and holding it there until the test is complete. Typical pulse duration is less than 0.2 seconds, providing good steering input power out to 3.5 to 4 hertz. Each repeat test is run in approximately the same location on the VDA.

DOUBLE LANE-CHANGE MANEUVERS - Double lane-change maneuvers (maneuver code LA, only one minor maneuver codes is used for this type of test) are run to provide data for characterizing the lateral handling mode of the test vehicle. Table 7 shows the test specifications for the nine double lane-change maneuvers run at test speeds ranging from 11 to 20 meters/second, with peak lateral accelerations ranging from 4 meters/second^2 to 8.5 meters/second^2. All of these maneuvers are run on the VDA through the same lane change course. Only the vehicle speed is varied. The course geometry is laid out using cones, with lane widths are 3.65 meters. The length of the gates are 18.3 meters, and the distance between the two gates is 22.9 meters.

Table 7. Double Lane-Change Maneuvers

Code	Vx (m/s)	Max. Ay (m/s^2)
LA00	11.0	-4.6
LA01	12.5	4.8
LA02	15	-6.0
LA03	11	-4.2
LA04	13	5.0
LA05	15.5	-5.0
LA06	16	-7.0
LA07	18	7.5
LA08	20	8.5

The data system is set to trigger off the steering wheel angle. Approximately 2 seconds of pre-trigger data are saved, and data is recorded until the driver hits the "Esc" key on the laptop. The driver is instructed to use the cruise control to set the desired test speed, arm the data system, and get the vehicle aligned with the entrance lane. The steering stop is not used for this test, so the steering control input represents the driver/vehicle closed-loop course-following performance. The driver's task is to keep the vehicle within the course boundaries marked by the cones. The driver is also instructed to steer as "smoothly" as possible. Unlike most of the maneuver types, repeat test are not run for the double lane-change maneuver. This is because the driver steering input is closed-loop, and is inherently non-repeatable.

Straight-Line Braking Maneuvers - Straight-line braking maneuvers (maneuver code S) are run to provide data for characterizing the braking characteristics of the test vehicle. Table 8 shows the test specifications for five straight-line braking maneuvers (minor maneuver codes B through F) with an initial test speed of 22 meters/second, with longitudinal accelerations ranging from -2 to -9 meters/second^2. All of these maneuvers are run on the skid pad.

Table 8. Straight-line Braking Maneuvers

Code	# Runs	Vx (m/s)	Ax (m/s^2)
SB	10	22	-2
SC	8	22	-3
SD	9	22	-5
SE	9	22	-7.5
SF	12	22	Max
SG	10		Brake on 12% slope
SH	10		Brake on 15% slope

The steering wheel stop is not installed, and the driver is instructed to keep the vehicle traveling in a straight line. The data system is set to trigger off the brake pedal force, and is setup to save approximately 2 seconds of pre-trigger data. The driver uses a switch to fire the pneumatic brake pedal ram. Data is recorded until the vehicle comes to a stop.

The maneuver starts with the brake ram air pressure set to give the desired deceleration. The test driver uses the cruise control to attain the initial test speed. With the data system armed, the driver pushes the switch to fire the ram. Each repeat test is run in approximately the same location on the skid pad. Because of heat build up in the brakes, the vehicle is driven for a few minutes between test runs to allow the brakes to cool.

Minor maneuver codes G and H are "stop on a hill" tests, and are used to provide data to evaluate the simulation's tire model at low speeds and when the vehicle is stopped (standard tire models used in handling simulations can not simulate tire force at low or zero speed, and special models must be developed for use in driving simulators). For these tests, the vehicle is driven onto the brake slope (either 12-percent or 15-percent slope) with an initial speed of approximately 11 meters/second (attained by the driver controlling the throttle, not using the cruise control). Using his foot to control the brake pedal, the driver brings the vehicle to a stop. The data system triggers off the brake pedal force, and saves approximately 2 seconds of pre-trigger data. The driver lets the data system record for approximately 5 seconds after the vehicle has stopped.

SLOWLY INCREASING STEER MANEUVERS - Constant speed, slowly increasing steer maneuvers (maneuver code XC, only one minor maneuver code is used for this type of test) are run to provide data for characterizing the lateral handling mode of the test vehicle. Table 9 shows the test specifications for the twenty slowly increasing steer maneuvers run at three test speeds of 11, 22 and 33 meters/second. Runs 0 to 5 have maximum lateral accelerations of approximately 4 meters/second^2, while runs 6 to 19 are run to the vehicle's maximum lateral acceleration (approximately 8 meters/second^2). All these maneuvers are run on the VDA.

The steering wheel stop is not installed for these tests, with the driver attempting to input a slow ramp input to the steering wheel. The data system is set to trigger off the steering wheel angle. No pre-trigger data is saved, and data is recorded until the driver manually stops the recording.

The maneuver starts with the test driver using the cruise control to attain the desired test speed. With the data system armed, and the vehicle traveling in a straight line, the driver starts the data recording. After a few seconds, the driver slowly starts to steer in the specified direction, trying to input a constant rate steering wheel angle ramp input. When the desired maximum lateral acceleration is reached, the driver stops the data recording, and brings the vehicle to a stop. At all test speeds, the maneuvers are run with both positive and negative steering inputs to characterize any vehicle asymmetries.

While this is a closed-loop steering maneuver, each vehicle speed/steering direction combination is repeated two or three times. These repeat tests are not used by the ensemble averaging routines, but are run to better characterize the vehicle steady-state limit performance.

COAST-DOWN MANEUVERS - Coast-down maneuvers (maneuver code XF, only one minor maneuver code is used for this type of test) are run to provide data for characterizing the aerodynamic and rolling drag of the test vehicle. Table 9 shows the test specifications for the 10 coast-down runs, all of which start at 33 meters/second. All of these runs are done on the skid pad.

The steering wheel stop is not installed for these tests, with the driver attempting to keep the vehicle traveling in a straight line with as little steering as possible. The data system is triggered manually by the test driver. No pre-trigger data is saved, and data is recorded until the vehicle speed drops below approximately 6.5 meters/second.

The maneuver starts with the test driver using the cruise control to attain the desired test speed. With the data system armed and the vehicle traveling in a straight line, the driver shifts the transmission into neutral, then starts the data system. The driver's task now is to keep the vehicle in its lane using as few steering corrections as possible.

ON-CENTER WEAVE MANEUVERS - On-center weave maneuvers (maneuver code XH, only one minor maneuver code is used for this type of test) are run to provide data for characterizing the on-center handling and steering system of the test vehicle. A detailed description of this test can be found in reference [10]. Table 9 shows the test specifications for the 25 on-center weave runs, which are run at speeds of 13, 22, and 33 meters/second. All these runs are done on the VDA.

The steering wheel stop is not installed for these tests, with the driver attempting to input a 0.2 hertz sinusoidal steering input with an amplitude to produce a maximum lateral acceleration of 2 meters/second^2. The data system is triggered manually by the test driver. No pre-trigger data is saved, and data is recorded until the driver manually stops the data system.

The maneuver starts with the test driver using the cruise control to attain the desired test speed. With the data system armed, and the vehicle traveling in a straight line, the driver starts the data system. The drivers task now is to input a 0.2 hertz sinusoidal steering input with an amplitude to produce a maximum lateral acceleration of 2 meters/second^2. The driver inputs one-and-a-half to two full cycles, then returns the steering wheel to zero (straight a head), and turns off the data system.

While this is a closed-loop steering maneuver, each test is repeated approximately six times. These repeat tests are not used by the ensemble averaging routines, but are run to better characterize the vehicle steering system.

On-Center Transition Maneuvers - On-center transition maneuvers (maneuver code XI, only one minor maneuver code is used for this type of test) are run to provide data for characterizing the on-center handling and steering system of the test vehicle. A detailed description of this test can be found in reference [10]. Table 9 shows the test specifications for the 49 on-center transition runs, which are run at speeds of 13, 22, 33 meters/second. At each test speed, runs with positive and negative steering inputs are run. All these runs are done on the VDA.

The steering wheel stop is not installed for these tests, with the driver attempting to gradually move the steering wheel from a "hands off" straight ahead condition to a low-g cornering condition. The data system is triggered manually by the test driver. No pre-trigger data is saved, and data is recorded until the driver manually stops the data system.

The maneuver starts with the test driver using the cruise control to attain the desired test speed. With the data system armed and the vehicle traveling in a straight line with his hands off the steering wheel, the driver starts the data system. The driver's task now is to lightly place his palms on the steering wheel, and slowly turn it either clockwise or counterclockwise.

The driver turns the wheel until the vehicle is cornering at 1 to 2 meters/second^2, then turns off the data system.

While this is a closed-loop steering maneuver, each test is repeated approximately six times in each steering direction. These repeat tests are not used by the ensemble averaging routines, but are run to better characterize the steering system.

COAST-TO-STOP ON SLOPE MANEUVERS - Coast-to-stop on slope maneuvers (maneuver code XP and XQ) are run to provide data for characterizing the low speed tire models used with driving simulators. Table 9 shows the test specifications for tests done on 12 and 15-percent slopes. All of these runs are done on the brake slope facility.

These tests are very similar to tests SG and SH, (described earlier) except rather than braking to a stop, the slope is used to stop the vehicle, before the brakes are applied. The data system is triggered manually by the test driver. No pre-trigger data is saved, and data is recorded until the driver manually stops the data system.

The maneuver starts with the test driver approaching the brake slope at approximately 10 meters/second. Before the beginning of the brake slope, the data system is manually triggered, and the throttle released. When the vehicle comes to a stop on the slope, the driver pushes the brake pedal to keep the vehicle from rolling back down the slope. After waiting a few seconds, the driver manually turns off the data system.

Table 9. Miscellaneous Maneuvers

Code	Description	# Runs	Vx (m/s)
XC00	Slowly Increasing Steer - negative	1	12
XC01	Slowly Increasing Steer - negative	1	22

XQ	Coast-to-stop on 15% slope	9	

DATA REDUCTION

Up to now, this paper has described the acquisition and storage of the "raw" vehicle data. This section will describe the processing of the raw data into a form suitable for simulation evaluation. The process may involve (depending on the test) removing offsets, digital filtering, computing derived channels from measured channels, ensemble averaging in the time domain, and/or conversion of the time-domain data into the frequency domain. All data processing is done using the software program MATLAB, version 4.2c[MATLAB® - Reference Guide, The Mathworks, Inc., July 1993.1511]. Some of the analysis also uses the Signal Processing Toolbox version 3.0b (the Signal Processing Toolbox is an add-on to MATLAB). All VRTC written MATLAB .M files (MATLAB's scripting language) used to process the data are available electronically from VRTC. All of the processing software is "hard coded" to read and write files based on VRTC's directory structure and file naming conventions.

OFFSET REMOVAL, DIGITAL FILTERING, AND DERIVED CHANNEL COMPUTATION - The first step in the processing of all raw data files is to remove channel offsets, digitally filter the data, and compute the derived channels. The MATLAB function BUTTER is used to design a two-pass phaseless Butterworth low-pass digital filter for all channels except longitudinal velocity, with a 3-dB down cutoff frequency of 10 hertz and a total of 12 poles. Because of significant cyclic noise in the longitudinal velocity channel (at the frequency of the fifth wheel rotational speed), a second filter is designed for the longitudinal velocity channel with a 3-dB down cutoff frequency of 2 hertz and a total of 6 poles. This additional filtering of longitudinal velocity was necessary to get "reasonable" wheel slip estimates.

The only exception to the above is for the filtering of the ultrasonic displacement transducers. These transducers tend to have drop outs of a few samples rather than the random noise found on the other channels. For this type of signal, a running median filter is more appropriate. A running median filter takes a window of data around each point of the raw data, computes the median of the data in the window, and puts this median value in the output matrix. This procedure is repeated for each point in the input matrix. This type of filter has the characteristic of rejecting large amplitude, short duration spikes in the data, such as a dropout. The wider the window, the wider the dropout that will be rejected, but the lower the filter's cutoff frequency will be. The MATLAB command MEDFILT1 is used to filter the ultrasonic transducer output with a window size of 10 points.

A few of the channels also have offsets removed. The tape reading program uses the data from the pre-test calibration run to compute the steering wheel angle offset and the offset of the ultrasonic transducer readings. These values are stored in the data files as Keywords, and after these channels are filtered, the offset values are subtracted from each data point. The rate transducers used to measure roll, pitch and yaw rate are known to have a slow drift. Since the transducers are not zeroed by the Megadac before each test run, the measurements can get an offset. If there is more than 1 second of pre-trigger data in the test, and the mean value of the steering wheel angle is less than 10 degrees, then the mean value of the rate measurement, from the first data point until 25 points before time zero, is subtracted from the entire rate measurement channel. This can only be done for runs where there is some "straight ahead" running at the beginning of the data. For runs where there is no pre-trigger data, the rate measurements may be offset, but there is no way for the processing software to know their magnitudes.

A number of "derived" channels are also computed and included in the output file. Derived channels are channels computed by combining other channels, for example chassis roll angle, which is computed from the difference between the two ultrasonic ride height measurements. The derived channels are front and rear strut lengths, average steering wheel torque, steering rack position, power steering assist force, transmission gear number, chassis roll and pitch angles, and longitudinal wheel slip ratios.

Time-Domain Ensemble Averaging - In the late 1980's, VRTC conducted a large simulation evaluation project [4, 5] whose aim was to rank NHTSA's vehicle dynamics simulations. Much of the methodology developed during that project has been used in the current project. One development of the earlier project was to measure random experimental error by running repeat tests, and ensemble averaging each data channel in the time domain. There are two significant benefits to this procedure. First, by repeating each test (typically 10 times at VRTC), the influence of unmeasureable disturbances is greatly reduced (a wind gust, or a small area of the test surface with reduced friction for example). Secondly, it provides a measure of experimental uncertainty. It is VRTC's opinion that when comparing simulation predictions to experimental measurements, that the required accuracy of the simulation predictions can only be assessed within the experimental uncertainty (e.g. if experimentally, the uncertainty of the chassis roll angle measurement is ±1 degree, then if the simulation's roll angle prediction is within 1 degree of the experiment, it is accurate to within the uncertainty of the experiment).

This section describes the time-domain ensemble averaging of the test data. For each channel (measured and derived) in the filtered data files, the mean value and the 95-percent confidence interval of the mean are computed as a function of time. The interpretation of the confidence limits is that given the number of experiments, the mean value of the data is within the confidence interval to within 95-percent confidence (it does not say that the data will fall within the confidence interval to within 95-percent confidence, just that the actual mean of the data is within the interval). The 95-percent confidence interval around themean is computed by:

$$\varepsilon = t_{\alpha/2,n-1} \cdot \frac{s}{\sqrt{n}} \qquad (1)$$

where ε is the distance from the mean to the upper or lower boundary of the confidence interval, $t_{\alpha/2,n-1}$ defines the spread of the Gaussian distribution using the student t-distribution, s is the standard deviation of the data normalized by n-1 (computed using the MATLAB function std), and n is the number of runs used to compute the mean (see references 4 and 5 for a more complete explanation).

COMPUTATION OF VEHICLE FREQUENCY RESPONSES - The filtering and ensemble averaging procedures

described in the previous two sections prepare the experimental data for use with time-domain simulation evaluation methods. At VRTC, simulation evaluation is also performed in the frequency domain. Vehicle frequency responses to steering inputs are computed from the pulse steer (maneuver code P) tests for lateral acceleration, yaw rate, roll rate, and roll angle. The method used to compute the frequency responses is described in detail in [12], and the mathematics are not repeated here.

The frequency responses are computed based on repeat pulse steer runs. The test matrix defines both positive and negative steering angle pulse inputs at each of the three test speeds, and frequency responses are computed for each of the six conditions. For each run, the Power Spectral Density (PSD) of the steering wheel angle, the Cross Spectral Density (CSD) between lateral acceleration, yaw rate, roll rate, and roll angle and steering wheel angle, and the coherence between lateral acceleration, yaw rate, roll rate, and roll angle and steering wheel angle are computed. The MATLAB functions PSD, CSD, and COHERE are used to compute the PSD, CSD, and coherence. These functions are from the signal processing toolbox. All three functions use Welch's averaged periodogram method, which averages overlapping windowed (Hanning window) segments of the input vectors. The segments are 256 points long with a 128-point overlap.

After the PSD's, CSD's, and coherences have been computed for each run, for each frequency response to be computed, the mean value of the PSD, CSD, and coherence is computed (refer to reference [12] for details). The mean value of the frequency response is then computed by dividing the mean PSD by the mean CSD. The magnitude and phase angle of the complex result are found using MATLAB's abs and angle commands. The 95-percent confidence interval is computed using the equation

$$\varepsilon(f) = \cos^{-1}\sqrt{\frac{1-\left(\dfrac{1-\gamma_{io}^{2}(f)}{\sqrt[n]{1-P}}\right)}{\gamma_{io}^{2}(f)}} \qquad (2)$$

where $\varepsilon(f)$ is the confidence as a function of frequency f, $\Upsilon^2_{io}(f)$ is the computed coherence, n is the number of runs used, and P is the confidence level (in this case P=0.95).

SAMPLE RESULTS

This section presents a sample of the experimental measurements in both its raw and processed form. Issues of both experimental noise and repeatability are discussed. Computed vehicle frequency responses are also shown.

While the repeat testing and ensemble averaging performed at VRTC reduces the effects of random measurement noise, it is still important to keep the noise levels low. The term "measurement noise" is used here to represent the random variations in the data from transducer uncertainty, electrical and digitizing uncertainty, road roughness, variations in the tire/road friction, wind noise, other vibrations from the car itself, etc. This list is meant to represent everything in the physical measurement process and the vehicle that is not modeled by the vehicle dynamics simulations. The simulations represent idealized, deterministic vehicles operating on smooth, constant friction roads. The actual vehicle/road/measurement system is a stochastic process, operating in the presence of unknown disturbances.

To demonstrate the nominal levels of measurement noise, Figure 6 shows the lateral acceleration measurement from an 11 meters/second longitudinal velocity, 2 meters/second^2 lateral acceleration J-Turn run (V0RCA05). The dotted line is the raw data, and the solid line is the digitally filtered data. In the time range of 2 to 5 seconds, the vehicle is in steady-state (from a vehicle handling point of view). Using the raw data in this time period, the mean lateral acceleration is 1.69 meters/second^2, and the standard deviation is 0.067 meters/second^2. Using two standard deviations around the mean to contain 95 percent of the data, for this run, 95 percent of the measured data is within 8 percent of the mean. Figure 7 shows the lateral acceleration measurement from a 33 meters/second longitudinal velocity, 6 meters/second^2 lateral acceleration J-Turn run (V0RCX06). For this run, the mean lateral acceleration is 6.11 meters/second^2, and the standard deviation is 0.195 meters/second^2, so 95 percent of the measured data was within about 6 percent of the mean.

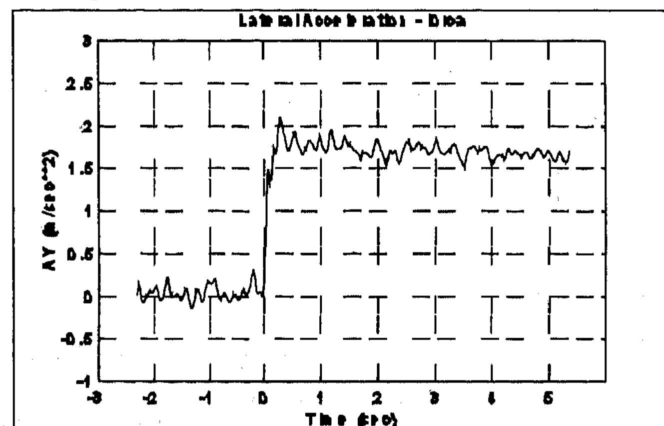

Figure 6. Lateral acceleration measurement from 2 m/s^2 J turn

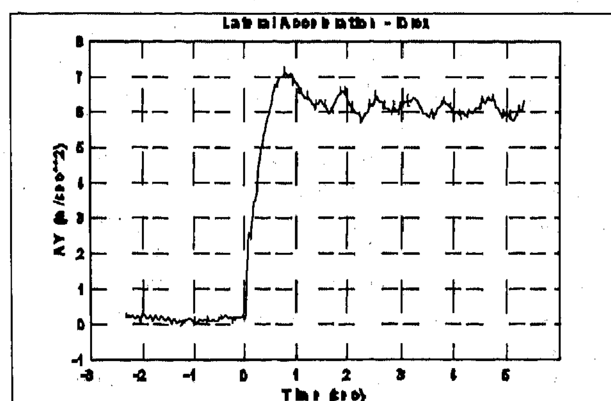

Figure 7. Lateral acceleration measurement from 6 m/s^2 J-turn

To show the test-to-test repeatability, the results of the ensemble averaging are used. Figure 8 shows the results of the time-domain ensemble averaging of the lateral acceleration of the 2 meters/second^2 J-turn used above. The dotted lines are the

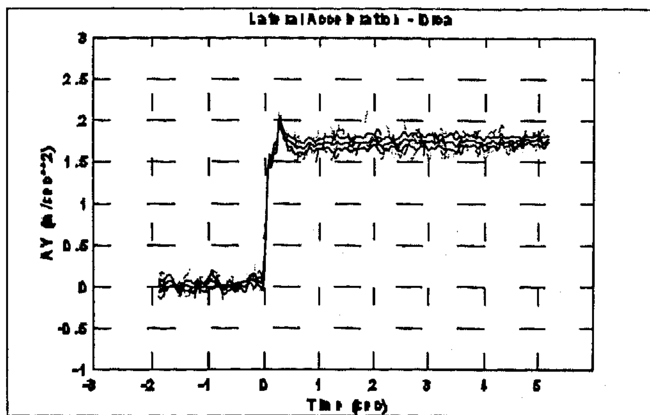

Figure 8. Ensemble averaging results from 2 m/s² J-turn filtered lateral acceleration measurements from the 10 repeat tests. The three solid lines represent the mean value, and the 95-percent confidence on the mean, based on the repeat tests. Figure 9 shows the same data with an expanded scale. As shown, the 95-percent confidence of the mean value is known to approximately ±0.05 meters/second².

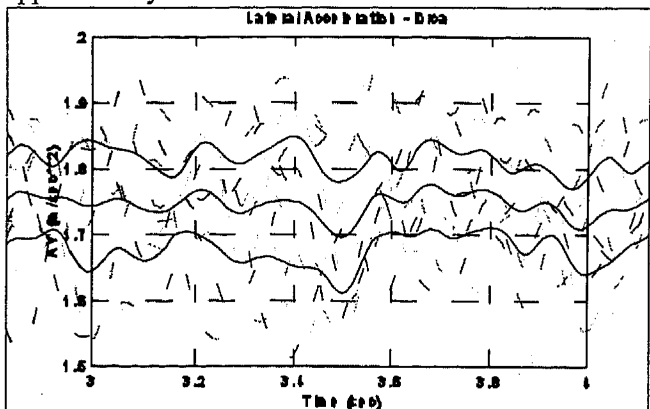

Figure 9. Ensemble Averaging Results - Expanded Scale

When running repeat testing, one source of test-to-test variation that can be controlled is the repeatability of the vehicle control inputs. For this testing program, the control inputs are steering wheel angle, brake pedal force, throttle position, and for the constant speed runs, cruise control speed setting. Using the 33 meters/second, 6 meters/second² J-Turn tests (V0RCX), the repeatability of the steering wheel inputs and the vehicle longitudinal velocity are demonstrated. Figure 10 shows the ensemble averaged results for the steering wheel angle. All of the filtered steering wheel angle data falls within approximately a 1-degree window, demonstrating that very good steering angle repeatability is achieved using the VRTC steering stop. Figure 11 shows the ensemble averaged results for the vehicle longitudinal velocity. As can be seen, the vehicle velocity from all 10 tests falls with in a window of approximately 0.5 meters/second.

Figure 12 shows the throttle position repeatability from the 50-percent throttle, straight-line acceleration runs (V0RAG). Excellent repeatability is achieved using VRTC's mechanical throttle pedal actuator, with all of the data falling within a window of approximately 1 percent of throttle position. Figure 13 shows the brake pedal force repeatability from the 5 meters/second² straight-line braking tests (V0RSD). The brake pedal force from all nine runs falls within a 6-newton window, demonstrating good repeatability using the pneumatic brake ram.

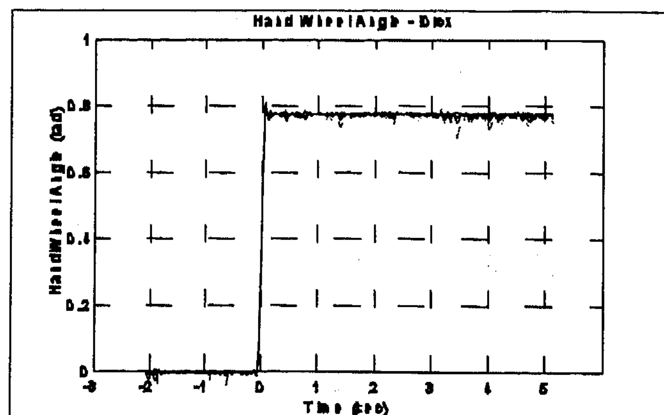

Figure 10. Steering Wheel Angle Repeatability

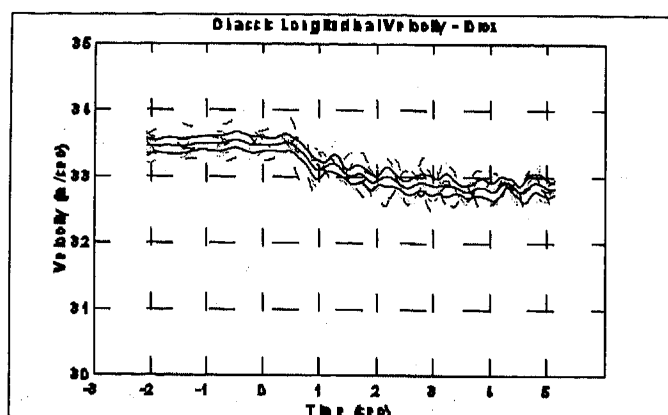

Figure 11. Longitudinal Velocity Repeatability

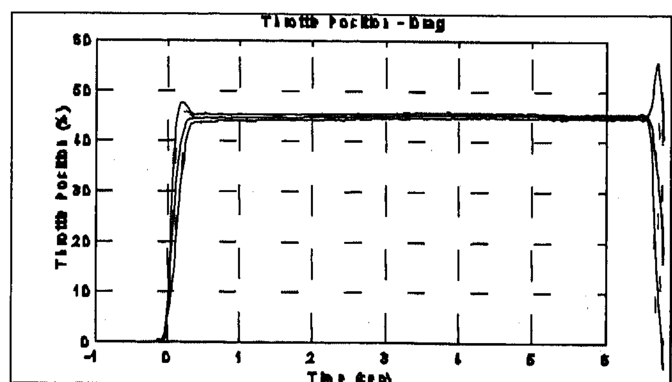

Figure 12. Throttle Position Repeatability

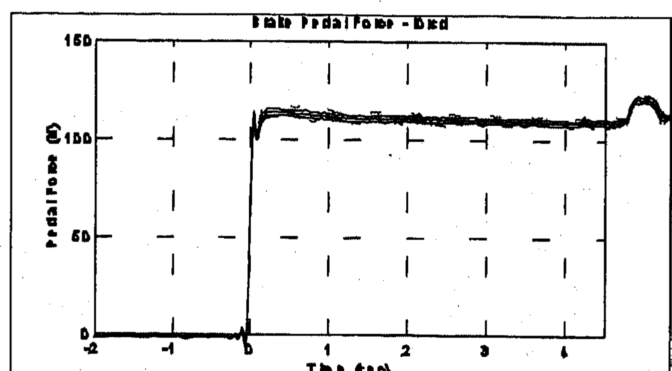

Figure 13. Brake pedal force repeatability

Figure 14 shows the vehicle yaw rate frequency response computed from the 22 meters/second runs (V0RPD). The frequency response is displayed from 2.5 to 20 radians per second (approximately 0.5 to 3 hertz). The top graph shows the magnitude mean and 95-percent confidence intervals of the mean. The center graph shows the phase angle mean and confidence intervals, while the bottom plot shows the mean coherence. As can be seen, for this set of runs, the mean coherence is near one across the entire frequency range. This indicates that there was sufficient input power at all frequencies, and that the input and output (steering wheel angle and vehicle yaw rate) are related in a "fairly" linear way under this maneuvering condition. The confidence intervals are relatively narrow, giving good confidence in all of this data.

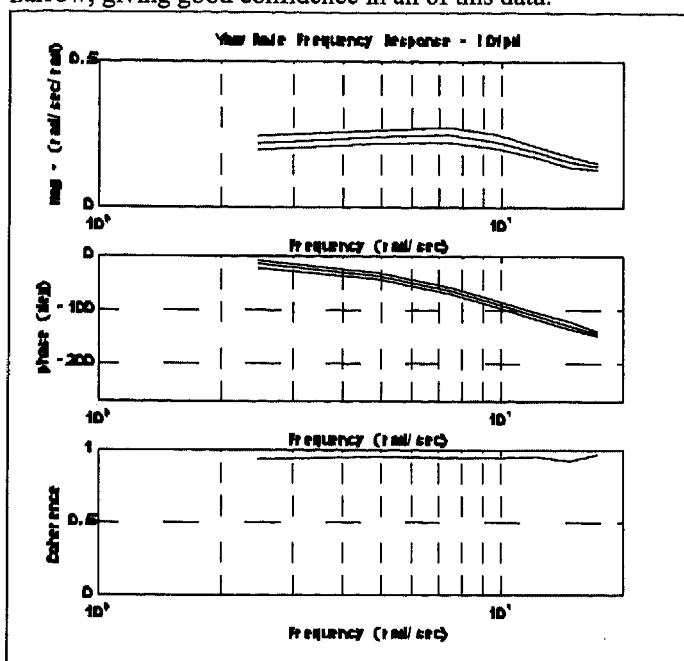

Figure 14. Computed yaw rate frequency response for 22 m/s runs

Figure 15 shows the lateral acceleration frequency response for the same set of test runs. Unlike the yaw rate frequency response, the coherence for the lateral acceleration starts to drop as the input frequency gets higher. Because of the lower coherence, the confidence intervals on the mean magnitude and phase angle get wider as the input frequency increases.

SUMMARY AND CONCLUSIONS

This paper describes the instrumentation and field testing of a 1994 Ford Taurus GL to generate benchmark data for VRTC's evaluation of the vehicle dynamics simulation to be used in NADS. The on-board instrumentation measured more than 40 transducers. The experimental program included 75 maneuver types/conditions and nearly 600 individual test runs.

The on-board instrumentation and data channels are listed. Each of the test maneuvers run by the Taurus is described, along with instrumentation setup, control actuation, test location, and driver procedures. The data reduction and data processing of the test data are detailed. Sample results of the testing, and an analysis of test repeatability and measurement noise, are also presented.

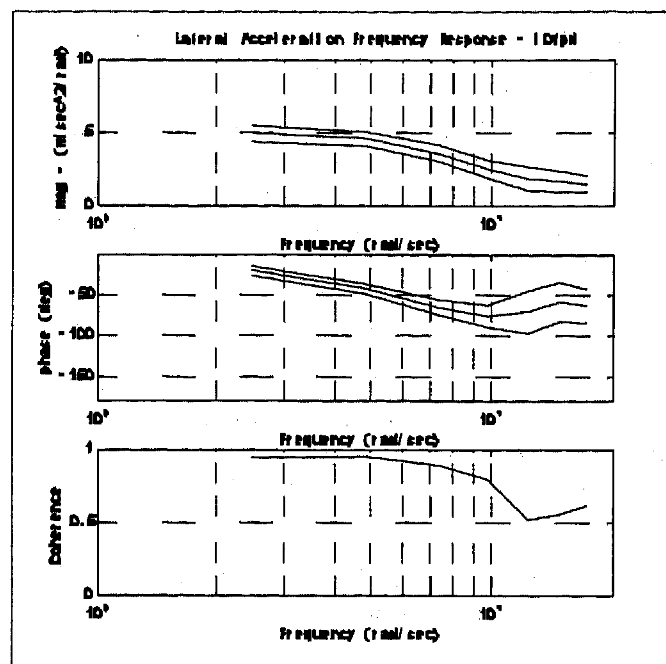

Figure 15. Computed Lateral Acceleration Frequency Response for 22 m/s Runs

VRTC performed this testing program to provide the data needed to evaluate the NADSdyna software. However, there is very little publicly available instrumented vehicle handling and braking test data, especially from a test program as comprehensive as the one described here. One of the purposes of this paper therefore is to make this test data available to other researchers. Electronic versions of the test data described in this paper can be obtained be contacting W. Riley Garrott at the Vehicle Research and Test Center at P. O. Box 37, East Liberty, Ohio, 43319, or via telephone at (937) 666-4511.

Future reports from the VRTC will describe the simulation parameter measurement and computation for the Taurus, and the simulation evaluation methodology and results. A similar program at VRTC will be performed using a Volvo-Fruehauf tractor-semitrailer, with reports and data to follow.

ABSTRACT

This paper discusses the development of a 1994 Ford Taurus vehicle model for the National Advanced Driving Simulator's planned vehicle dynamics simulation, NADSdyna. The front and rear suspensions of the Taurus are modeled using recursive rigid body dynamics formulations. To complement vehicle dynamics, subsystems models that include steering, braking, and tire forces are included. These models provide state-of-the-art high fidelity vehicle handling dynamics for real-time simulation. The realism of a particular formulation depend heavily on how the parameters are obtained from the physical system. Therefore, the development of a data set for a particular model is as important as the model itself. The methodology for generating the Taurus data set is presented. The power train model is not yet included, so the simulation is run with the vehicle either at constant speed or decelerating.

INTRODUCTION

The U.S. Department of Transportation's (DOT) National Highway Traffic Safety Administration (NHTSA) is pursuing the development of the National Advanced Driving Simulator (NADS), an operator-in-the-loop high fidelity real-time vehicle driving simulator. NADS will materially assist NHTSA, other federal agencies, and commercial organizations in enhancing human factors and crash avoidance research. Research areas include: driver-vehicle-road interactions like driving under the influence of alcohol, human factors research concerning driver workload and adaptation to emerging Intelligent Transportation System (ITS) equipment and technology, and regulations regarding automotive safety. A realistic mathematical vehicle dynamics model is a prerequisite for performing this complicated task. Therefore, this research is principally concerned with developing a vehicle dynamics model of a typical passenger car with a high degree of realism for safety and stability analysis. A data set for the 1994 Ford Taurus is developed for simulation validation [27,28].

With the advent and proliferation of powerful computer hardware and with the availability of better DAE (Differential Algebraic Equations) numerical solutions, general purpose software based on multi-body formalisms have emerged and are playing the same role for mechanical systems as finite element methods are playing for complex structures. The multi-body program Real Time Recursive Dynamics (RTRD) was developed at the University of Iowa Center for Computer-Aided Design (CCAD) to solve general purpose multi-body dynamic systems, and will provide the core dynamics for the NADS. The RTRD is based on a topological analysis of a rigid mechanism formulated as modified recursive dynamics equations using minimum relative joint coordinates, and can be implemented with parallel computational algorithms [3, 18]. To simulate a vehicle, CCAD, aided by Iowa State University and the University of Wisconsin, has supplemented the RTRD(Figure 1). The RTRD with these subsystems are called NADSdyna. This program provides capabilities close to those offered by leading commercial multi-body dynamics software, such as ADAMS and DADS, in terms of rigid-body mechanism modeling. However, only a limited number of vehicle models have been developed using the RTRD [21], and a comprehensive validation of these models under severe crash avoidance scenarios has not yet been assessed.

Users of the multi-body approach must still understand and specify the vehicle response effects that they wish to model and work this into the multi-body approach allowed by a given formulation [15]. Furthermore, the multi-body dynamics do not cover wheel spin dynamics, tire forces, engines, aerodynamics, power steering systems, automatic controls, etc. These subsystems are among the primary elements that dominate vehicle behavior and control.

MULTI-BODY DYNAMICS MODELING

A passenger vehicle is a mechanical system consisting of a number of constrained rigid bodies. It depends on the vehicle type and the dynamic problem under consideration what type of constraints, how many bodies, and which degrees of freedom have to be assigned. In the proposed model, all the bodies are constrained

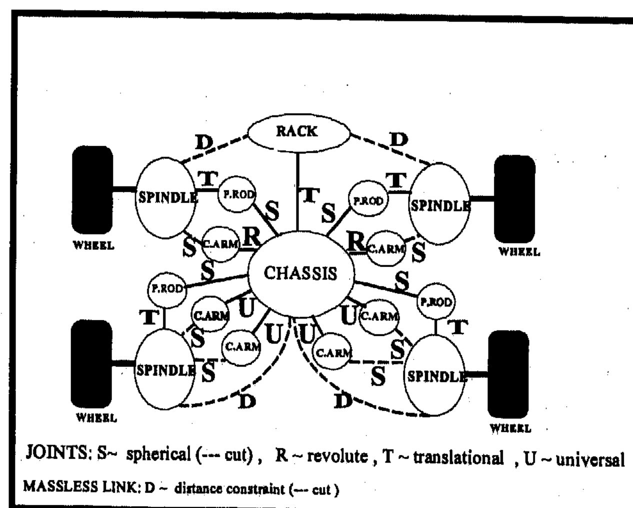

Figure 6. 1994 Ford Taurus RTRD Model

with rigid connections or joints. The left and right side of the vehicle are assumed to be symmetric. Friction forces in the suspension system exist at all metal-to-metal bearings. All the joints forming the suspensions are assumed to be frictionless.

FRONT SUSPENSION - The front suspension is a MacPherson strut type as shown in Figure 2. The kinematics of the model is similar to [12], and the spindle, lower control arm, and the piston rod are modeled as rigid bodies. The constraints are spherical joints between the spindle and the lower control arm, a spherical joint between the piston rod and the chassis, a translational joint between the piston rod and the spindle, and a revolute joint between the chassis and the piston rod. The tie rod connecting the spindle with the steering rack is not modeled as a rigid body; a kinematic distance constraint is used since its dynamics have a minor effect on the steering and suspension dynamics. If a rigid body had been used instead, the constraints would be a spherical joint between the tie rod and the spindle, and a universal joint between the steering rack and the tie rod. The steering rack and the chassis are connected with a translational joint that allows the steering rack to move parallel to the chassis frame to steer the front two wheels. This model provides the front suspension with two degrees of freedom with respect to the chassis; vertical movements, and rotations about the king pin axis. The model is shown in Figure 3.

REAR SUSPENSION - This suspension is a MacPherson strut type with two parallel control arms as shown in Figure 4. The multi-body model has the spindle, the piston rod, and the two control arms modeled as rigid bodies. The constraints are, a universal joint between the chassis and the control arms where rotations are around the vertical and horizontal axes, a spherical joint between the control arms and the spindle, a spherical joint between the piston rod and the chassis, and a translational joint between the spindle and the piston rod. The tension strut is not modeled as a rigid body, but with a kinematic distance constraint between the chassis and the spindle. This model gives the rear wheel one degree of freedom about the chassis, a circular vertical movement around the tension strut link. In the actual vehicle, due to bushing compliance, the wheel moves in an "elliptical" circular direction as forced by the control arms and the tension strut. The model is shown in Figure 5.

MODEL TOPOLOGY - The RTRD's recursive formulation requires rigid bodies to be connected in an open loop structure, or a spanning tree [1, 2]. The Taurus model contains ten closed loops, a joint on each loop is "cut" to get a spanning tree and the constraint equations associated with Lagrange multipliers are imposed on these cut joints to represent kinematically admissible motion. The procedure is based on cutting the joints that will result in a model with optimum computational efficiency characterized by the minimum number of coordinates and constraint equations [3]. Graph theory is used to identify the topological structure of multi-body dynamic systems, and weighting factors of some general kinematic joints are used for the purpose of minimizing the chain length and maximizing efficiency in parallel computation. For the dynamic steering system, the rack reaction forces can be derived from the Lagrange multipliers that correspond to the cut distance constraints between the wheels and the rack. The overall model is shown in Figure 6.

MULTI-BODY DYNAMICS PARAMETER MEASUREMENT - The vehicle center of gravity position, and mass moments of inertia were measured at VRTC on the Inertial Parameter Measurement Device (IPMD) [32]. The IPMD is a facility used to measure total vehicle center of gravity height and its mass moments of inertia about its center of gravity around its x, y, and z axis (as defined by SAE). The IPMD is a simple stable pendulum structure that the vehicle is driven onto and secured. Center of gravity height is estimated by applying a torque about the IPMD's pivot axis. Mass moments of inertia about the vehicle's X and Y axes (roll and pitch) are estimated by causing the vehicle/IPMD to oscillate about its pivot axis, and measuring the period of oscillation. Mass moment of inertia about the vehicle's Z axis (yaw) is measured by connecting springs to a table bearing that supports the vehicle, and causing the system to oscillate and measuring the period of oscillation. The location of the vehicle center of gravity in the horizontal plane and the total vehicle mass is estimated by measuring the four wheel weights. The location of all suspension attachment points on the chassis, the geometry of each suspension component, the mass, the center of gravity location, and mass moments of inertia were measured for VRTC by the Transportation Research Center Inc. Bi-filar and tri-filar torsional pendulum's are used to measure the mass moments of inertia of small components, and the charts and schematics are included in [25].

The geometric data consists all the three-dimensional coordinates of all connecting joints of the rigid bodies included in the dynamic formulations. These geometric data are transformed to generalized data format that consists of points and vectors forming the connectivity and constraints of the model with respect to a chassis reference point. The spindle assembly is made of the following components: wheel, brake rotor, strut without spring, knuckle, and brake caliper. The chassis inertia, mass and center of gravity are approximated by deducting the properties of the four spindles from the total vehicle. The chassis roll, pitch, and yaw inertia's are computed as follows :

$$I_{xc} = I_{xx} - m_c(z_t - z_c)^2 - 2m_f\left((z_f - z_t)^2 + y_f^2\right) - 2m_r\left((z_r - z_t)^2 + y_r^2\right) - 2I_{fx} - 2I_{rx} \quad (1)$$

$$I_{yc} = I_{yy} - m_c\left((z_t - z_c)^2 + (x_t - x_c)^2\right) - 2m_f\left(l_f^2 + (z_t - z_f)^2\right) \quad (2)$$
$$-2m_r\left(l_r^2 + (z_t - z_r)^2\right) - 2I_{fy} - 2I_{ry}$$

$$I_{zc} = I_{zz} - m_c(x_t - x_c)^2 - 2m_f\left(l_f^2 + y_f^2\right) - 2m_r\left(l_r^2 + y_r^2\right) - 2I_{fz} - 2I_{rz} \quad (3)$$

Where:

I_{xx}, I_{yy}, I_{zz} : Roll, pitch and yaw inertia of the total vehicle

I_{xc}, I_{yc}, I_{zc} : Roll, pitch and yaw inertia of the chassis

I_{fx}, I_{fy}, I_{fz} : Inertia of the front spindle

I_{rx}, I_{ry}, I_{rz} : Inertia of the rear spindle

l_f, l_r : Front and rear x-distance of the spindle c.g. to the vehicle c.g.

y_f, y_r : Y-distance from the vehicle x-axis to the front and rear spindle respectively.

m_t, m_c, m_f, m_r : The total vehicle, chassis, front spindle, and rear spindle masses respectively.

x_t, x_c, x_f, x_r: x-distance from the reference point to the c.g. of the total vehicle, chassis, front spindle, and rear spindle respectively

z_t, z_c, z_f, z_r : z-distance from the reference point to the c.g. of the total vehicle, chassis, front spindle, and rear spindle respectively

The multi-body model was first implemented in DADS [27]. After satisfactory qualitative results were achieved, the data were transformed to RTRD formulations. To transform the geometric data to a relative coordinate system, the direction cosine of each rigid body is computed with respect to the global coordinate system to obtain the orientation matrices. All the coordinates and

constraint vectors are transformed to global vectors with origins at the local frame center, then transformed to local frame orientations. The assembly is checked using the generalized inverse or pseudo inverse method to solve the nonlinear constraint equations [18].

The inertia is transformed to local frame, using the similarity transformation as follows,

$$J' = A^T J A \qquad (4)$$

where:

- J : Inertia in global coordinate system
- J' : Inertia tensor in local frame
- A : Transformation matrix of the rigid body

The RTRD rigid body preprocessor is used to analyze and generate topology and rigid body input files using the geometric and inertial data [18]. The initial conditions that consist of rigid body position and velocity are determined from a drop test simulation.

SPRING AND SHOCK ABSORBER - The two main dissipative elements of the suspension are dry friction and shock absorber viscous damping. For general handling maneuvers, cubic spline interpolation of the velocity-force shock absorber experimental curve is a good approximation (Figure 7). The springs and bump stops are modeled as nonlinear springs (Figure 8). In the multi-body formulations, these forces are formulated as external forces [18, 19].

The stiffness and the damping characteristics of the four strut units on the Taurus were measured for VRTC by Heitz Automotive Testing, Inc. A fixture was built to hold the strut top mount, with or without the spring installed, and drive the strut body using a hydraulic servo cylinder. The stiffness test was run by stroking the cylinder slowly (0.1 in/sec). A small amplitude, 100 Hz dither, was added to the input to simulate the vibration during actual driving. Force levels were between 0-1600 pounds, which provided data from the spring and the bump and rebound stops of the strut. The damping was measured by removing the springs and commanding ± 3 inch triangular inputs with varying ramp velocities between 1 and 70 inches per second. The spacing between velocities was closer for the lower velocities, and greater for the higher velocities.

VEHICLE SUBSYSTEMS MODELING

For a complete vehicle model, the multi-body formalism is augmented with other subsystems consisting of engine, power train, wheels, tires, steering, braking, aerodynamic forces, and terrain database. The power train and engine models are important to study vehicle traction characteristics, traction control systems, and the influence of drive-wheel traction on steering control [15]. A Ford Taurus model of the power train and engine is currently under development. At this phase of the project a simple cruise control is used to keep the vehicle at constant speed.

WHEEL KINEMATIC VARIABLES - The wheels are not modeled as rigid bodies, only the spin degree of freedom is formulated using this equation:

$$J\dot{\omega} = T - F_x r \qquad (5)$$

Where :

- J : Wheel spin inertia
- T : Applied torque
- $\dot{\omega}$: Wheel spin acceleration
- F_x : Tire longitudinal force
- r : Wheel rolling radius.

The longitudinal and lateral slips are solved using first-order differential equations as suggested by Bernard et al. [10]. The equations are the following;

$$\dot{\kappa} + \frac{|u|}{\lambda}\kappa = \frac{|u| - r\omega sign(u)}{\lambda} \qquad (6)$$

$$\frac{\partial\, tan(\alpha)}{\partial t} + \frac{|u|}{\beta} tan(\alpha) = \frac{v}{\beta} \qquad (7)$$

Where:

- κ : Longitudinal slip
- λ : Longitudinal relaxation length
- u : Longitudinal velocity of the wheel center
- ω : Wheel spin velocity
- α : Lateral slip
- β : Lateral relaxation length
- v : Lateral velocity of the wheel center.

The lateral relaxation length is obtained from experimental lateral dynamics testing. The phase angle of the lateral slip differential equation is the following,

$$\phi = tan^{-1}(f\tau) \qquad (8)$$

Where:

- ϕ : is the phase angle (rad)
- τ : time constant (sec)
- f : frequency (rad/sec)

The relaxation length is,

$$\beta = \tau \times u \qquad (9)$$

From experiment:

$\phi = 0.785$ rad

$f = 21.4$ rad/sec

$u = 13.5$ m/sec

then $\tau = 0.0468$ sec [4, 23] and $\beta = 0.628$ m (22). A procedure to measure longitudinal relaxation length has not yet developed. The longitudinal relaxation length is set to $\lambda = 0.25$ m, which is according to simulation frequency and how responsive the tire is to longitudinal force excitation.

TIRE FORCES - The vertical tire force is computed from a spring/damper/mass tire model using either the point contact follower or the envelope contact method. The contact follower model has been extensively used by others, and is valid for the frequency range of interest (~10 Hz), when the surface profile inputs do not contain short wavelengths compared to the tire contact patch. The tire vertical force is then formulated as follows:

$$F_n = k\delta + B\dot{\delta} \qquad (10)$$

Where:

- F_n : Tire normal force
- k : Tire vertical stiffness
- B : Tire vertical damping
- δ and $\dot{\delta}$: Tire vertical deflection and deflection rate respectively

The vertical tire stiffness, *220.3* KN/m, is determined using linear regression of sinusoidal vertical loads applied on the wheel, and the vertical damping is estimated to be 500 Ns/m [27].

A clear understanding of the lateral and longitudinal tire forces is the key for any successful vehicle simulation. These forces depend on the complex interaction of properties of these three subsystems: tire kinematics and elasticity, road profile, and the tribology of the contact. These forces are best formulated empirically using either Pacejka [9], or STI [5,6] models. These models are a means for presenting a complex mechanics problem as cost effectively as possible. The STI model provides good predictions in severe combined braking and cornering maneuvers, and better insight to the mechanics of the tire, since most of its parameters correspond to some physical properties. The lateral force dynamic effect is included as part of the lateral slip angle first order linear differential equation.

The tires used on the Taurus during all field testing were General Ameritech P205/65R15 steel belted radials. Twenty six tires were purchased from a single manufacturing batch in an attempt to minimize the tire to tire variability. Six of these were sent to Smithers Scientific Services, Inc., and were tested on their MTS Flat-Track II [31] flat-belt tire force and moment measuring machine. A complete description of these testing and data can be found in [4], and the complete test matrix is documented in its Appendix A. Seven types of tests were run at three normal loads (560, 930, and 1300 lb.), and at a variety of severity's. The tests are:

1. Quasi-static steering
2. Quasi-static braking/driving
3. Dual step steering
4. Pseudo pulse braking
5. Pseudo pulse steering
6. Discrete sinusoidal steering
7. Discrete sinusoidal loading

The parameters for the STI model are determined using a local VRTC STI preprocessor [23], and the model compared to experimental measurements are shown in Figures 9-13. The rolling resistance was determined from averaged coast down tests (starting at 33 m/sec) using the following equation,

$$R_r = \sum_{i=1}^{n} \frac{m a_{xi} - 0.5\rho C_F A_F V_i^2}{nW} \qquad (11)$$

where:

m : Vehicle mass (kg)

a_x : Vehicle deceleration (m/sec^2)

$0.5\rho C_F A_F V_i^2$: Aerodynamic drag force (N)

W : Vehicle weight (N)

R_r : Rolling resistance

n : Number of runs $(n = 10)$

This value is actually the consolidation of tire rolling resistance, bearing friction, and drive line drags. Since vehicle deceleration is small, and noise to magnitude ratio is significant, the deceleration is determined by numerically differentiating the longitudinal velocity as follows,

$$V_i = \sum_{j-5}^{j+5} \left(V_j / 10\right) \qquad (12)$$

$$c_2 t_i^2 + c_1 t_i + c_0 = V_i \qquad (13)$$

$$a_{xi} = 2c_2 t_i + c_1 \qquad (14)$$

Where:

V_i: Filtered velocity

V_j: Measured velocity

a_{xi}: Longitudinal acceleration

c_2, c_1, c_0 : Coefficients determined using least square of (i-10,i+10) data points.

The friction coefficient between the tire and the road is of a paramount importance. However, it is impossible to get the exact value, since the friction is dependent on many uncontrolled variables, such as road profile, road contaminants, temperature, and tire wear during testing. Based on prior testing experience, a nominal value of 0.85 is used. This might mask errors if the center of gravity height of the vehicle and other vehicle parameters are erroneous.

COMPLIANCES - Compliances result from flexibility and deflection of the suspension components. These deflections cause some additional steering angle to be produced by the wheels which affect understeer properties and consequently lateral/directional handling and stability [11]. The compliances can be modeled either by a quasi-static change of the steer and camber angles, or by an addition of stiff compliant elements in bushing localities. However, quasi-static implementation is sufficient since compliances have a much higher frequency than vehicle handling dynamics response and the inclusion of compliant elements result in a dramatic decrease of the integration time step that would impede real-time practicality. Stiff compliant elements will be important if wheel shimmy effect or any other high frequency vibration modes are to be analyzed. The deflection of the wheel due to compliance effects is formulated as follows,

$$\gamma_c = \lambda_{\gamma y} F_y + \lambda_{\gamma z} M_z \qquad (15)$$
$$\delta_c = \lambda_{\delta y} F_y + \lambda_{\delta z} M_z$$

Where:

$\lambda_{\gamma y}$, $\lambda_{\gamma z}$, $\lambda_{\delta y}$, and $\lambda_{\delta z}$: Compliance coefficients

γ_c, and δ_c : Camber and steer angles due to tire forces

F_y and M_z : Lateral force and alignment moment of the tire.

The camber, and lateral slip angles used in the tire model are adjusted as follows,

$$\gamma_t = \gamma + \gamma_c \qquad (16)$$
$$\alpha_t = \alpha + \delta_c$$

Where:

γ : Wheel camber angle

α : Lateral slip angle

γ_t : Camber angle used in tire forces computations

α_t : Lateral slip angle used in tire forces computations

The suspension compliances to tire forces for the Taurus were measured for VRTC by Heitz Automotive Testing, Inc. Heitz has developed the "Heitz Topsy chassis parameter measurement system" that secures a passenger vehicle to a base-plate frame, and applies forces at the tire contact patch. Wheel steer and camber angles are measured along with the transitional motions of the wheel center. The chassis can be adjusted vertically, allowing the compliance tests to be run at different tire normal loads. Forces at the tire contact patch are supplied by two hydraulic servo cylinders that can be configured to provide lateral and longitudinal forces and aligning moments individually or in combination [22, 33]. The data were measured for left and right sides individually. In the rear, they can be expected to be independent, since left and right sides are not connected. In the front, opposing and adding configurations are different when reacted differently through the compliance of the steering gear and column.

ROLL STIFFNESS - Maneuvering causes normal load to be transferred from the inside to the outside tires away from the direction of the turn due to vehicle lateral accelerations, which degrades lateral force sensitivity of the inside tires. The stability effects that are influenced by load transfer include directional and roll motions and rear axle wheel lockup. The effect of roll stiffness can be modeled either by simply applying quasi-static forces, or by including rigid bodies connected by stiff torsional springs. Since the contribution of the stabilizing torsional bar to the vehicle handling dynamics is a low frequency adjustment of the applied vertical tire force, it is not necessary to add more computational burden by including more bodies and stiff springs. This element is modeled by applying external forces on the spindle as follows,

$$F_t = \frac{K_t(\varphi_c - \varphi_w)}{t_w} \qquad (17)$$

Where:

φ_c and φ_w : Chassis roll angle and wheel axle roll angle respectively (rad)

k_t : Torsional stiffness of the bar(N.m/rad)

t_w : Track width (m)

F_t : Applied force on the spindle (N)

A restoring moment acting about the longitudinal x-axis of the chassis is applied as follows,

$$M_t = -K_t(\varphi_c - \varphi_w) \qquad (18)$$

Where:

M_t : Applied moment about the chassis x-axis.

The value of the stiffness can be approximated theoretically using strain energy formulations. However, experimental procedure is used because it is simple and the results are more comprehensive. The roll stiffness are measured at VRTC using the roll test described in [29]. The roll moment is applied by mounting a beam under the vehicle, parallel to the vehicle's Y-axis. A weight is placed on the beam at various locations to apply various roll moments.

AERODYNAMIC FORCES - Aerodynamic forces and moments acting on moving vehicles are of growing interest to the vehicle dynamicist. Through the motion relative to the air, a pressure field is generated on the vehicle surface whose integral effect is felt as a resultant aerodynamic force with time-varying points of contact. Positive lift on front wheels reduces the tire-to-road forces, and leads to decrease of effective wheel torque in tractive wheels. As lift forces increase, handling quality such as lateral guidance can rapidly deteriorate, reducing driving comfort and creating dangerous maneuvering at high speeds. A review of road accidents due to wind effects shows that these are caused during high speed travel and rapid temporal change of ambient wind [14]. The cause of these accidents is the slow response of the vehicle to corrective measures of the driver that leads to collision or displacement off the road.

SAE J1594 JUN87 aerodynamic recommended practice is used to model aerodynamic forces [17]. These forces are formulated by first computing the relative wind velocity in the chassis coordinate system as follows:

$$V_{rw} = A_c^T(V_w - V_c) \qquad (19)$$

Where:

V_w : Wind velocity in global coordinate system

V_c : Chassis velocity in global coordinate system,

V_{rw} : Velocity of the wind relative to the chassis in chassis local coordinate system.

Then the forces and moments are computed as follows,

$$F_a = AQ(C_x, C_y, C_z)^T$$
$$M_a = AQL(C_{mx}, C_{my}, C_{mz})^T \qquad (20)$$

$$Q = 0.5\rho V_{rw}^2 \qquad (21)$$

Where:

A : Vehicle frontal area

L : Vehicle wheel base

Q : Aerodynamic air pressure

ρ : is the air density

C_x, C_y, C_z : Aerodynamic force coefficients

C_{mx}, C_{my}, C_{mz} : Aerodynamic moments coefficients.

These coefficients are obtained from cubic spline interpolation of the aerodynamic curves (Figure 14) using the slip angle β.

$$\beta = tan^{-1}\left(\frac{V_{rw}(2)}{V_{rw}(1)}\right) \qquad (22)$$

Aerodynamic force and moment coefficients were measured at the Lockheed Aeronautical Systems Company's Low Speed Wind Tunnel (LSWT) in Marietta, Georgia. The LSWT is "...horizontal, atmospheric pressure, single return circuit, closed throat system having an overall circuit centerline length of 238 meters" [30]. The test section where the Taurus was tested is 23.5 feet wide by 16.25 feet high. The vehicle sits on a six-component pyramidal external balance system. The balance is a small-seeking balance with weights driven by lead-screws. The aerodynamic coefficients were measured at 25, 45, and 65 mph air speed. The yaw angle was varied from -90 to 90 degrees. The data are expanded to include full vehicle yaw rotation using vehicle geometric symmetry [27]. Other aerodynamic effects, such as wind gusts, will be added to a later version of the simulator software.

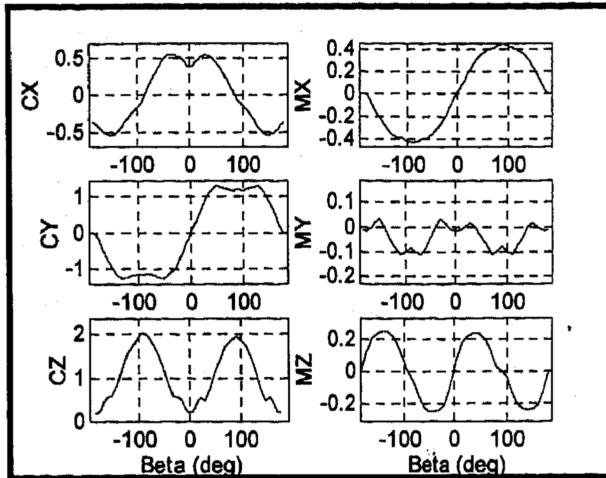

Figure 14. Aerodynamic Curves

BRAKE SYSTEM - The brake system is formulated as follows,

$$\tau \dot{P}_f + P_f = f_1(F_b) \qquad (23)$$

$$P_r = P_f \qquad P_f \le P_l$$
$$P_r = P_l + K_p(P_f - P_l) \qquad P_f > P_l \qquad (24)$$

$$T_{bf} = f_2(P_f) \qquad (25)$$

$$T_{br} = f_3(P_r) \qquad (26)$$

Where:

F_b : Applied brake pedal force

P_f : Front line brake pressure

P_r : Rear line brake pressure

T_{bf} : Front brake torque

T_{br} : Rear brake torque

τ : Brake system time lag

$f_1(F_b)$: Function relating brake force to front-line brake pressure

$f_2(P_f)$: Function relating front-line brake pressure to wheel brake torque

$f_3(P_r)$: Function relating rear-line brake pressure to wheel brake torque

K_p : Rear-to-front brake line proportion after knee point

The hysteresis effect is not modeled, but the parameters will be estimated within the hysteresis envelope. Suspension deflection effect is not included so far; a more comprehensive model will be developed later.

The measurements of brake pedal force, front-line brake pressure, and rear-line brake pressure were done at VRTC. The vehicle was stationary and the engine was running, then a cyclic increasing brake pedal force was applied slowly. The brake pedal force to front-line brake pressure relation (Figure 15) was obtained, and linear regression was used to determine the curve data points used in NADSdyna. The rear line brake pressure to front line brake pressure proportioning (Figure 16) was determined using the same experiment. The brake line pressure to brake torque relation is determined using VRTC's Road Transducer Plates (Figure 17).

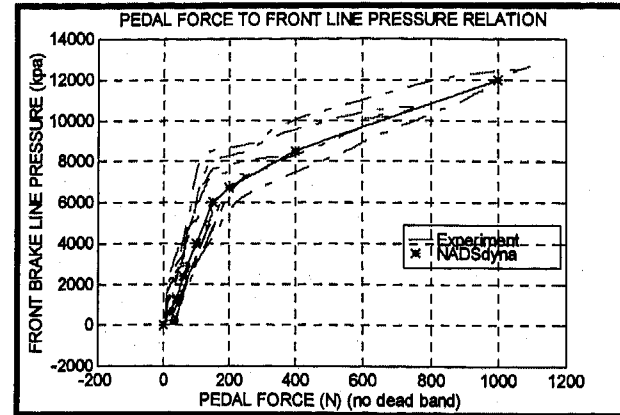

Figure 15. Front Line Brake Pressure to Brake pedal Force

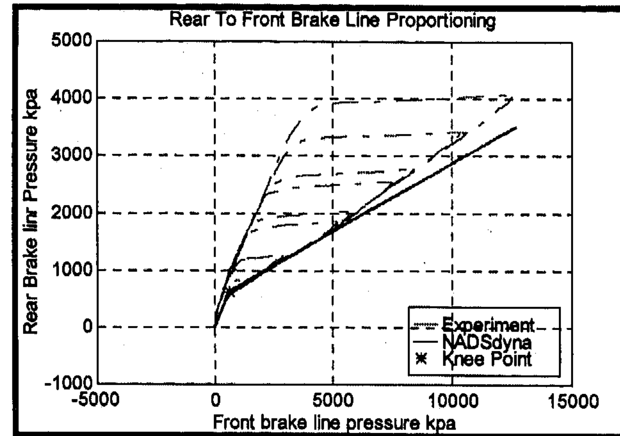

Figure 16. Rear To Front Brake Line Pressure Proportioning

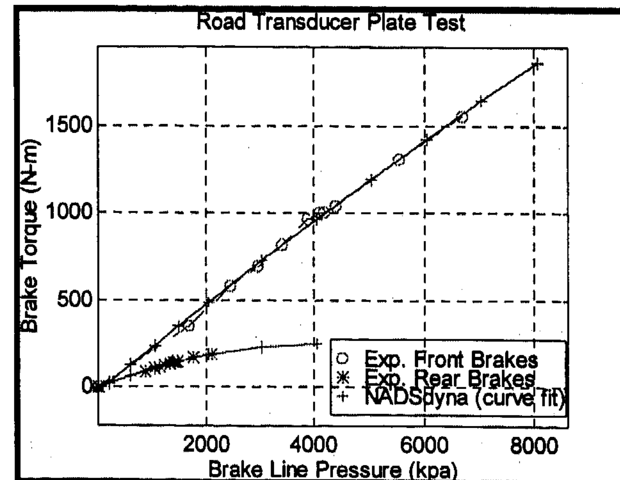

Figure 17. Brake Line Pressure to Braking Torque

STEERING SYSTEM - The rack is kinematically driven through a translation joint relative to the chassis. Its displacement is computed as follows,

$$d_{rack} = \frac{\omega_s}{r_p}$$
$$\dot{d}_{rack} = \frac{\dot{\omega}}{r_p} \quad (27)$$

Where:

d_{rack}, $\dot{d}_{rack}$: Rack displacement, and velocity respectively

ω_s, $\dot{\omega}_s$: Handwheel steering angle, and velocity respectively

r_p : Effective pinion pitch radius (134.8 mm/rad)

This model lacks the dynamics of the steering system from steering handwheel to the rack and the torque feedback to the driver. A variable assisted dynamic model is currently under development.

CRUISE CONTROL - The power train subsystem used in NADSdyna is based on a one-dimensional torque formulation that includes the torque and angular velocity transmitted through each model component [18]. The components include engine, automatic transmission gearbox, and open differential. Since at this phase of the project, measurement of power train data of the Ford Taurus has not yet been completed, the vehicle is simulated at either constant speed or in a deceleration state. Therefore, a cruise control model is applied to a quasi-steady-state engine model, and it is formulated as follows:

$$\delta_{th} = k_v\left(u_d - u_x\right) + k_a a_x \text{ if } u_x < u_d$$
$$\delta_{th} = 0 \qquad \text{if } u_x \geq u_d \quad (28)$$

Deactivate control if brake is applied

Where:

δ_{th} : Throttle input

k_v , k_a : Control constants

u_x , a_x : Longitudinal vehicle velocity and acceleration

u_d : Desired vehicle longitudinal velocity

The data of the power train are adopted from [18] of the HMMWV vehicle. The power train data do not affect simulation results, since only a small drive torque feedback to the wheel spin dynamics is applied to keep the vehicle at constant speed.

CONCLUSION

The model developed is for high fidelity vehicle dynamics simulation. Recursive multi-body dynamic formulations are used to model rigid-body nonlinear motions, compliances with high spring stiffness have been modeled as quasi-static force elements. The vehicle subsystems models constitute the fundamentals to complement vehicle dynamics simulation. These are as important as rigid body dynamics, especially tire forces that determine vehicle motion on the ground. Power train and variable assist dynamic power steering system models will be included in a later version of model development.

This model is evaluated in [28], and the results show promise that the Ford Taurus NADSdyna model is a high fidelity vehicle dynamics simulation.

Report [25] contains a complete description of the model and the data set, and report [26] discusses its validation. The modeling effort is being extended to include a complete dynamic steering system, as well as other vehicles including a tractor semi-trailer.

ABSTRACT

This paper presents an evaluation of a vehicle dynamics model intended to be used for the National Advanced Driving Simulator (NADS). Dynamic validation for high performance simulation is not merely a comparison between experimental and simulation plots. It involves strong insight of vehicle's subsystems mechanics, limitations of the mathematical formulations, and experimental predictions. Lateral, longitudinal, and ride dynamics are evaluated using field test data, and analytical diagnostics. The evaluation includes linear and non-linear range of vehicle dynamics response.

INTRODUCTION

The utility of the analysis of the simulation depends on the extent to which it has been validated. The inconsistencies between computer models and actual vehicle response could be due to problems in several areas that include model formulation, simulation programming, vehicle parameter identification, numerical accuracy and stability, and low quality experimental results. The evaluation methodology is to compare simulation results with experimental measurements using the same driver control inputs [1]. This method is compelling and sound, but it should be necessarily applied with some analytical diagnostics and common sense, because the simulation might mask errors that could not be detected from comparisons with experiments.

The dynamic characteristics of road vehicles include complex interactions between many subsystems. Trying to find sources of discrepancy between simulation and experiment by looking at the vehicle as one unit is a hopeless practice. Thus, each subsystem must be evaluated and checked separately. The requirements for the appropriate vehicle dynamics response intended for handling and ride behavior are outlined in the following table:

MANEUVERS :	REQUIREMENTS :
Vehicle linear handling range	Proper non-linear geometry of roll-steer, camber angle, steering kinematics. Requires accurate tire stiffness, suspension compliances, lateral tire dynamics, and proper inertial and geometric data.
Trends in the nonlinear handling range	Accurate suspension kinematics, and advanced tire ground force model.
Accurate predictions in the nonlinear range, up to the limit maneuvers	Measure tire data specific for the particular tire/surface used for maneuvering experiments, accurate nonlinear suspension kinematics, tire data at extreme loads and combined orientations, and nonlinear characteristics of compliant elements.
Ride Analysis	Tire contact model should be appropriate for the particular surface in testing and desired frequency range. Nonlinear suspension spring stiffness, bushings, and damping are required for extreme road disturbances.
Straight Line Braking	Requires appropriate tire data for the particular tire/surface combination, proper inertial and geometric data for longitudinal load transfer and squat/ lift forces characteristics, accurate wheel spin dynamics algorithm, and accurate brake model with the appropriate dynamic lag.
Braking in a Turn	Accurate tire data for a combined lateral and longitudinal slip ratio for the particular tire/surface used, and an advanced tire model has to be used.

Table 1. Vehicle Simulation Guidelines

The vehicle dynamics simulation, NADSdyna, was developed primarily by the University of Iowa [7].

NADSdyna uses a multi-body recursive formulations to solve the dynamics of rigid bodies [2]. Subsystem models for the tires, aerodynamics, steering system, braking systems, and power train are coupled with the recursive dynamics core of NADSdyna. Iowa State University implemented four existing tire models which are available within NADSdyna. Iowa State University also developed models for the wheel spin dynamics for zero longitudinal speed.

The vehicle simulated is a 1994 Ford Taurus. The Taurus model, developed at the Vehicle Research and Test Center (VRTC), is detailed in [15]. Details of the model parameter determination procedures executed by VRTC are given in [13]. All experimental field testing of the Taurus was done by VRTC at the Transportation Research Center, Inc.

VEHICLE FIELD TESTING

The vehicle was instrumented at VRTC, and the schematics of the channels of data are shown in Figure 1. The vehicle field testing was designed to minimize the effects of driver variability and provide repeatable open loop experimentation. For each maneuver, the driver control inputs were repeated, then the mean values and 95% confidence intervals were computed. The mean experimental driver input used to drive the simulation (~250 Hz), is obtained using linear interpolation of experimental sampled values (100 Hz). The following maneuvers are compared with simulation: slowly increasing steer, step steer, pulse Steer, double lane-change, straight line braking, brake-in-a-turn, and ride. Maneuvers involving vehicle acceleration were also performed, but this paper does not include these results. However, the power train model evaluation will be presented at a future date.

Experimental determination of the model parameters result unavoidably in stochastic variability due to some uncontrolled conditions. These parameters are estimated and implemented in the mathematical models that approximate the physics of the desired vehicle dynamic response through numerical simulation. This simulation is compared to field test data which are characterized also by some variabilities due to the undetermined nature of the tribological contact between the tire and the ground, tread wear, tire temperature, changes in control inputs and others. Therefore, the experiments and the measurements have to be designed based on strong understanding of vehicle dynamics and insights of parameters sensitivities. Comparing analytical approximations with experimental measurements is not an easy task that guarantees acceptable results or explanation of discrepancy within a statistical bound, particularly when extreme maneuvering conditions are considered. For limit performance maneuvers, only the trends or relatively close results should be expected, since the mechanics at these extreme conditions (especially tires) is still an open area for the natural philosopher to device a theory.

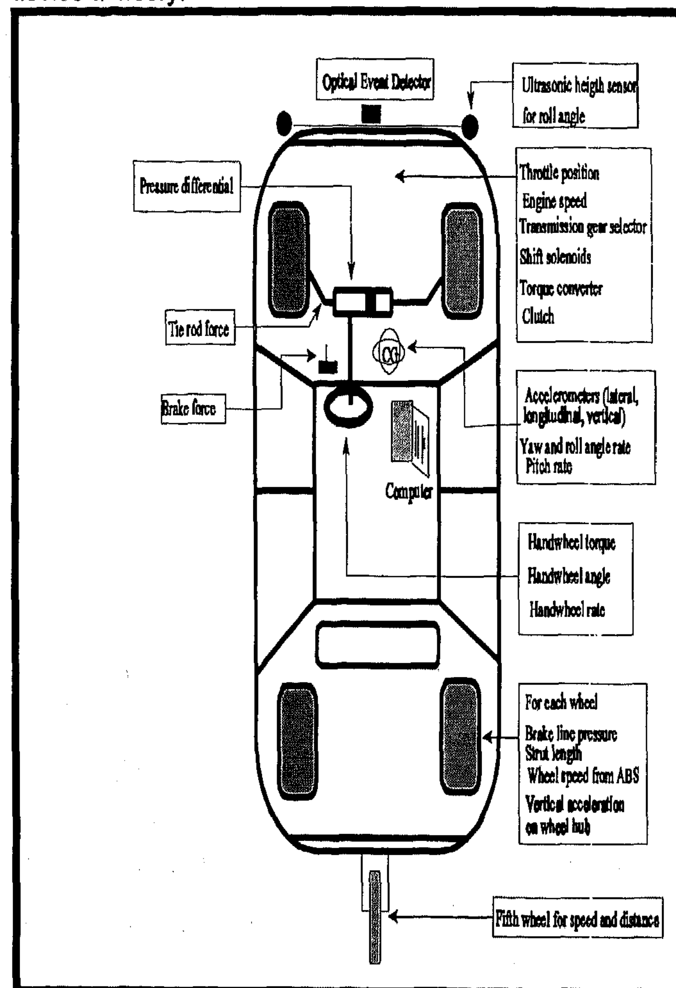

Figure 1 Vehicle Data Channels

VEHICLE DIRECTIONAL DYNAMICS

SLOWLY INCREASING STEER - The slowly increasing steer maneuver involved supplying the simulation with a slowly increasing handwheel angle, while maintaining a constant vehicle speed, until maximum vehicle lateral acceleration, rollover, or a spinout is achieved. A typical rate for handwheel angle that would eliminate dynamic effect and maintain steady state properties is on the order of *10 deg/sec.*

Figures 2-6 compare the simulation with the experimental results for the following variables: steering wheel input, roll angle, yaw rate, and lateral acceleration. These Figures show that the simulation predictions are close to the experiments including the severe cases. From Figure 3, the slope of the roll angle versus lateral acceleration is about *3.9 deg/g*, and the slope of the hand wheel angle versus lateral acceleration is about *235 deg/g*. Steering angle versus lateral acceleration gives an indication of vehicle linear understeer behavior which includes the effects of roll steer, compliance steer, and front to rear tire loading.

At higher g level (Figures 4-6), the front tire force saturation comes into play, and the steady state curve is asymptotic to some limit of lateral g level, which is an indication of limit understeer effect. The handwheel rates are slightly greater than *10 deg/sec* because experimentally the tires get too hot if the duration of this maneuver is long. The maximum lateral acceleration achieved was followed by a reduction, because the tire lateral forces saturated and the front tires 'wash out'. As a result, further increase in the hand wheel angle no longer increases lateral acceleration.

The results of this maneuver indicated that the vehicle model has the appropriate non-linear suspension properties, as well as the tire model is appropriate to model severe cornering. No statistical analysis was performed because the steering input is controlled by the driver which is not repeatable.

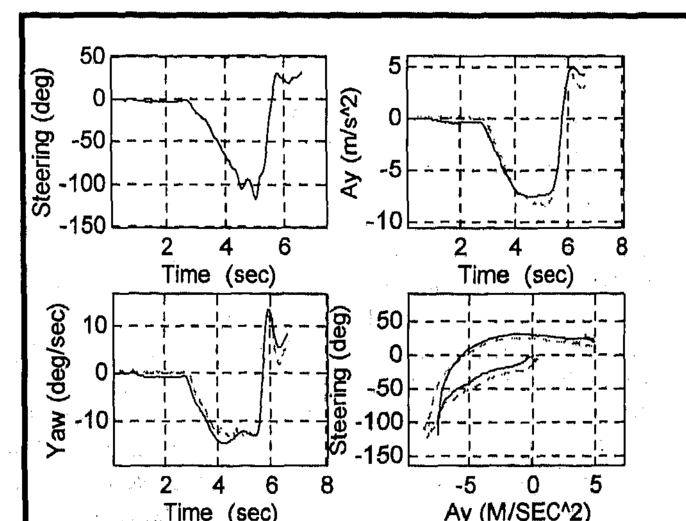

Figure 6. Slowly Increasing Steer at Vx = 32 m/sec
(solid: simulation, dashed: experiment)

STEP STEER INPUT - This maneuver (J-turn) is a pseudo-step input of handwheel angle. The J-turn maneuvers are simulated to determine steady-state as well as transient responses. A physically realistic input rate on the order of *500 deg/sec* is used. A pure step input is not even mathematically feasible for the multi-body formulations applied in this simulation, because kinematics constraints diverge.

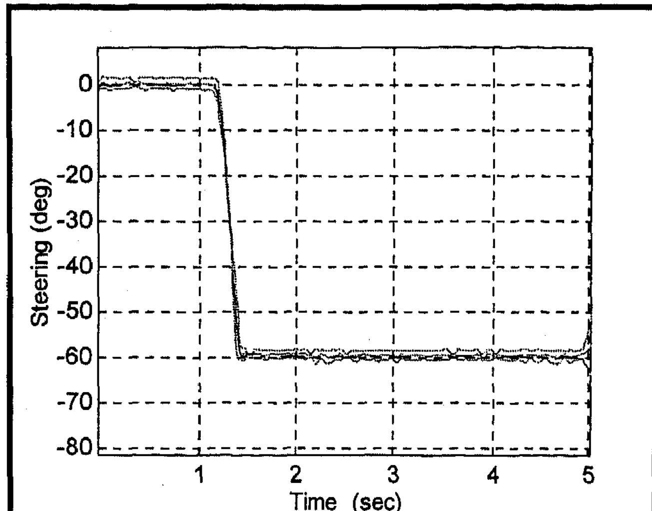

Figure 7. Step Steering Input at Vx = 32 m/sec
(Solid: experiment (95% confidence interval), dashed: Simulation)

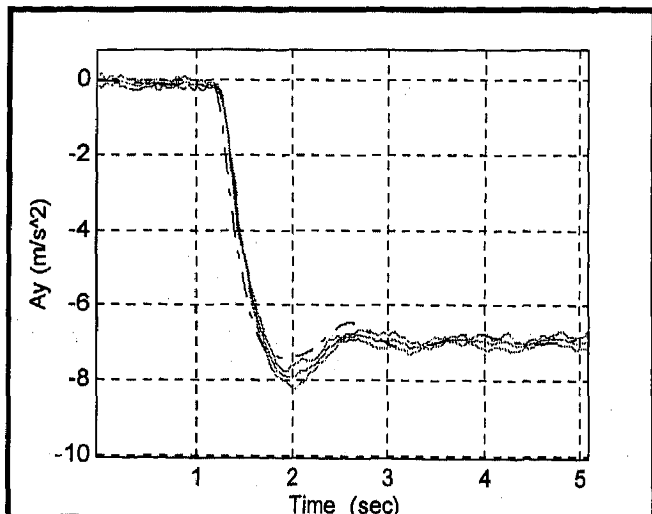

Figure 8. Lateral Acceleration at Vx = 32 m/sec
(Solid: experiment (95% confidence interval), dashed: Simulation)

For the simulated vehicle, the steering system dynamics from handwheel to steering rack are not yet modeled, and the tire force model is only quasi-static. However, lateral force dynamics are included using a first order lateral slip angle differential equation. The longitudinal lag is included in the differential equation of wheel spin rate, and has minimum effect within the frequency span considered in handling analysis. The complexity of the structure and dynamic behavior of the tires are such that no complete and satisfactory theory has yet been propounded. Figures 7-10 show a severe simulated step steering input compared with experimental results. The transient response comparisons between field test and computer model show good agreement in terms of timing of the transient events and peak levels of the variables that indicate limit performance conditions.

(Solid: experiment (95% confidence interval), dashed: Simulation)

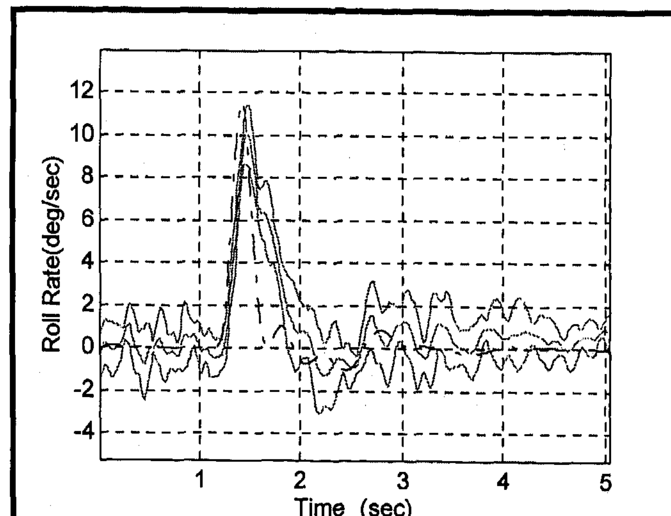

Figure 10. Roll Angle Rate at 32 m/sec
(Solid: experiment (95% confidence interval), dashed: Simulation)

PULSE STEER (DIRECTIONAL DYNAMICS FREQUENCY RESPONSE) - The frequency responses in vehicle dynamics are mostly computed from sinusoidal sweep input, random input, or discrete sinusoidal input testing, and only recently pulse testing was taken in consideration [9]. By judiciously selecting the proper short duration of pulse input to drive a system, it is possible to excite a full range of frequencies using a single experimental test or simulation run.

Linear frequency responses can be developed for linear, time invariant systems, or approximated for a nonlinear system about some linearized operating condition. For vehicle handling dynamics models, linear transfer functions can be derived only for constant speed

maneuvers, since handling responses are speed dependent. Additionally vehicle handling behavior becomes increasingly nonlinear as lateral acceleration level increases, and linear models for passenger vehicles are assumed applicable below lateral acceleration levels of *0.3-0.4* g's. Computer simulations of vehicle handling are typically more linear than actual vehicles because many of the physical non-linearities within the vehicle system are not precisely modeled in the simulation. If the input of the pulse has too little power for a particular frequency range, the frequency response will not be meaningful in that range. Without sufficient power, noise will dominate the signal and produce invalid numbers in the frequency response. An ideal pulse produces power over all frequencies; however, this is not possible in the physical world. In experiments, the pulse was generated by a sequence of step increase and step decrease steer with a total duration on the order of *0.2 sec*, which provides good steering power up to the 3 to 4 Hertz of frequency range [9]. Experimental frequency domain results from one pulse test to the next are considerably different unless the system is nearly linear and the data have little noise. In this case the test results are quite similar, and an ensemble frequency response is found by dividing the sum of the cross-spectral densities of the output channels by the sum of the power spectral densities of the input channels. The error bounds of the frequency responses are computed using the coherence between the averaged channels. This technique produces better results then by computing point-by-point mean of the response function, and provides an effective reduction of any random noise in the individual signals.

The time domain, Figure 11, of steering wheel input, lateral acceleration, yaw rate, and roll angle rate show that the simulation predicts these variables well. The frequency responses of lateral acceleration, yaw rate, and roll rate (Figures 12-14) , show that the simulation predictions are reasonably between the statistical bounds of the mean experimental results. The coherence function is plotted to show the validity of the experimental measurements for the frequency range considered. The closer the coherence to one, the better the experimental data are in terms of noise effect and system linearity. The directional dynamic properties of the simulation are reasonable as indicated by the agreement with the yaw rate frequency response field test data. For the phase angle plots, the experiments showed higher order than the simulation but close values.. This may be explained by the lack of dynamic steering system model between the handwheel and steering rack, lack of a complete dynamic tire model, and other systems that are modeled with lower order. The lateral acceleration frequency response shows reasonable agreement which gives some credibility to the composite lateral/directional dynamics. However, the roll angle measurements have a high noise signal ratio, and the dynamics trends are reasonably predicted. The bandwidth, peak amplitude ratio, and peak frequency of yaw rate, lateral acceleration, and roll angle frequency response to steering input are speed of response type measures. A wider bandwidth indicates the vehicle response characteristics are maintained for a higher frequency input. Yaw rate frequency response to hand-wheel angle gives an indication of the frequency where the vehicle starts becoming less responsive. The graphs confirm that the simulation predicted well these measures.

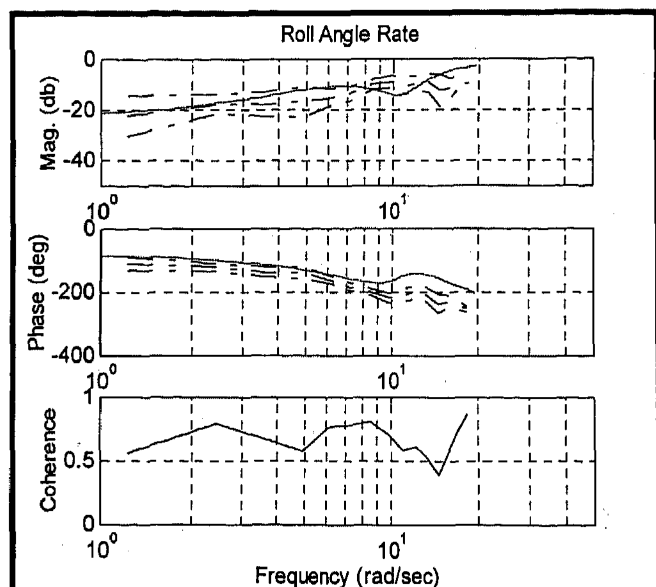

Figure 14. Roll Angle Rate
(Solid: experiment (95% confidence interval), dashed: Simulation)

LANE CHANGE MANEUVERS - Once the steady state, transient, and frequency response predictions of the simulation have been evaluated, the simulation is checked against more complex maneuvers designed to simulate real world driving conditions, like lane change maneuvers. In this maneuver the steering input represents the driver/vehicle closed loop following performance. These lane change maneuvers are applied with sufficient amplitude to produce limit maneuvering performance conditions. The timing of steering profile is such to avoid rollover for the test vehicle. Figures 15-16 show that the simulation predicted well the lateral acceleration, and the yaw rate. No statistical analysis was performed since only one run was performed for each maneuver.

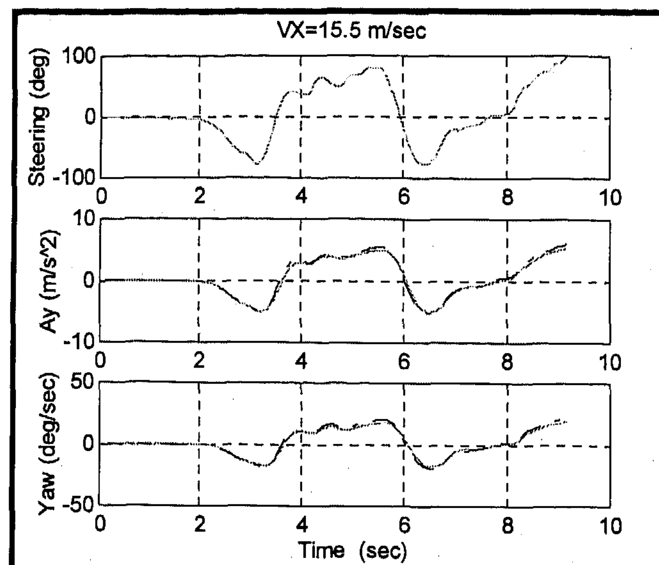

Figure 15. Lane Change Maneuver
(Solid: experiment, dashed: simulation)

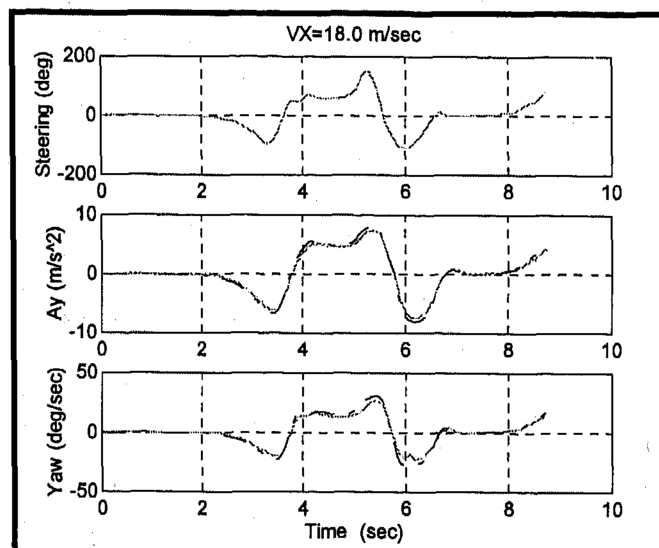

Figure 16. Lane Change Maneuver
(Solid: experiment, dashed: simulation)

VEHICLE BRAKING DYNAMICS

STRAIGHT LINE BRAKING - The braking maneuvers are performed at different levels of severity from low g up to the limit. Despite uncertainty in road friction and other parameters, Figures 17-20 show the simulation predicted reasonably the longitudinal velocity, longitudinal deceleration, pitch angle, and the wheel spin rate. The comparison between the simulated and the measured wheel spin rate shows that the wheel spin dynamics mathematical model is adequate. The brake model is adequate as can be seen from the relation between brake pedal force and brake line pressures. The tire force model is adequate to predict longitudinal braking as can be noticed from the close relation between simulation and experiment of vehicle deceleration.

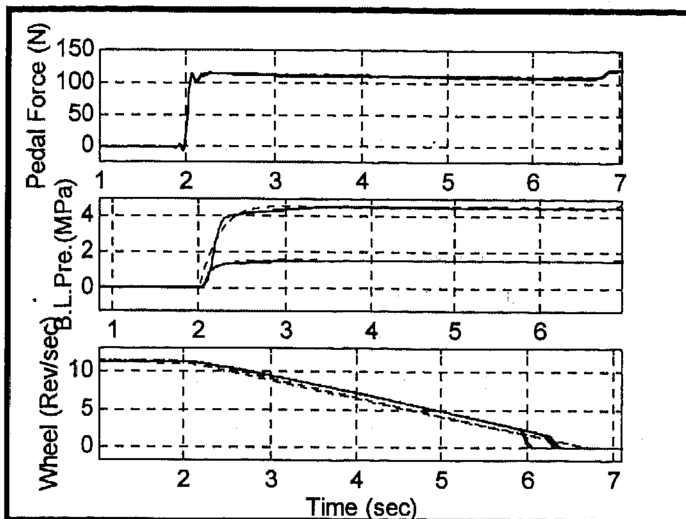

Figure 17. Brake C
(Solid: experiment, dashed: simulation)

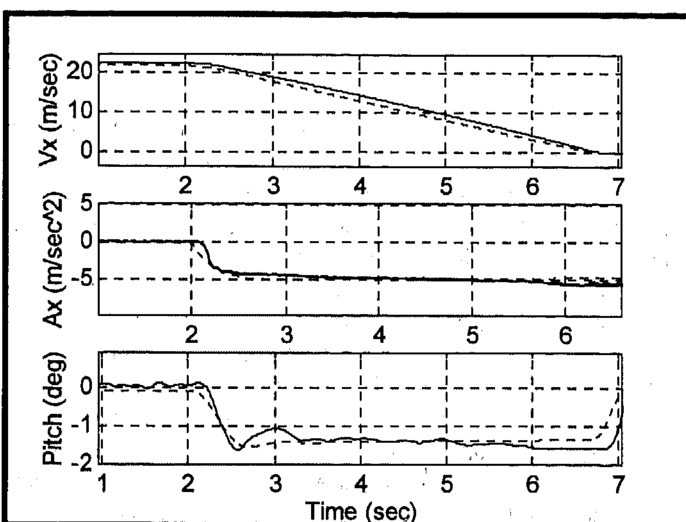

Figure 18. Brake C
(Solid: experiment, dashed: simulation)

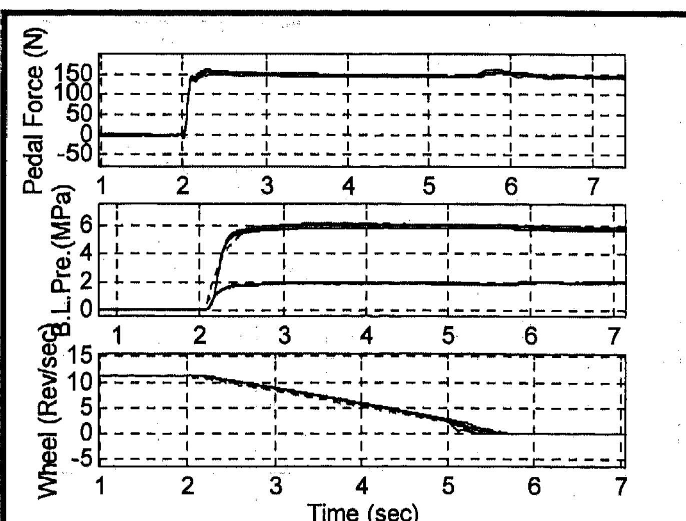

Figure 19. Brake D
(Solid: experiment, dashed: simulation)

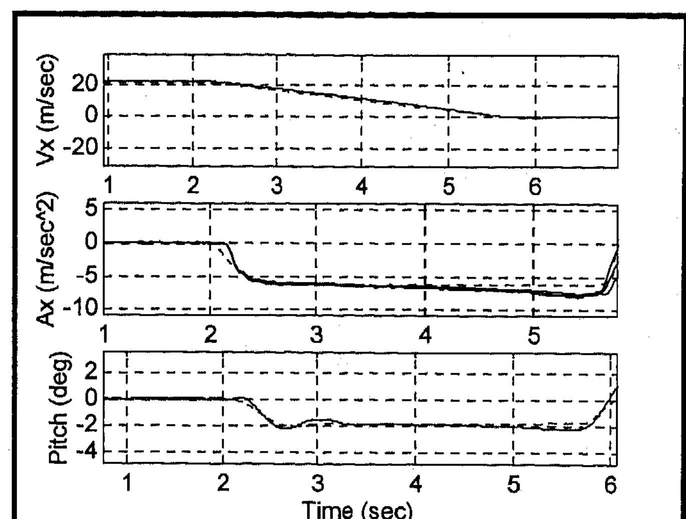

Figure 20. Brake D
(Solid: experiment, dashed: simulation)

BRAKING IN A TURN - Once steering and braking maneuvers are validated, a combined maneuver is not necessarily valid since the tire forces are extremely non-linear. Predictions for this maneuver require accurate tire force model for the particular tire/surface used. Despite the complications of this maneuver, the trends of the simulation predictions are reasonable compared to experiments. Figures 21-22 show a comparison between the simulation and experiment of brake pedal force, brake line pressure, steering wheel input, longitudinal velocity, longitudinal deceleration, lateral acceleration, yaw rate, pitch angle, front left wheel angular velocity, and front right wheel angular velocity. The tire model does not fit well the experimental data at composite slip conditions [15]. The tire model should be improved to better predict the composite longitudinal and lateral forces.

RIDE ANALYSIS

Ride is a subjective perception, normally associated with the level of comfort experienced when traveling in a vehicle. The vehicle experiences a broad spectrum of vibrations in response to excitation inputs that include road roughness, tire/wheel, drive line, and engine. These vibrations are the source of road feel considered to be an essential feedback to the driver of a motor vehicle, and should not degrade his driving performance.

In this analysis, a simplistic approach is applied where road roughness is considered to be the input of vehicle vibration response. This roughness is described by the elevation profile that excited the bounce and pitch motions along the wheel tracks over which the vehicle passes. The most meaningful measure of ride vibration is the acceleration produced. The attenuation of this high frequency input is an important aspect of the ride isolation behavior obtained via vehicle suspensions. To determine the sprung mass transmissibility of road excitation, we determine the dynamic transfer function between road acceleration input and vehicle vertical acceleration at the center of gravity of the chassis. The acceleration spectrum at the vehicle center of gravity have high amplitude at the sprung mass resonant frequency, moderate attenuation through the resonant frequency of the wheel, and a rapid attenuation thereafter. The experimental transfer function is obtained from the vehicle vertical acceleration and road input acceleration. An analytical function is used to compute road elevation for the simulation. The road elevation function has amplitude and frequency as a linear function of time. The acceleration has the appropriate power spectrum density function (Figure 24), where the amplitude increases as frequency increases to fully excite the higher frequencies of vehicle's systems.

The simulated road input elevation, $h(t)$, is formulated as follows:

$$h(t) = A(t)\sin\left(Bt^2\right) \qquad (1)$$

$$A(t) = A_{max} - \frac{A_{max} - A_{min}}{t_{max}}\,t \; ; B = 2\pi\,\frac{f_{max} - f_{min}}{t_{max}} \qquad (2)$$

where:

A_{max} : Maximum road elevation
A_{min} : Minimum road elevation
t_{max} : Maximum time of simulation
f_{max} : Maximum frequency of road input
f_{min} : Minimum frequency of road input
t : Time

and the road acceleration input is as follows;

$$\ddot{h}(t) = \left(4Bt\dot{A}(t) + 2BA(t)\right)\cos(Bt^2) - 4B^2t^2A(t)\sin(Bt^2)$$

$$\dot{A}(t) = -\frac{A_{max} - A_{min}}{t_{max}} \qquad (3)$$

The measured road elevation is actually an approximation of road roughness. The road used has random bump height and spacing. One stream of vertical road deviation (vehicle left side) is measured and filtered, then differentiated to obtain road input acceleration. The power spectra of the road input acceleration is shown in Figure 23. The ride gain is determined from the chassis vertical acceleration to the road input acceleration. Figure 25 shows a comparison between the simulation and experiment, which is meaningful only up to *25 Hz*, since the experimental data are filtered with a cut-off frequency of *25 Hz*. The natural frequency of the chassis, and wheels, as well as the amplitude attenuation at higher frequencies are reasonably predicted by the simulation.

CONCLUSION

The evaluation of the 1994 Ford Taurus NADSdyna model have shown that the simulation predicted the fundamental mechanics of vehicle handling responses in general. The steady state response is close to experiments for up to the asymptotic limit that characterizes limit understeer effects. The transient response show good agreement in terms of timing of the transient events and peak levels of the variables that indicate limit performance conditions. The directional dynamics properties are in agreement with experiments which give credibility to the composite lateral/direction dynamics. For braking, the longitudinal velocity, longitudinal acceleration, pitch angle, and wheel spin rate are close to experiments. For the combined steering and braking, the trends are reasonably predicted, but an improved tire model should be used. The transfer function of ride analysis shows that natural frequency peaks and attenuation at high frequency are predicted by the simulation.

The results presented show promise that NADSdyna will provide the fidelity required for the NADS vehicle dynamics simulation. In general, the vehicle directional, braking, and ride responses match those measured from the Taurus. This evaluation effort is being extended to include acceleration maneuvers, a complete dynamic steering system, as well as other vehicles including a tractor semi-trailer.

After the off-line evaluation of the model has been completed, the model will be subjectively evaluated once NADS is operational. This will be the most important test of the model, and the NADS must "feel" like an actual car.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

A sled-to-sled subsystem side impact test methodology has been developed by using two sleds at the WSU Bioengineering Center in order to simulate a car-to-car side impact, particularly in regards to the door velocity profile. Initially this study concentrated on tailoring door pulse to match the inner door velocity profile from FMVSS 214 full-scale dynamic side impact tests. This test device simulates a pulse quite similar to a typical door velocity of a full size car in a dynamic side impact test. Using the newly developed side impact test device three runs with a SID dummy were performed to study the effects of door padding and spacing in a real side impact situation. This paper describes the test methodology to simulate door intrusion velocity profiles in side impact and discusses SID dummy test results for different padding conditions.

INTRODUCTION

Side impacts have been shown to produce a large portion of both serious and fatal injuries in automotive crashes. A new federal standard for car-to-car broadside collisions, FMVSS 214, was implemented as of September 1, 1996. Occupant protection in side impact has emerged as a most important issue in automotive safety. The new dynamic side impact regulation requires all new passenger cars sold in the United States to pass the new standard specified in FMVSS 214. Intensive research and much progress have been made in side impact safety in the last fifteen years. For side impact research the Heidelberg-type sled test set-up has been widely used. A test subject slides on a long bench seat during sled deceleration, then impacts a stationary side wall [1]*. Eppinger et al. conducted forty-nine side impact cadaveric tests using this type of test set-up and developed a side impact injury criteria, Thoracic Trauma Index (TTI), based on these results [2]. Cavanaugh et al. performed seventeen side impact cadaveric tests using a similar test set-up at the Wayne State University and developed another injury criterion, Average Spine Acceleration (ASA) [3, 4]. The viscous criterion was developed by Viano and Lau, which is utilized in the BIOSID dummy [6]. The controversy regarding acceleration and compression-based criteria has resulted in two different injury criteria in the United States and Europe, and three different side impact dummies, SID, BIOSID, and EUROSID. These issues make it difficult for safety engineers to determine how to design a safer car for side impact.

In a side impact, an initially stationary occupant is impacted by the struck car door. Lau et al. [7] and Deng [8, 9] made a good comparison of frontal and side impact using a spring-mass model and concluded that without simulating key side impact characteristics the results can be misleading. They found that Heidelberg type tests and free flight pendulum tests did not simulate the side impact punch, and may not be valid for the study of real-world side impacts. In the Heidelberg-type sled the test subject has a nominal constant velocity before impacting a stationary wall, while in real-world side impacts, an occupant is impacted by a door velocity pulse. Several dynamic side impact subsystem test procedures have been developed [10,11]. These procedures were based on a similar principle: A moving door, which was initially far away from the test subject, was accelerated to a desired velocity and impacted a stationary test subject. The door velocity was constant or decreased during the impact. Therefore these procedures did not simulate the whole door velocity pulse during contact with occupant, and also were difficult to use to study some basic side impact issues, such as effects of door padding and spacing.

Under the sponsorship of the Centers for Disease Control and Prevention, a sled-to-sled subsystem side impact test methodology was conceived and has been developed at the WSU Bioengineering Center. This test device simulates a pulse quite similar to the typical door velocity profile of a full size car in a dynamic side impact test. This device has been used to study the biomechanical response of side impact dummies, and injury tolerance of human surrogates.

* Numbers in parentheses designate references at end of paper.

Three runs with a SID dummy for different padding conditions, soft, stiff, and no padding, were performed using a simulated door velocity profile of a full size car based on FMVSS 214 full-scale dynamic side impact tests. The objectives of these early stage tests were to simulate side impacts similar to the real-world situation and to study the effects of door padding and spacing in this situation.

SIDE IMPACT MECHANISM

Injury potential of side impact is mainly related to the interaction between a struck car door and occupant. The intruding door velocity-time history, the shape and material property of the door padding and the space between door and occupant can have major effects on injury severity in side impact. A typical velocity time history of the door inner panel can be characterized by a velocity that rapidly increases, then quickly decreases and increases slightly again, then decreases, as shown in Figure 1. The struck car door strikes the stationary occupant directly. The overall door kinematics is influenced very little by the interaction between the door and the test subject and behaves like a high energy, limited-stroke velocity punch during this initial door intrusion. Occupant contact time to door depends on initial door spacing and most interesting events influencing occupant injury occur very early during side impact. In general, the door hits the occupant within 15 - 25 milliseconds and the most important events in occupant injury are over within 50 milliseconds. Hobbs made a good analysis of the sequence of events in side impact [12]. Energy absorbing materials like door padding occupy space and thus advance and prolong occupant contact with the door.

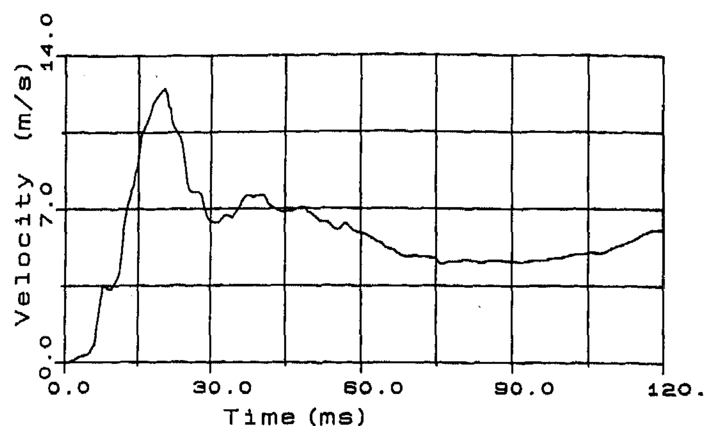

Figure 1. Example of a door velocity profile during side impact [7].

Normally padding does not significantly influence peak spinal acceleration but substantially reduces peak rib accelerations. However, padding can increase the chest deflection due to an increase of energy transfer to the occupant during the impact. These conflicting trends between TTI(d) and chest deflection have already been reported [7, 8].

TEST METHODOLOGY

Initially this study concentrated on tailoring a door pulse to match the inner door velocity profile from an FMVSS 214 full-scale dynamic side impact test. The test device consists of a striking sled and a struck sled with a movable door fixture and a low friction seat covered with Teflon™ sheet. The seating fixture is similar to that of a Heidelberg-type test set-up. The configuration of the WSU sled-to-sled side impact test set-up is shown in Figure 2.

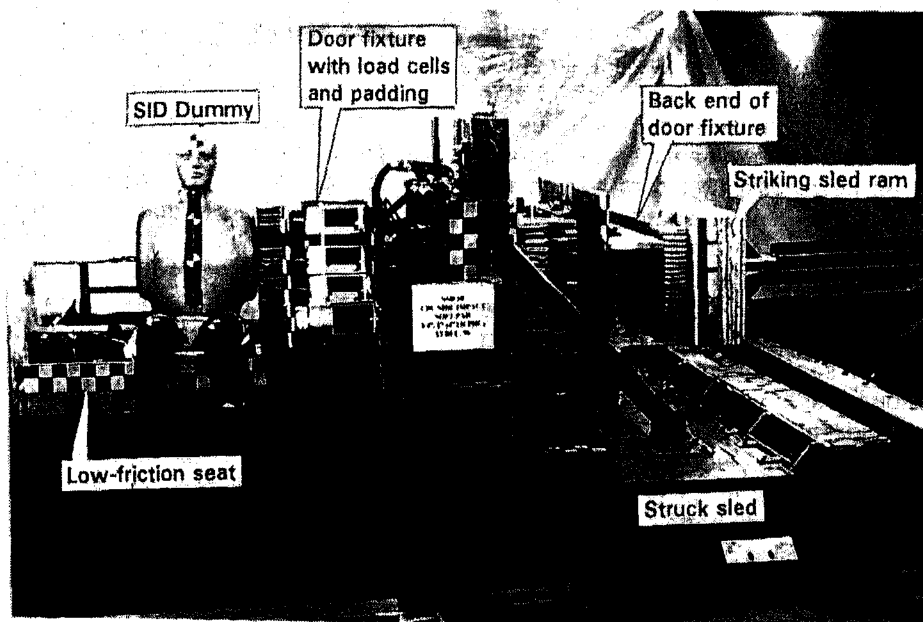

Figure 2. Photo of WSU sled-to-sled side Impact sled test set-up

The sleds run on the WHAM III track (Wayne Horizontal Accelerator Mechanism), a versatile experimental research facility for studying all types of collision environments. Each sled measures 2.0 m wide by 3.66 m long and is accelerated on the 40 m track. The striking sled is accelerated up to a desired velocity by a pneumatic propulsion device and then strikes the simulated door mounted on the struck sled and the struck sled itself at the same time. A hydraulic stopper system was implemented in the door system in order to prevent door rebound motion after maximum door intrusion. The door velocity profile can be tuned by using different dimensions of energy absorbing stiff paper honeycombs placed at three interfaces: (1) the door system, (2) striking-to-struck sled interface, and (3) impacting ram mounted on the striking sled, which impacts the struck sled door system. Five load plates instrumented with nine load cells were mounted on the door wall to measure interaction forces between test subject and door wall surface at each body region: shoulder, thorax, abdomen, pelvis, and knee. Two load cells were used at each load plate except for one at the knee plate. In the padded runs each load plate was covered with a piece of 4 inch thick paper honeycomb pad. The contact forces for each body region give very useful information for test subject responses during impact. Details of the load plates on the door wall are shown in Figure 3. With the SID dummy the shoulder and thorax load plates hit the rib cage as shown in Figure 4.

The first version of the test device was used in eight SID dummy and two cadavers tests. However, the SID TTI(d) and Average Spine Acceleration (ASA) were high and cadaver thoracic injuries were also severe in all test conditions.

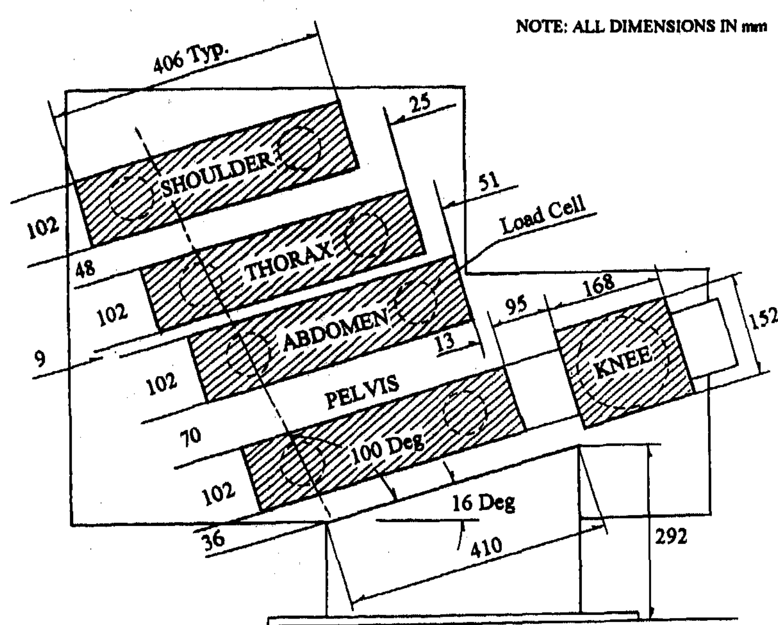

Figure 3. Diagram of impacting door wall showing load plates at each body region instrumented with nine load cells.

The 1st peak door velocity of previous tests was not high (10-11 m/s) but the peak duration time was somewhat long. We modified the fixture to obtain a new door velocity profile with the 1st peak door velocity close to the previous one but with a shorter duration. Newly simulated door velocity profiles look quite similar to a full size car inner door panel velocity from FMVSS 214 full-scale test. The weight of the simulated door wall assembly including all instrumentation is about 800 lbs. It can be seen that door velocity did not vary much with different door padding conditions as shown in Figure 6a at the end of this paper.

EFFECTS OF DOOR PADDING AND SPACING

It can be argued that energy dissipation in door padding can reduce injury severity in side impact. On the other hand, door padding can increase the amount of energy transferred to the occupant during impact and result in increased chest deflection. The spacing hypothesis suggests that increasing space between the inner door panel and the occupant will reduce injury due to the door velocity characteristics because the occupant can be spaced to avoid impact with the door during the high initial peak of door velocity. Intensive research into padding performance with various types of padding has been done at the WSU Bioengineering Center [4, 5]. Different properties of paper honeycombs (PHC) and closed cell foams were used in this research to determine the effect of crush force on dummy response and cadaver injury. Three different padding conditions were run in an initial evaluation of the newly modified sled-to-sled test device: (1) 4 inch thick soft pad, no space, (2) 4 inch thick stiff pad, no space, and (3) no pad, 4 inch space.

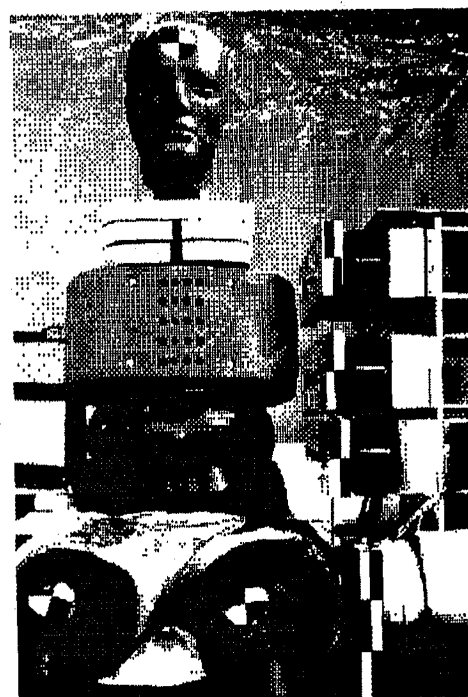

Figure 4. Photo of SID dummy (without jacket) adjacent to the impact door wall.

The crush strengths of the PHC used in these current tests are summarized in Table 1. For soft and stiff padding, two different combinations of PHC were used as shown in Table 2. The 4 inch thick PHC was precrushed up to 1/2 inch in order to get rid of initial force peaks. The PHC was then attached to the face of each load plate of the door wall. Figures 5a and 5b show 4 inch soft PHC before and after impact.

Table 1. Door padding properties

Paper honeycomb cell sizes (inches)	Tested crush strength (psi)
1	10.1
3/4	20.6
5/8	34.9

* Note: Padding crush strength at 35% of pad thickness

Table 2. Configuration of door padding combination

Body region	Soft padding cell size (inches)	Stiff padding cell size (inches)
Shoulder	3/4	5/8
Thorax	1	3/4
Abdomen	1	3/4
Pelvis	3/4	5/8
Knee	3/4	5/8

* Note: Padding size is 4 inches thick and 4 inches wide by 16 inches long for each load plate except for knee padding.

SID DUMMY TEST RESULTS

Comparisons of tests for three different padding conditions were made. A summary of parameters for three SID dummy tests is presented in Table 3. The striking sled velocity was measured with a velocity pick-up sensor and the door velocity was obtained from the 1st integration of acceleration measured at the moving door wall. The door intrusion was calculated by the difference between the struck sled displacement and the door displacement.

The comparison plots of door velocity and SID dummy acceleration-time histories are shown in Figure 6. It can be seen that the door velocity profiles for three tests were quite similar to each other (Figure 6a). The peak values are less than in the full-scale test shown for comparison. However, it was felt that since our door was rigid rather than deformable, lower peak velocities were justified in the initial studies. The peak accelerations to be used for TTI(d) evaluation are summarized in Table 4 and comparison of TTI(d) and ASA are presented in Table 5. The comparison plots of SID dummy chest pot displacement and contact force-time histories at each body region are shown in Figure 7 and the peak contact forces are summarized in Table 6. The contact force was computed by summing the load cell responses of the two load cells at each body region and correcting for inertia forces due to the added mass of load cell and load plate. Raw data of accelerations were filtered with FIR100 software and contact forces and chest pot deflections with a digital Butterworth filter at 300 Hz.

Figure 5b. Four inch thick soft paper honeycomb after impact.

Table 3. SID dummy tests parameters

Padding type	Striking sled velocity (m/s)	Door peak velocity (m/s)	Max. door intrusion (in)
Soft	11.3	10.7	6.2
Stiff	11.1	10.4	6.1
No pad	11.1	10.3	6.8

Table 4. Comparison of SID dummy acceleration

Padding type	Upper rib-y (g's)	Lower rib-y (g's)	T1-Y (g's)	T12-Y (g's)	Pelvis (g's)
Soft	59.6	52.0	41.1	21.7	37.5
Stiff	67.2	59.0	40.0	55.5	50.2
No pad	108.2	93.6	49.2	53.8	54.7

Table 5. Comparison of SID dummy TTI(d) and ASA

Padding type	TTI(d) (g's)	Spine acceleration (g's)		
		ASA10	ASA15	ASA20
Soft	40.7	16.9	17.1	16.9
Stiff	61.4	38.1	38.4	37.6
No pad	81.0	29.0	36.5	43.0

Table 6. Comparison of SID dummy force

Padding type	Shoulder (N)	Thorax (N)	Abdomen (N)	Pelvis (N)	Knee (N)
Soft	4,708	4,355	2,030	6,063	4,206
Stiff	5,054	4,741	2,905	7,991	5,486
No pad	4,147	7,243	779	13,041	881

DISCUSSION

Door Velocity and Intrusion - Simulated door peak velocity and intrusion were limited to peak values within 11 m/sec and 7 inches, respectively, to prevent the possibility of test subject damage. In view of overall shape of velocity profile a quite similar door velocity-time history to one of a full size car was simulated (Figure 6a). A good correlation of velocity profiles can be seen within 30 milliseconds after starting to move the door wall assembly. The discrepancy after 30 milliseconds may have little effect on test subject impact responses for this basic study because most important events occur earlier in contact time. However better engagement of the door wall assembly to the struck sled after maximum door wall intrusion should improve this discrepancy.

SID Dummy Acceleration - Different padding conditions mainly effected rib cage acceleration rather than spine acceleration. TTI(d) is lowest for soft padding, intermediate for stiff padding and highest for no padding. ASA is also lowest for soft padding and more than double this for stiff and no padding. The ASA data suggested that stiff padding may be worse than no padding, while TTI(d) indicated the opposite.

Contact Force - Benefits of padding as force-limiting material can be noticed particularly in the thorax and pelvic regions (Table 6). The second peak force for soft and stiff padding was generated due to padding bottoming-out (Figure 7b, c). These were much less than in the unpadded case. Interestingly, the peak force of abdomen and knee region for no pad were quite lower than for padding conditions.

Chest Pot Displacement - Peak values of chest potentiometer displacement were 29 - 30 mm in all three tests.

CONCLUSIONS

1. A sled-to-sled subsystem side impact test methodology has been developed and used to simulate desirable door velocity profiles for the fundamental study of biomechanical response and injury mechanisms in side impact.

2. The simulated door velocity profile is repeatable and was not effected by the choice of padding or door spacing.

3. Based on the SID dummy tests, this device shows promise in demonstrating door padding and spacing effects that can occur in a real-world side impact.

4. The contact force data was useful in getting a better understanding of test subject response during impact. The soft padding was the best force limiting device at the thoracic level in this initial study.

FUTURE STUDIES

This paper describes the SID dummy test results with three trial runs. The door peak velocity can be increased up to 12 m/sec because SID dummy response was still below the 85 g's cut-off in all three test conditions. More runs with SID, BIOSID, and cadavers will be performed to analyze padding and spacing effects. Tests will also be run with and without the shoulder load plate to test the effect of door sill height on occupant response. It is hoped that this new device will clarify conflicting issues in side impact crash protection and help determined the best injury criteria for side impact safety.

Sled Testing Procedure for Side Impact Airbag Development

P. Michael Miller II and Hai Gu
MGA Research Corp.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Side impact crashworthiness development presents a unique challenge to auto safety engineers. One fundamental issue is how to evaluate side impact air bags with a component test that realistically simulates the kinematics of a full scale side impact crash test. This paper presents a test methodology that can be used to evaluate side impact air bags utilizing an accelerator-type sled typically used for frontal impact simulation. The approach uses a "two carriage" system, whereas the struck door and vehicle acceleration profiles are simulated. These acceleration responses are matched through a series of sled variables including thrust column setting, metering pin shape and an on-board pneumatic cylinder which controls the relative response between the two carriages. The mechanical operating principles behind this testing methodology, the approach used to conduct baseline matching tests, data showing the level of correlation achieved with this testing technique, and side impact air bag test results is presented. Correlation of this type of testing is based upon both the vehicle response and the acceleration responses of a Side Impact Dummy. Readers of this paper will gain a greater understanding of how accelerator-type sleds can be used to realistically simulate dynamic side impact conditions.

INTRODUCTION

Side impact crashworthiness presents a complex problem with regard to development due to the lack of commonly accepted component test methodologies. The automotive industry has been seeking effective methods for side impact testing of their vehicles and components. A system utilizing an accelerator type sled has been developed for side impact crash test simulation. This methodology is refered to as the Side Impact Test and Evaluation (SITE) sled technique (patent pending). The SITE sled system simulates the dummy and door interaction witnessed in full scale crash tests. Exact representation of the vehicle interior and dummy positioning is achieved with this system. The SITE test procedure has been developed as a basic methodology for side airbag development. The SITE procedure has many of the same advantages typically associated with accelerator sled testing including low test to test variability, ease of setup, high correlation with crash test results and realistic deployment of air bags.

As is the case with most simulation approaches, it is important to first establish a "baseline" test case. For the SITE system, the baseline case is a test condition where the SITE results correlate very closely with full scale side impact crash test results. Correlation is based on a number of test variables, including the door acceleration and Side Impact Dummy (SID) lateral accelerations. Once a baseline condition has been established, this test condition can be used to evaluate design changes, or more specifically, the effectiveness of a side impact air bag. The main challenge in the development of the SITE system has been in converting an accelerator-type sled system typically used for frontal impact simulation to be used for side impact simulation. When comparing the kinematics of a frontal impact case to the side impact crash test case, it is obvious that the vehicle accelerations produced in a side impact will be much greater than the frontal case due to the limited crush space for a side collision. Essentially, the closeness of the occupant to the impact area and crush zone is why side impact occupant protection is so difficult. In order to produce the high accelerations of a struck door, the basic operating conditions must be altered. There are a number of approaches that can be implemented, examples of which include an actual carriage to carriage impact, the use of a crushable material to control the response between two carriages, or increasing the distance between the occupant and the door panel, thus allowing the main sled carriage to reach the desired door velocity prior to contacting the occupant.

The approach used with the SITE system is to reduce the mass of the upper carriage so that higher accelerations may be achieved, and controlling these accelerations through the optimal design of a metering pin. In conjunction, the upper carriage (which simulates the door response) is connected to the lower carriage with a pneumatic cylinder. Likewise, the relative response between the upper and lower

carriage is controlled via the onboard pneumatic cylinder. The lower carriage response mimics the unstruck side of the vehicle. Thus, with the SITE system, both the intruding door and floor pan acceleration can be simulated at the same time. This results in a test which accurately simulates what occurs during a side impact crash test.

For side impact air bag development, an accurate side impact sled simulation is an essential tool to control both cost and time expenditures. The SITE system is one option which can be used for evaluation of side impact air bags. Subsequent discussion include an overview of the FMVSS 214 crash test, operating principals and SITE setup, baseline correlation testing, and air bag testing.

FMVSS 214 CRASH TEST

It is assumed that the reader is familiar with the basic requirements of the FMVSS 214 crash test; however, specific details are available in the literature (1, 2, 3). Here, only a very general review is presented in order to set the stage for for the rest of the paper.

The test configuration, as specified by the National Highway Traffic Safety Administration (NHTSA) is shown in Figure 1. Schematically, a Moving Deformable Barrier (MDB) is shown impacting the side of a stationary vehicle at 33.5 mph. The MDB is towed at a crabbed angle of 27° to its longitudinal axis. This configuration is intended to simulate a striking generic vehicle (MDB) moving at 30 mph, perpendicularly into the side of the struck vehicle (test item), which is traveling at 15 mph.

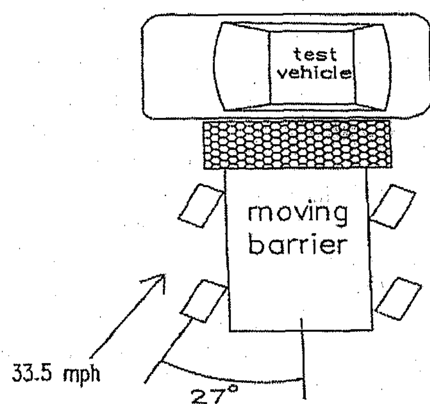

Figure 1. FMVSS 214 Crash Test Configuration

NHTSA Side Impact Dummies are placed in the front and rear seating positions on the struck side of the stationary test vehicle. An occupant injury criterion is based upon the lateral acceleration (Y axis) of the SIDs' upper and lower ribs, lower spine, and pelvis. A photograph of an actual crash test is presented in Figure 2.

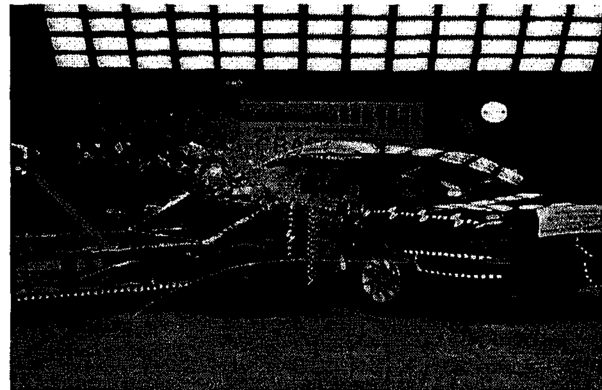

Figure 2. Photograph of FMVSS 214 Crash Test

It is emphasized that the injury criteria for the SID are based solely on the lateral acceleration responses measured in the dummy. In addition, it is also evident that the struck door and vehicle are accelerated primarily in the lateral direction, especially during the time when the dummy impacts the inner door panel. From a test simulation stand point, most of the effort can be directed toward controlling the lateral vehicle and door response and producing the desired SID response. Simulation of only one dimension also greatly reduces the complexity of any side impact sled simulation, since a typical acceleration type sled is designed to produce responses in only one direction. The problem is greatly simplified because now one-dimensional analysis and tests can be used to approximate the more complex FMVSS 214 test condition.

In a typical FMVSS 214 test, instruments will include accelerometers on the MDB, struck vehicle and SID. For the purposes of the approach outlined in this paper, it is important that further instrumentation be placed on the struck door and vehicle. This instrumentation is needed to set up the appropriate dynamic environment with the SITE system.

Accelerometers should be placed on the inner door skin behind the trim panel attachment. The placement of these accelerometers (longitudinally and vertically) should be in the general area of the dummy loading. Typically, accelerometers are mounted on the upper, center and lower positions very near to the dummy contact area. Accelerometers should also be mounted on the undeformed areas of the vehicle such as the seat attachment, floor pan, and unstruck side B-pillar. All of the accelerometers on the door and vehicle are in the Y direction. The data from these accelerometers are critical for setting up the SITE test and for precisely sensing when to and triggering a side impact air bag.

SITE OPERATING CONCEPTS

Presented in Figure 3 is a schematic drawing showing all of the basic components of the SITE system. As shown by this drawing, the upper carriage rests against the thrust column piston and rides on top of the lower carriage on a rail system. The lower carriage is attached to the sled rail system via a pressurized braking system. A pneumatic cylinder is used to

control the relative response of the two carriages. A door trim and other components (such as a pillar) that the occupant may interact with are attached to a flat surface on the upper carriage. A seat (with the dummy placed in it) is attached to the floor of the lower carriage.

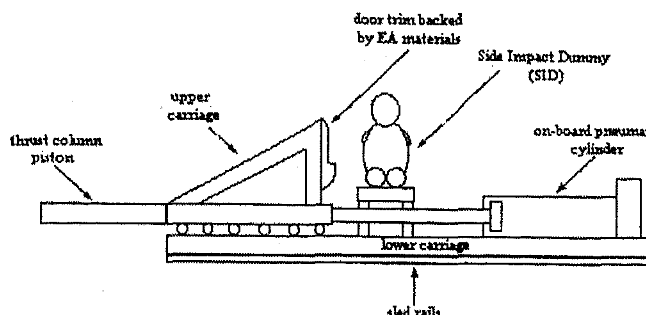

Figure 3. Basic Components of SITE System

When the sled is fired, the thrust column piston will push the upper carriage. The response of the upper carriage is controlled primarily by the shape of the metering pin and load pressure. Since the mass of the upper carriage is significantly lower than a normal carriage, the accelerations which can be produced are very high. The lower carriage will not begin to move until sufficient pressure is produced inside the onboard cylinder. Once the forces generated inside the cylinder exceed the braking forces produced by the braking system on the rails, the lower carriage will then begin to move. Thus, this approach allows you to produce different dynamic responses that simulate the struck door and vehicle simultaneously. The ability to control these responses results in an ideal tool for simulating a variety of vehicles including small cars through sports utility type vehicles. The overall capabilities of the system demonstrated through development are as follows:

- Upper Carriage Maximum G's ≈ 160 G's (with a 600 lb payload)
- Upper Carriage Maximum Velocity ≈ 30 mph
- Upper Carriage into Lower Carriage Maximum Intrusion ≈ 18 inches

The capabilities listed above are variables which are considered the most relevant for side impact simulation. The maximum values for the lower carriage are much lower, but the range is comparable to that seen in FMVSS 214 crash testing for the unstruck side.

An actual SITE test is conducted by attaching the seat to the lower carriage and placing an instrumented SID in it. A door trim is placed on the facing of the upper carriage and energy absorbing material is placed behind it. The role of the material is to attenuate the response of the SID so that it matches the crash test results. In essence, the crush of this material mimics the crush of the door during the crash test. Once the SID responses have been "tuned" to match the crash results, the simulation meets the key requirements (door, vehicle, SID responses) for an ideal simulation and that test condition can then be used to evaluate side impact air bags.

SITE COMPUTER SIMULATION PROGRAM

To conduct SITE testing it is important to be able to produce both the struck door and unstruck vehicle responses. A computer program was designed to simulate door and vehicle acceleration profiles from actual full scale side impact crash tests. There are a few parameters considered in the program, such as:

- pressures and volumes in the sled thrust column
- pressure in the on-board pneumatic cylinder
- lower carriage braking pressure
- total weights of upper and lower carriage
- fire pressure
- metering pin shape

The program works by accepting these inputs and predicting the upper and lower carriage responses by solving the governing equations for the system. The output of the program are the acceleration, velocity, and displacement response of each carriage. The pressures and volumes in the thrust column determine the total amount of energy which can be generated by the sled. The total mass of the upper carriage and the total mass of lower carriage are two variables which can affect the peak values of the acceleration profiles. The lower carriage braking pressure and sled fire pressure are secondary variables and have less influence on the acceleration profiles. The most important variable in the simulation is the shape of the metering pin. The shape which is typically used to match the door response is one which initially allows a large flow of gas through the orifice, and then chokes off the flow very quickly. This is what produces the very high acceleration response early and what causes the immediate decrease in G's.

BASELINE MATCHING

The first step which must be completed before airbag development work can be started is to establish a baseline test which correlates very well with full scale crash test data. Once this has been achieved, side impact air bags can be tested and the effects of the air bags on occupant injury levels can be evaluated.

Presented in Figure 4 is a flowchart showing the general steps involved in achieving a baseline test condition which correlates with the full scale crash test results. The first step (Step 1) is to determine specific information and data from the full scale crash test on the baseline vehicle. This step is somewhat crucial as this information is a direct input into the baseline and the accuracy of the input data is very important with regard to the overall validity of the model. Following is a listing of what is needed to conduct the baseline matching test series.

- struck door and unstruck side vehicle accelerations
- SID responses including upper rib, lower rib, upper spine, lower spine, and pelvis Y axis accelerations
- High speed films showing SID interaction with door and other vehicle structures.
- dimensional data including relative positions of the SID, seats, door, and other components

Initially, the only information which will be used is the door and unstruck side vehicle acceleration responses. As shown on the flowchart, the next task (Step2) is to utilize the SITE computer model to determine appropriate setup variables to match the door and vehicle accelerations with the upper and lower carriage accelerations, respectively. Using the computer model developed specifically to predict upper and lower carriage responses (as well as previous experience), the metering pin configuration, pressures, and volumes can be determined. Next, the thrust column and onboard backing cylinder should be set to these variables. Once this is done, sled pulse trials (Step 3) are completed until good correlation of the upper and lower carriage to the struck door and unstruck vehicle acceleration, respectively, is achieved. The most important response to match is the door acceleration, while the unstruck side of the vehicle is considered a secondary effect. It should be noted that for other vehicle types such as light trucks or sport utility vehicles, the response of the unstruck side of the vehicle may be of greater importance. The upper carriage acceleration should match very closely with the door acceleration through the dummy injury phase of the event. Correlation of these responses include both magnitude and timing.

Following this, the upper and lower carriages must be setup for the full system tests (Step 4). Most of the effort here is directed toward fixturing of the door trim, pillars, and seat so that the geometry and spacing are identical to the baseline vehicle. It is important that the exact geometry of these items is duplicated because of the implication of deploying a side impact airbag properly (once a baseline condition has been established).

Steps 5 and 6 consist of conducting full system tests while analyzing the dummy responses. The main variables influencing the SID response are the energy absorbing padding placed between the flat plate and the door trim. The padding choice of the first test is based mostly on previous experience. Based on the initial test results, the dummy responses can be tuned in by changing the location, thickness, and stiffness characteristics of the padding materials. The decision of what padding configuration to use is based mostly on the SID responses. To conduct this part of the baseline matching testing, a wide range of padding materials must be available. Also, the sled test films showing the dummy motion must be compared to the crash test films. If there are significant differences in the dummy kinematics, the setup variables must be carefully reviewed.

Following multiple test iterations, a reasonable baseline condition should be achieved. Once this has been done, an additional one or two tests should be conducted for repeatability purposes. It is thought that the baseline matching can be completed in approximately 6-8 full system tests.

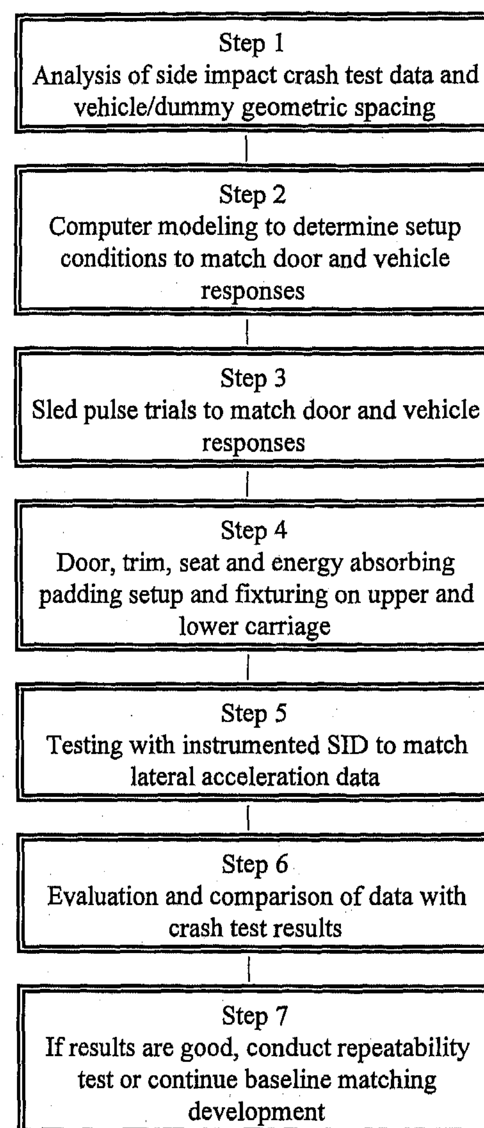

Figure 4. SITE Baseline Matching Flowchart

BASELINE TESTING RESULTS

As part of the overall development of the SITE system, a "baseline" test condition was established using a 2-door mid-size vehicle. The baseline crash test was a FMVSS 214 crash test that was part of a federal crash test program, of which the results are publicly available. The crash test was conducted using the government compliance test procedure. Following the steps listed in Figure 4, a baseline condition was established. Referencing Figure 4, the results for Step 3 (door and vehicle response matching) are presented in Figure 5. As shown by these over-plots, the inner panel struck door acceleration was matched reasonably well by the SITE system. The overall magnitude, timing, and general shape of

the response was reasonably simulated. The unstruck side vehicle response (which is not presented here) was not considered to be of significance for this simulation because the vehicle data showed only a very small amount of displacement during the injury phase. Also presented in Figure5 is the velocity-time overplot.

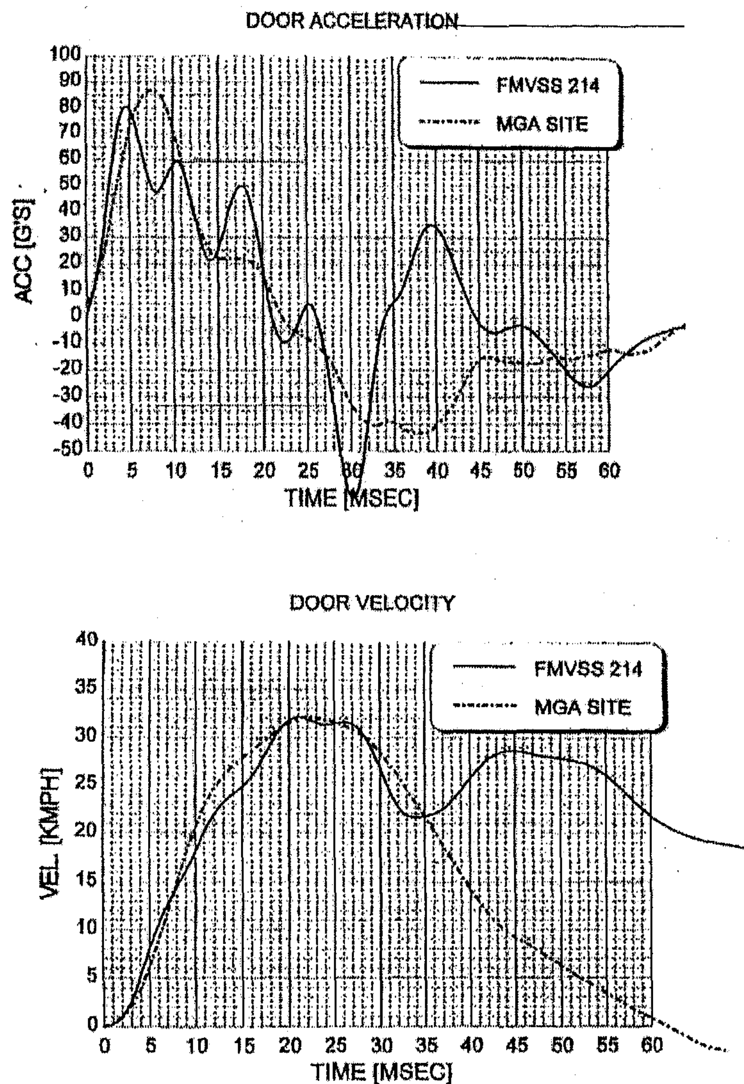

Figure 5. Door Acceleration Overplots

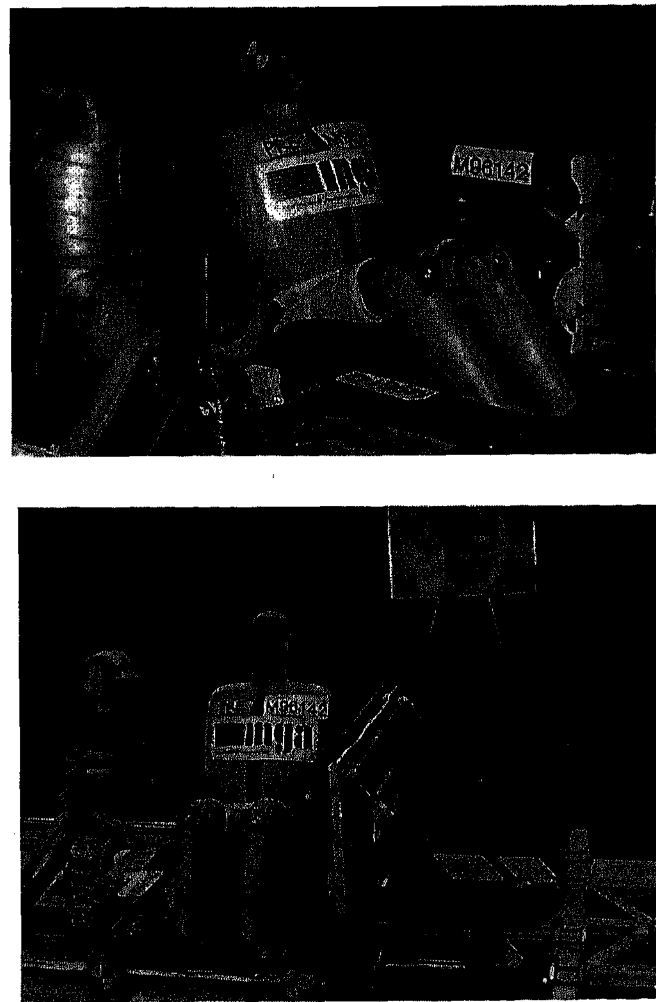
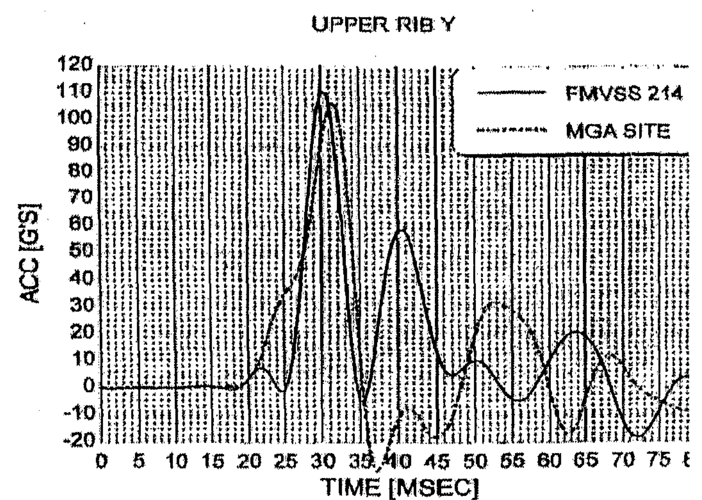
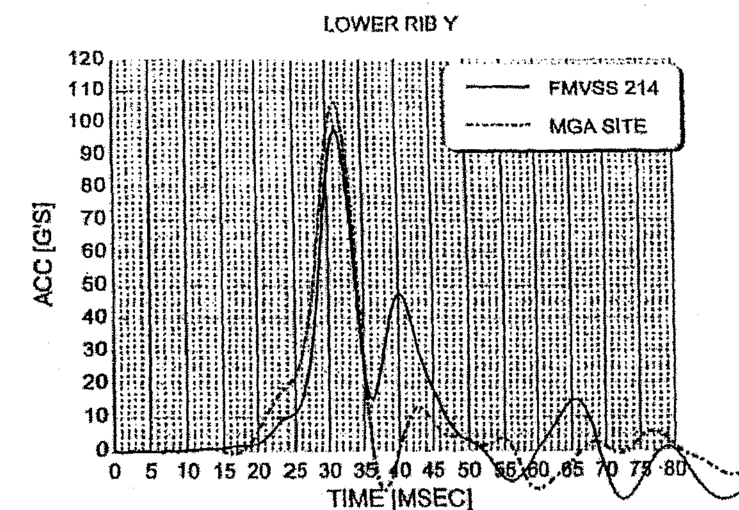
Once the upper carriage response was established, the setup for the first SID test was completed. The vehicle components for this test included the door trim and seat. Presented in Figure 6 are two photographs from this testing. Following an iterative testing process, a baseline was established. This baseline condition was based upon the door and SID lateral responses. Presented in Figure 7 is a series of overplots comparing SITE results with FMVSS 214 results. Based on the data, the SITE SID results were within approxmiatley 10% for the peak accelerations and 5 msec for the timing of the peaks. Likewise, the injury criteria values for the crash and SITE results showed the same level of correlation. Analysis of the crash and SITE films demonstrated that the SID's motion was very similar for each type of test.







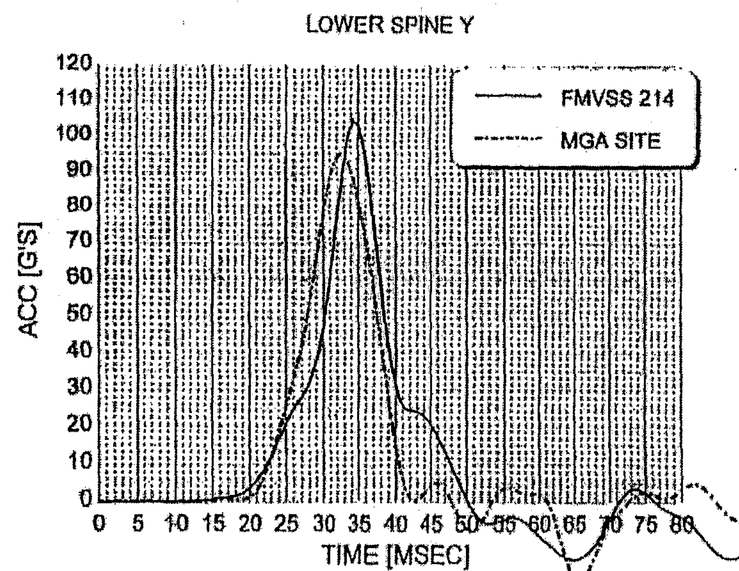


Figure 6. Photographs of SITE Sled Test

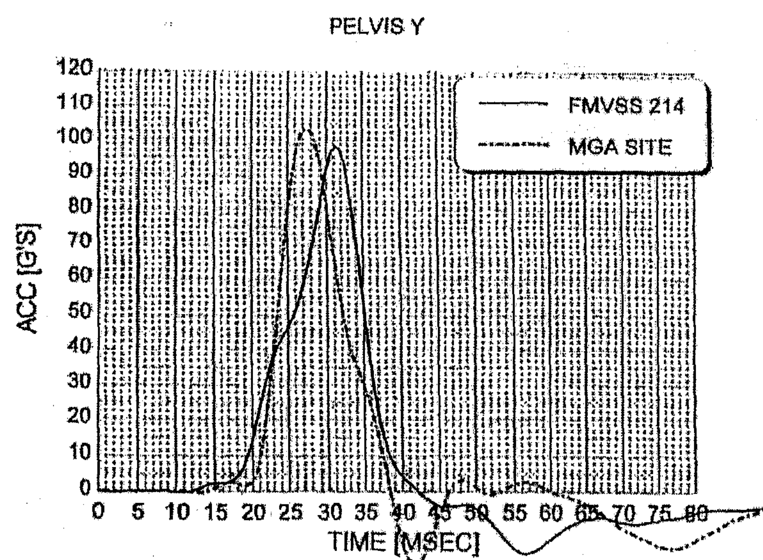

Figure 7. SID Acceleration Overplots

SIDE IMPACT AIRBAG TESTING

In order to further develop the SITE methodology, testing was conducted with and without side impact air bags. The air bags were provided by Breed Technologies to aid in the development of the methodology. It should be noted that the air bags which were used were "generic" in nature and not developed specifically for the baseline vehicle. The air bag was a seat back mounted unit which was attached to the seat back frame. The air bag was triggered based upon the upper carriage acceleration and was positioned to deploy so that it filled the space between the occupant and inner door. Presented in Figure 8 is a series of photographs taken from high speed photography, which show the deployment sequence.

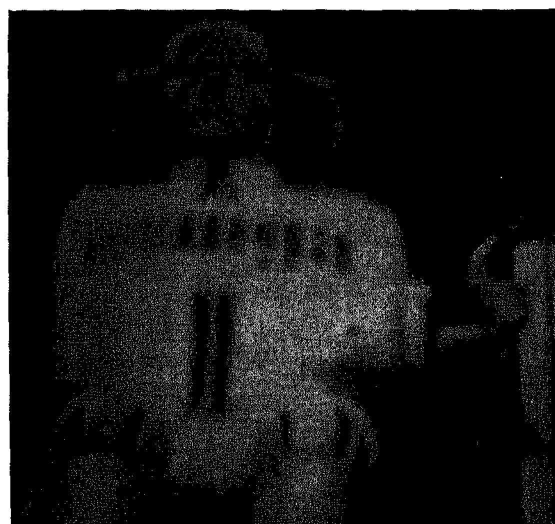

Figure 8a. Pre-deployment

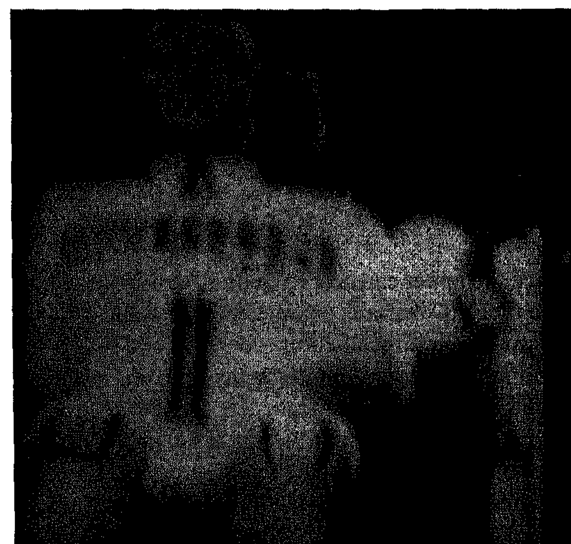

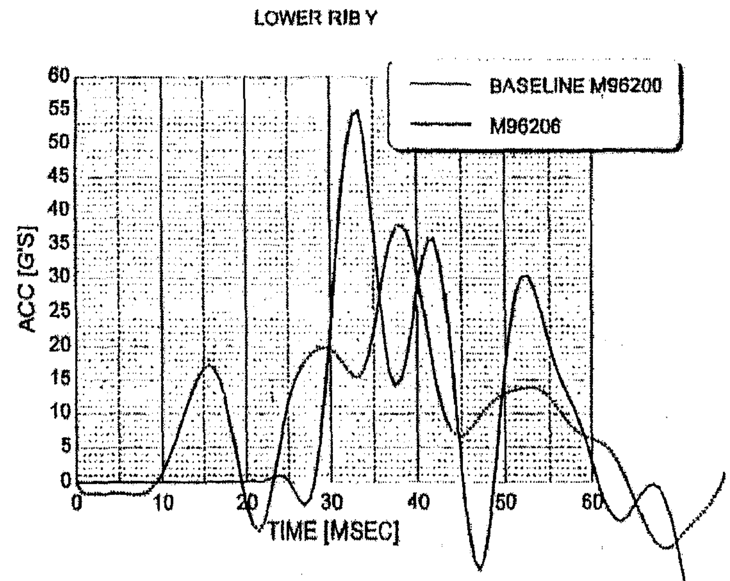

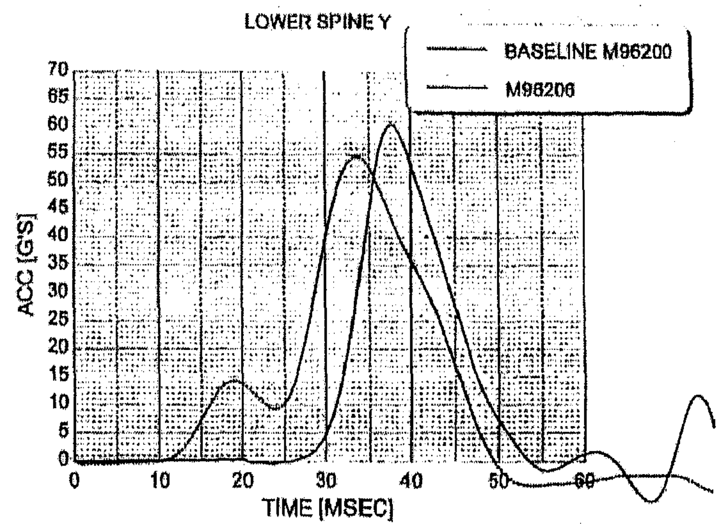

Figure 8b. Space between the SID and the door panel being filled up by the side impact airbag

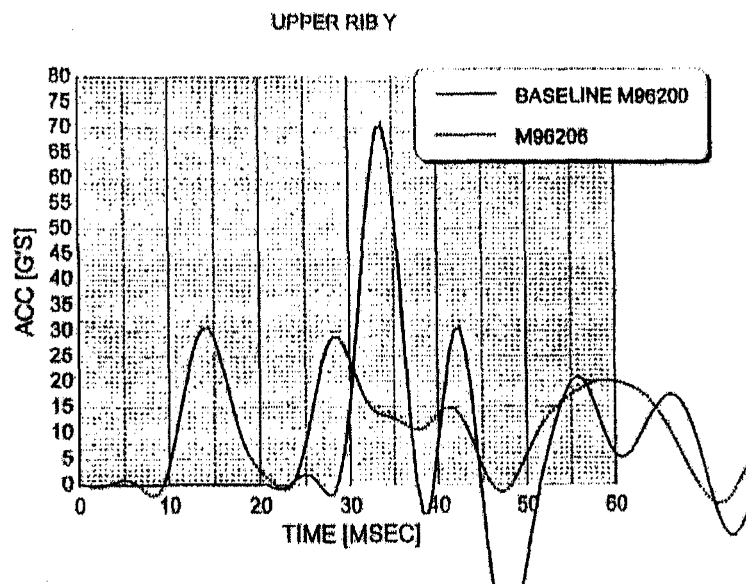

Figure 8c. Full Deployment

The overall effect of the air bag on the occupant response is shown through a series of overplots presented in Figure 9. As shown by this data, the air bag did provide some benefit to the occupant in terms of reducing the magnitudes of the peak accelerations and injury criteria values. In general, the loading on the dummy occurs earlier in the event and produces lower peak accelerations. The upper and lower rib responses were reduced by approximately 40%, while the lower spine and pelvis responses were reduced by approximately 10% with the airbag. It is at this point when the real benefits of the SITE are evident. This test methodology could now be used to further develop and fine tune the air bags without having to conduct a full vehicle crash test. Since this test requires so few components (door trim, seat, air bag), the costs to evaluate a new potential design are considerably reduced.

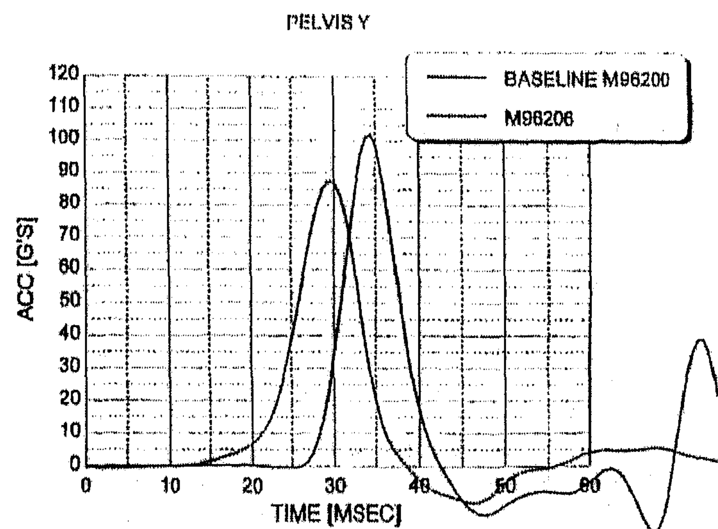

Figure 9. Side Impact Airbag Test Results (M96206)

CONCLUSION

This paper presents a component level test methodology which can be used for side impact air bag development which utilizes both technology and facilities commonly used for accelerator-type frontal impact sled simulation. The test which is presented is a very straight forward and simplified approach which requires very few parts. The level of correlation with actual full scale test results is reasonably high. Although results are not presented, the test to test repeatibility using the procedure is similar to what is shown for full scale FMVSS 214 testing.

The purpose for this paper was not to highlight specific strong points of the SITE system, but more to describe the procedure and indicate how this type of testing could be implemented into side impact air bag development. At this point, future development of this system is being directed towards including a complete door which is impacted with a moving barrier. It is thought that perhaps this approach may be more suitable for padding or door structure development. Results for this effort will be presented through future SAE proceedings.

ACKNOWLEDGMENTS

The authors of this paper wish to express appreciation to associates at MGA, as well as customers of MGA who have supported the development of the SITE system. In addition, a special thanks is given to Breed Technologies for providing air bags and technical assistance on this project.

ABSTRACT

The introduction of the dynamic FMVSS 214 crash test requirement has prompted the need for an economical test method for the development of side impact occupant protection devices. Full scale side impact crash testing is too costly for the development testing of occupant protection components.

This paper describes a unique test method for side impact sled testing which utilizes a standard 12-inch HYGE type sled facility. It has been demonstrated, with several hundred tests, to provide high repeatability and good correlation with full vehicle side impact crash tests. An overview of the device and details on how it is used is provided. Typical data correlation between sled tests and crash tests is shown for FMVSS 214(dynamic) testing. EEVC side impact and lateral crash tests into a rigid pole have also been correlated with this device and will be made available upon request.

INTRODUCTION

Development testing of frontal impact protection components relies heavily on crash simulation tests. These tests are frequently conducted using devices like the CVC HYGE sled, which accelerates the occupant compartment of a vehicle in reverse with a controlled "crash pulse" that reproduces the acceleration and relative velocity of the vehicle during a crash test. The velocity change occurring between the occupant and vehicle interior during a side impact crash, however, occurs too quickly for most acceleration based sleds to simulate directly. Until recently, many believed that side impact tests could not be simulated using a HYGE type sled.

When modeling frontal impact tests, the occupant compartment structure is generally modeled as a rigid body due to minimal deformation rearward of the A-pillar in most frontal crashes. In side impact tests, however, the door, b-pillar, seat, roof rail, and floor pan of the struck vehicle all move different amounts at different times. The term "crash pulse" as it is normally understood for frontal impacts, does not apply for side impact. Instead, the dynamics of those components that directly effect occupant injury must be considered separately.

For the FMVSS 214 dynamic certification test condition, occupant injury is attributed primarily to dummy interaction with the intruding door of the vehicle. As the moving deformable barrier (MDB) crashes into the side of the stationary target vehicle, the struck door is crushed externally, and accelerated into the occupant. The inner door stiffness (a result of external intrusion) and the door velocity profile as it strikes the occupant are the primary factors resulting in specific occupant injury.

It is the door velocity profile that creates the greatest difficulty in simulating the side impact event on a conventional HYGE type sled test device. In a side impact crash, the door is accelerated from zero to approximately 10 m/sec in only about 20 ms. Over this 20 ms, the inner door only moves about 100 mm before impacting the occupant. The HYGE type accelerator sled, when used in the conventional way, is unable to accelerate the door to the needed velocity this quickly.

Consider a side impact crash event reduced to this simplified model:

An intruded door, with its deformed interior geometry and stiffness, is accelerated to some velocity before impacting a stationary test dummy.

If the door geometry, stiffness, and impact velocity profile from this crash can be reproduced in a component level test, the response of an impacted dummy should be nearly equal to that of a vehicle level test. Then, if some energy absorbing device, such as padding or an air bag, is placed between the door and occupant, the effect of the device on dummy response can be measured. It is this logic that provides the basis for the test device and methodology described in this paper.

SIDE IMPACT TEST DEVICE

Sled testing to simulate the side impact crash event has often been achieved on a HYGE sled by positioning the dummy far enough away from the door to allow the required velocity to be attained prior to impact (Heidelberg method). Although this method may be satisfactory for testing door trim and padding materials, it does not produce the geometry or timing correlation needed for dynamic side airbag testing. Relative positioning between the door, seat, and test dummy must be maintained to properly reproduce the air bag deployment space actually available during door intrusion. Timing must also be correlated between the sled and crash tests to enable air bag deployment times to be established and reproduced.

To fulfill these required test conditions, a unique test device and methodology has been developed and patented. The test device was developed to utilize a standard 12-inch bore HYGE sled facility. All facility support items, such as photographic equipment, lighting, data acquisition system, and sled braking apparatus are unchanged between frontal impact and

side impact test configurations. This commonality minimizes the complexity and time required for change-over between frontal impact and side impact sled tests. The side impact test device is fully contained on top of the existing accelerator sled carriage, as shown in Figure 1, and is attached using existing mounting holes.

The device consists of a ram, a dual guide-rail system, a secondary carriage or "dolly", and an aluminum honeycomb crush element. The dolly represents the occupant compartment of the struck vehicle. An aluminum base plate and vertical steel tube structures contain mounting hole patterns for universal mounting of test components. For FMVSS 214 test simulations, the dolly is typically outfitted with a trimmed door shell (without internal mechanisms), a B-pillar segment with trim, seat belts, and a seat which is mounted to the floor of the dolly using a sliding seat base to enable the seat to slide laterally. When properly configured for a test, the seat, door, b-pillar, and test dummy are positioned the same as in the subject vehicle. The dolly is mounted to the sled carriage through linear motion bearings to two guide-rails bolted to the top of the carriage in its longitudinal direction. The bearings and rails allow the dolly to slide in the subject vehicle's lateral direction (same direction as sled carriage motion).

A rigid ram is bolted to the front of the sled carriage in such a way that its flat impact surface is parallel to the leading face of the dolly. On the ram impact surface, a block of aluminum honeycomb is mounted as a crush element between the ram and the dolly. Typically, the honeycomb crush element is a block of Hexel Specification Grade aluminum honeycomb with a nominal crush strength of 1241 kPa (180 psi), a cross-section area of 0.1858 m^2, and a crush depth of 20 cm.

At the start of a test, the dolly is positioned approximately 75 cm away from the impact surface of the honeycomb. When the sled is activated, the dolly remains stationary (due to its inertia) as the sled carriage is accelerated to the desired velocity. When the honeycomb strikes the dolly's impact face, the kinetic energy of the sled carriage is used to accelerate the dolly while crushing the honeycomb. As the dolly (with the door rigidly attached) accelerates, the seat and dummy, which are on the sliding seat base, remain stationary due to their inertia. Therefore, like a side impact crash test, the door is accelerated toward the seat and occupant. The door will then strike the seat, pushing it from under the dummy until, finally, the door strikes the dummy. With this scenerio, the dynamic relationship between the door and occupant, and between the door and a seat mounted airbag module, can be simulated.

It must be pointed out, that this test device is not intended to simulate the entire duration of a side impact crash event. Only the time frame in which the occupant is subjected to the primary injury causing loads is evaluated. It is during this time, usually from 0 to 45 milliseconds, that an airbag must deploy into the available space and provide protection to the occupant. When the primary interaction between the door and dummy is complete, the onboard sled carriage brakes are activated. Two latches, activated during the crush of the honeycomb, hold the dolly to the carriage while braking.

TEST METHODOLOGY

For any side impact test device to be suitable for side impact air bag evaluation, the following elements of the crash event must be accounted for:

GEOMETRY - It is important that all components in the air bag deployment zone be positioned so that the target vehicle geometry is modeled. The shape of the air bag, the output of the inflator, and the mounting scheme used are based, at least in part, on the vehicle interior geometry and the reaction surface for the air bag as it deploys. For all side impact testing conducted with this device, the door, seat, air bag module, and test dummy are positioned in proper relationship to each other as defined by customers' vehicle layout drawings.

VELOCITY / TIMING - Because the air bag must be able to deploy into position within about 15 milliseconds after impact, it is important that the door intrudes upon the dummy at the correct velocity and timing. To protect the occupant from serious injury in most vehicles, the air bag module must be activated about 5 ms after impact and be into position to provide protection within another 10 to 12 ms. Geometry and timing work together to ensure the deployment environment, as a function of time, is properly simulated. Figure 2 illustrates the relationship between sled carriage, sled fixture door, and crash vehicle door velocities. Note the time it takes for the sled carriage to attain the required velocity.

DOOR CRUSH CHARACTERISTICS - If the door geometry and timing are correct, the only other variable that will significantly effect dummy response is the crush characteristics of the door surface. To establish the correct crush stiffness for the door, a door from the crash tested vehicle is examined for deformation from exterior intrusion and from dummy impact. Deformation to the door's exterior ultimately has the effect of reducing available crush space inside the door, particularly in the lower portion of the door where intrusion from the bumper shape of the moving deformable barrier (MDB) has intruded. The door targeted for sled tests can be modified by adding structure to the inside of the door. This structure is designed to model the intruded shape of the external door surface, thus reducing available inner door crush distance. Because the deformation to the door during a crash test occurs before the dummy is involved in the crash, pre-test modification to the door should not adversely affect dummy response correlation.

A component level test device is not intended to provide a perfect simulation of a crash. Crash tests contain many variables, both in vehicle structure and in test setup, which create test repeatability issues. These variables can be reduced significantly on a component test device, but not without some loss of model accuracy. This device is no exception. By understanding these limitations and concentrating on the primary vehicle to dummy interactions, the effects of these limitations can be tolerated.

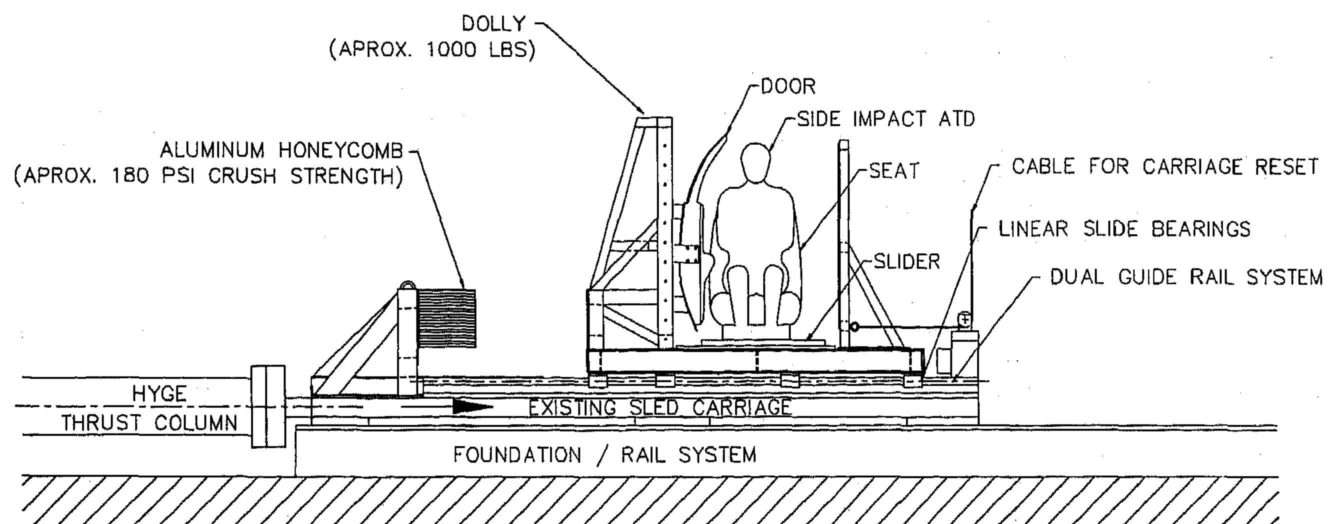

Figure 1. Side Impact Sled Test Device

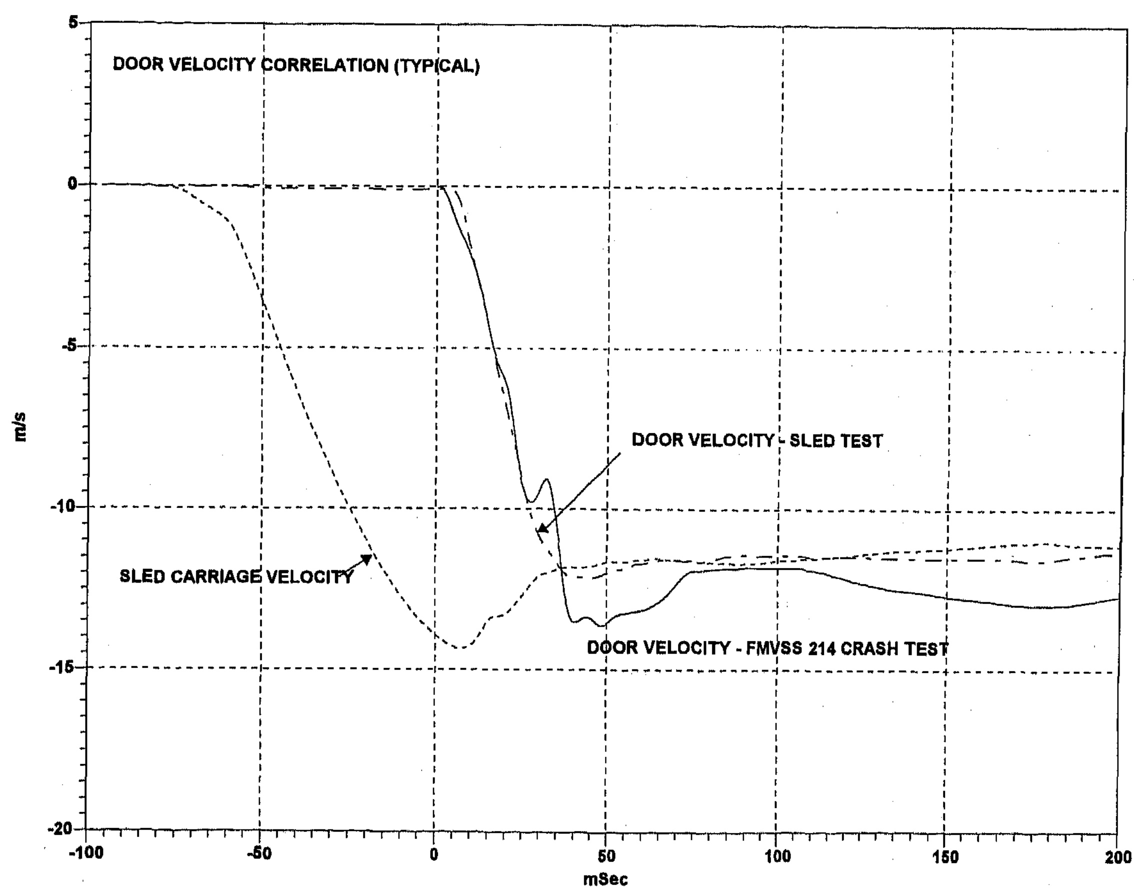

Figure 2 - Correlation of Door Velocity (typical)

Because the door and b-pillar are rigidly attached to the dolly, it is difficult to simulate door intrusion in cases where there is significant rotation (for example, when the bottom of the door intrudes more quickly than the top). If the rotation occurs prior to impact with the dummy, it can be simulated by pre-positioning the door in it's tilted position. Many tests have been conducted with the bottom of the door tilted inboard about 10 degrees. If the door rotation is still occurring at the time of dummy impact, pre-positioning will not be completely effective. Either the pelvis will be impacted too slowly in order for the rib impact velocity to be correct, or the rib impact will be too fast if the pelvis velocity is targeted. Because we are typically interested mainly in the effects of side air bags on thoracic injury, the rib impact velocity is our primary concern.

When simulating ECE side impact tests with the seat in full rear position, head to b-pillar impact correlation is also difficult to simulate. In this type of crash test, the upper b-pillar intrudes much more slowly than the lower b-pillar and door. This is because the upper b-pillar is attached to the roof, which only moves after significant intrusion of the MDB into the door and lower b-pillar has occurred. When simulating this test condition, the head impact velocity and the time of head impact must be addressed. Head impact timing can be accommodated by pre-bending the b-pillar to represent it's configuration at the time of head impact (through crash test film analysis). Unfortunately, in many tests there is still some difference in velocity between the upper and lower pillar at the time of head impact. Because the sled test device moves the upper and lower b-pillar at the same velocity, the head impact velocity is slightly higher than in the crash test. An over speed head impact means the head portion of a head/thorax side air bag will be over tested, which is not bad if the error is not great.

Side pole impact tests are often conducted to evaluate worse case head impact from the vehicle sliding laterally into a pole or tree. For most vehicles, the velocity at which the vehicle impacts the pole is only slightly greater than the velocity at which the pole hits the occupant's head. There is very little resistance to the initial pole intrusion into the vehicle. For pole impact simulation, some simplifications to this complex crash event are needed. The pole intrusion into the vehicle is quite severe, making the ability to simulate the event with this test device seem unlikely, due to its inability to simulate dynamic deformation of the door. But consider the actual impact with the dummy. Again there is simply a door, bent and stiffened by the pole, which strikes the dummy, and a pole which strikes the dummy's head. We could pre-deform the door to represent it's configuration at the time of dummy impact, but that would create an unrealistic deployment surface for the air bag to deploy against. Normally, the pole impact test is configured so the pole is aligned with the center of the dummy's head. With the door deformed as it is, the pole becomes the primary dummy loading device, with only the trim panel and crushed door sheet metal between the pole and dummy.

To simulate this on our apparatus, we start with the same setup as used for FMVSS 214 simulations. A pole segment is mounted to the fixture in the door window opening, and extends from the door belt line to the roof, with it's leading edge at the door-to-trim panel interface line. Below the pole, the door shell is rigidized to simulate the heavy intrusion of the door by the pole in a crash test. Only the area of the door directly impacted by the pole is rigidized, leaving the remaining door structure unsupported. The loading to the dummy from the unsupported door surface is relatively insignificant compared to the loads imposed by the reinforced segment below the pole. With the test configured in this way, we can closely reproduce the significant dummy loading paths while maintaining the door trim surface for air bag deployment. This method has been correlated successfully on many vehicle programs and used as an aid in head protection air bag development. Remember, the primary intent of this test setup is to evaluate an air bag's ability to protect an occupant when impacted by a rigid pole at a given velocity. This method will obviously not be of any value in evaluating door or vehicle structural changes.

EFFICIENCY - In the development of any air bag module, a large number of tests are needed to optimize the system and verify performance for a variety of conditions. A test method which is simple, quick, easy to setup, consumes minimal test hardware, and is highly repeatable is a real asset. This test device provides this efficiency. A primary goal in the design was to simplify the crash event to its main injury causing interactions. Only those vehicle components that interact with the dummy during the critical, injury generating time of the event are consumed during a sled test. Typically, the only parts consumed during a sled test are the door, door trim panel, and the seat. Any other vehicle parts utilized are used as part of the fixture to generate the proper geometry and air bag reaction surfaces. Because minimal parts are consumed, there is little effort required between tests. Turnaround time between tests is typically less than for frontal impacts due to the reduction in replacement parts.

Setup change between frontal impact sled tests and side impact sled tests is minimal, requiring no more time than a frontal impact changeover. The side impact device is contained in two sub assemblies that bolt onto the sled carriage just like a normal sled "buck". All support equipment, such as photographic lighting and cameras, data acquisition wiring, sled carriage braking, and system operational devices are left unchanged.

As with most testing, repeatability of data is directly related to the number of uncontrollable variables. The HYGE sled system, if well maintained, has proven to be very repeatable when used for frontal impact testing. Side impact testing with the HYGE demonstrates the same high level of repeatability, minimizing the number of repeat tests required to filter out test variability. Repeat tests are typically conducted only for verification testing, or when expected variance from a design change is small. Sled testing continues to be a much more efficient tool for sorting design parameters than full barrier frontal or side impact tests.

The following two pages contain data plots showing the correlation attained in an actual sled test series (Figures 3 through 6). This sled test was conducted to establish baseline (no air bag) data correlation at the onset of an air bag development program. The solid line in each plot indicates the dummy data recorded during an FMVSS 214 crash test, while the dashed line denotes sled test dummy data. Correlation to this level can typically be attained in two to three tests by an experienced test engineer.

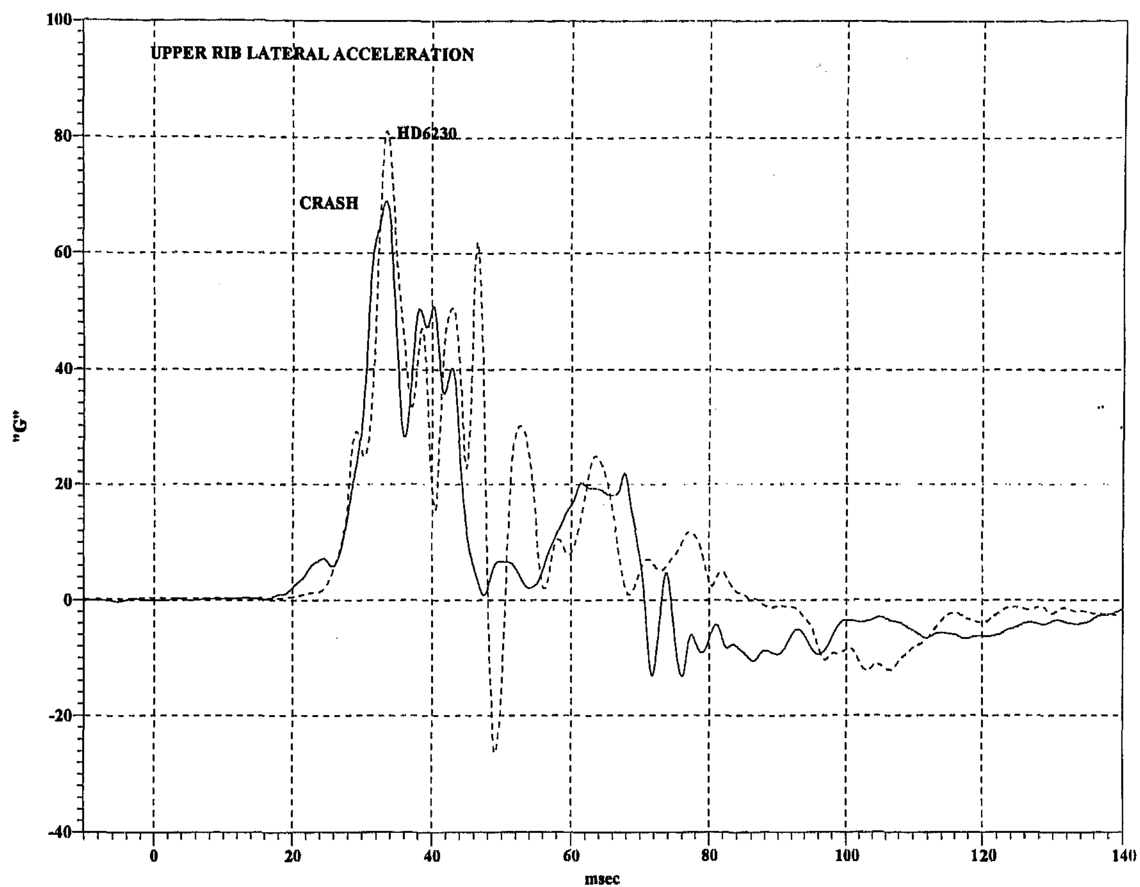

Figure 3. Correlation of Lateral Upper Rib Acceleration

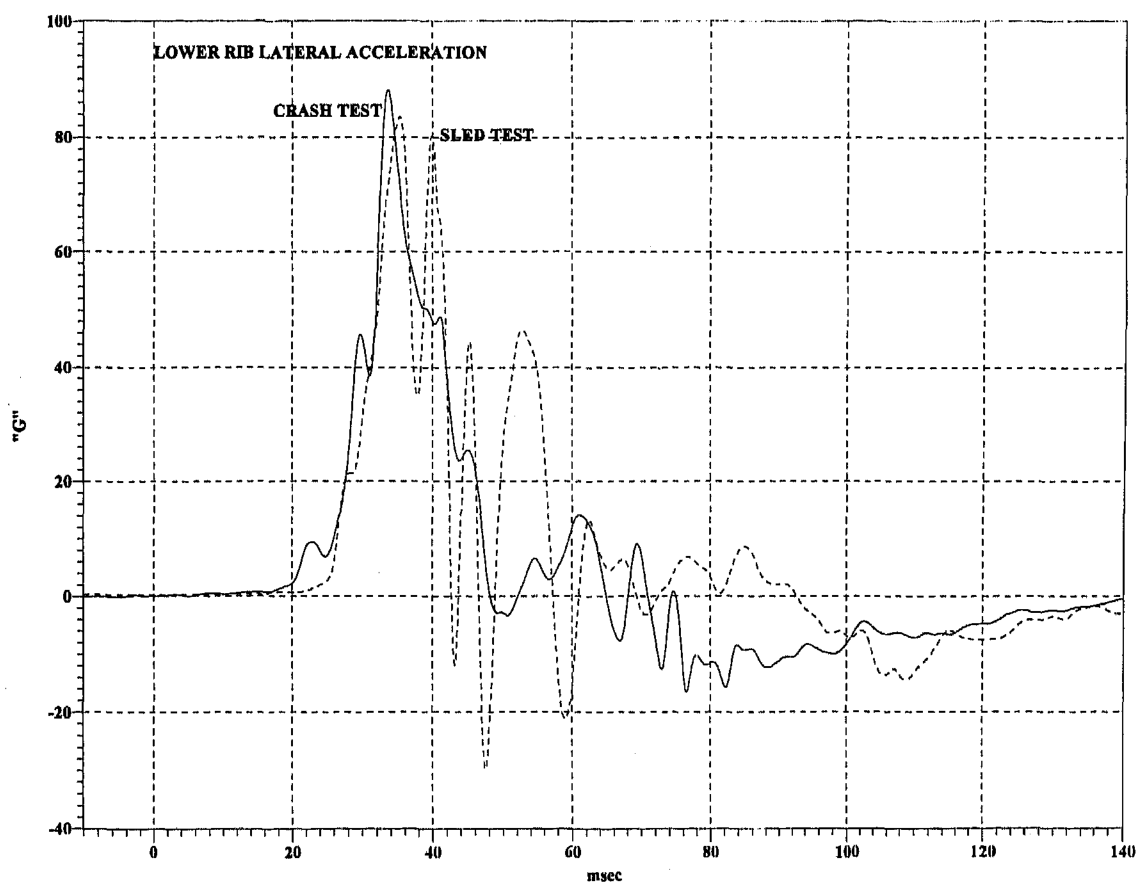

Figure 4 - Correlation of Lateral Lower Rib Acceleration

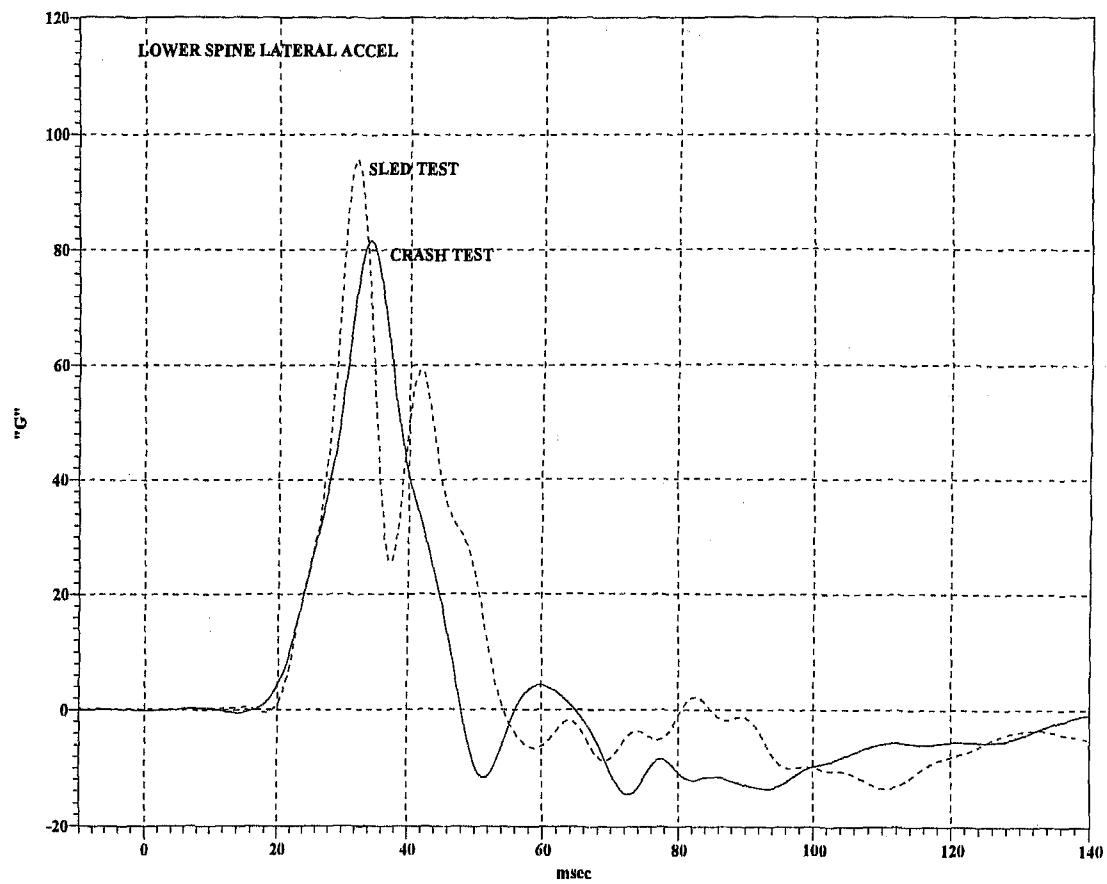

Figure 5. Correlation of Lateral Lower Spine Acceleration

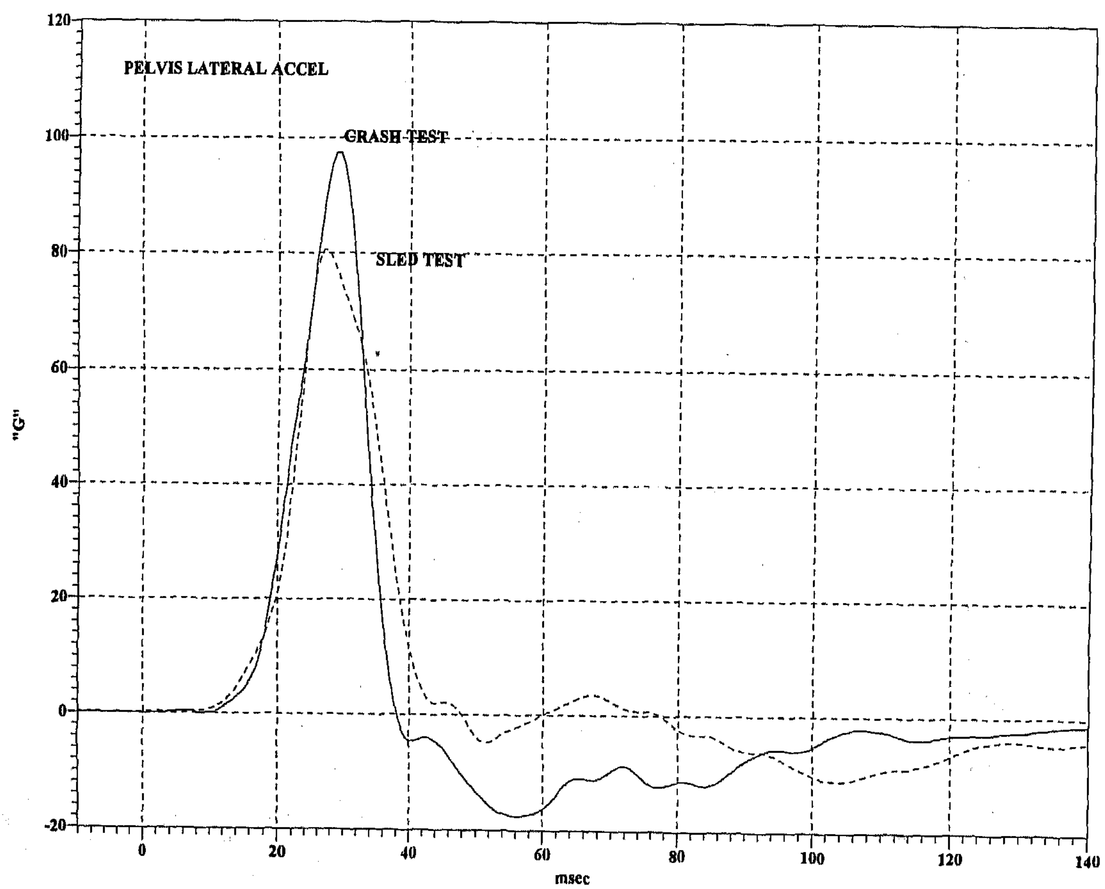

Figure 6. - Correlation of Lateral Pelvis Acceleration

SLED TEST CORRELATION:

The typical procedure for side impact air bag development programs is shown below:

- Receive vehicle and occupant test data from a baseline crash test (no air bag).
- Baseline sled correlation is obtained in 2 or 3 tests.
- The side air bag module is developed using the sled test as the primary system performance measure.
- The module is tested to other conditions such as EEVC or Pole impact requirement and "Out of Position" tests using adult and child dummies.
- One or more crash tests are conducted by the customer using the new air bag module to verify system performance.

Occupant data from the baseline crash test should be provided along with vehicle data. The data provided by accelerometers mounted to the struck vehicle's b-pillar or door sheet metal may not provide usable data for establishing sled correlation. Oscillations and noise in the data caused by the flexibility and deformation of these components during a crash test often make the data unusable for velocity computations.

Dummy response provides a good means for door velocity correlation. The initial accelerations of the test dummy ribs, being light by comparison, are affected to a high degree by the velocity of the approaching door. The total change in velocity of the larger dummy masses, obtained through integration of the spine and pelvis accelerations, indicate the energy transfer into the dummy over time. These velocities are not so much indicative of the inner door sheet metal velocity, but of the average velocity of the intruding barrier.

It is also helpful to have the dummy data available when tuning sled performance for optimum correlation in occupant response. If the velocity is correct, and the time to impact is correlated based on dummy impact timing, then the door stiffness may need adjustment to improve correlation. The best way to tune the door stiffness is to analyze dummy response as a result of impact with the door, and adjust accordingly. Once some experience is gained, a satisfactory correlation can be attained in 3 to 4 tests. It is possible to correlate the door stiffness by measuring the force vs deflection characteristics from a door taken off a crash tested vehicle, then matching that stiffness in the sled test door. This option, however, requires more testing to obtain correlation than tuning the door through sled testing.

Dolly velocity is adjusted by changing the "load" pressure in the HYGE cylinder. The particular pulse generated by the thrust column is not important here, as the acceleration of the dolly is controlled only by sled carriage velocity at the time of impact and by the crush characteristics of the honeycomb crush element. It is important that enough gap between the honeycomb and dolly is provided to ensure the sled carriage attains constant velocity (zero acceleration) before impacting the dolly. Otherwise, the actual velocity at which the carriage strikes the dolly becomes dependant also upon the spacing between the honeycomb and dolly, adding one more variable to the test conditions.

The rise rate for the dolly velocity curve is directly proportional to the stiffness of the honeycomb crush element. Therefore if a 20 percent increase in rise rate is needed to correlate with door velocity, simply increase the honeycomb cross section area by 20 percent. Aluminum honeycomb has a relatively constant crush force for a given section size. As it crushes, the force (and therefore the acceleration) on the dolly is relatively constant.

CONCLUSION

The side impact test device described in this paper has been used in over 1000 tests. It has been demonstrated to provide the high level of correlation and repeatability necessary to develop side impact air bag modules and demonstrate air bag system performance in the test conditions required. To date, this device has been used on CVC 12-inch HYGE sleds, 24-inch HYGE sleds, and on a Schenk servo-hydraulic sled using variations of the mounting scheme. It has been used to simulate FMVSS 214, EEVC, and lateral pole impact crash tests using the US-SID, BIOSID, and EUROSID side impact dummies. The HYBRID III 95th% frontal impact ATD has also been utilized for air bag integrity and bag coverage in lateral pole impact tests. Because the interior geometry of the vehicle is simulated, the setup is also used for static testing to evaluate air bag interaction with child and adult occupants.

Intrusion Factors and Their Effects on Steering Column Movements During Vehicle's Frontal Impact Testing

Bahig Fileta and Xinxin Liu
Ford Motor Co.

ABSTRACT

Significant dashpanel intrusion is seen in some cars after severe frontal crashes at high speeds or after offset impact with rigid barrier or both. This intrusion may also result in severe steering column displacements and rotation. Knowledge of both responses is critical for designing an efficient vehicle front end that will respond well in crash. The intrusion has an effect on deciding the car front end length, while the column movements have an effect on the driver dummy's response. For reasons of developing efficiency and safety in vehicles and due to lack of published research, studies were conducted to understand the nature of the intrusion phenomenon as well as the mechanics of the steering column movement in the presence of intrusion.

This paper describes an experimental investigation on intrusion and steering column movements. The different factors causing intrusion modes are identified, and the contributions of these factors to the movement of the steering column are determined. A front part of a midsize front-wheel drive vehicle was used as the design for test structures. A crusher testing approach was used in accordance with a comprehensive test matrix that included eight different tests. In each test the dashpanel of the test structure was crushed at single or multiple points to generate a different intrusion mode, thus simulating the sources of motion that occurs in frontal barrier tests. Intrusion as well as movements of the steering column were among the significant data collected during these tests. The paper presents the results as well as comprehensive implications of the findings on evaluating the capacity of the vehicle structure and steering column support for resisting intrusion.

INTRODUCTION

During severe frontal barrier impact testing, some vehicles exhibit significant upward displacement and rotation of the steering column relative to the motion of the passenger compartment. Examples of the types of severe vehicles' frontal impact tests are full barrier impact tests at speeds higher than 56 kph and offset impact tests at speeds of 56-64 kph. This upward column displacement is a result of the increased intrusion into the vehicle's passenger compartment. At this point, the term intrusion may be inadequate to explain how it affects the movement of the column. But it is easy to show that during these tests there is an increase of demand on the vehicle's front structure to absorb more energy and consequently the vehicle requires a longer crush distance to stop. That increase in crush translates into added deformation of the passenger compartment structure and the dashpanel, toe-board, and cowl. It is the deformation of these closure panels, mainly by primary structural parts at the passenger compartment, that is referred to as intrusion in this paper. In addition, how this intrusion influences the upward displacement of the steering column will be investigated.

The above definition of intrusion is quite different from what was published in the literature. For example, the term intrusion has been used in References [1][1] and [2] to describe the displacements of the steering column inside the vehicle. In another reference [3], the authors indicated that intrusion is a response (primarily due to powertrain) that is responsible for moving interior surface, such as knee bolsters as well as the steering column, toward the dummy driver. Yet, in a different paper, the author used intrusion implicitly to refer to the deformation of the dashboard while studying the effect of steering column movement on the occupant [4]. But regardless of how the term intrusion was used in the past, it involved negative implication, which is not totally true. The front closure panels of the passenger compartment may have some deformation without an effect on the column movement, as will be shown later in this paper.

Besides the above mentioned severe impact testing, excessive intrusion and upward displacement of steering column may be also observed during the development of vehicles for standard impact testing. For example, a steering column may show excessive upward movement when crash testing a vehicle that is fitted with an alternative larger size powertrain or when testing a vehicle with heavier optional equipment before properly engineering the vehicle's energy absorption capabilities.

Although vertical displacement of the steering column is not restricted by FMVSS 204 or 208 (Federal Motor Vehicle Safety Standard), for years most vehicle safety engineers preferred designing vehicles with some limits on the upward displacement of the steering column during frontal impact testing. Some of the reasons are: (1) to allow the steering column to collapse axially when it is impacted by the torso of driver's dummy, (2) to

1. Numbers in parentheses designate references at end of paper.

provide a stable base for the airbag as it restraints the impacting dummy's head and chest, and (3) to decrease the possibility that the dummy's neck or head will be caught by a moving steering wheel rim. In fact, recognizing these benefits, the proposed European regulation on offset barrier testing of vehicles has a requirement to limit the upward displacement to a maximum of 80 mm [5].

To manage the upward movement of the steering column, vehicle engineers devised different approaches. One approach was to design the various components of the steering system with improved capacity in resisting the modes of intrusions into the passenger compartment. In other words, they focused on improving the component's strength to withstand the loads from the deforming dashpanel and primary structural members at the front section of the passenger compartment. Toward that goal, component's engineers have been experimenting with several new steering system designs and innovations including improved steering columns, collapsible steering drive-shaft, and modified column support to the vehicle structure.

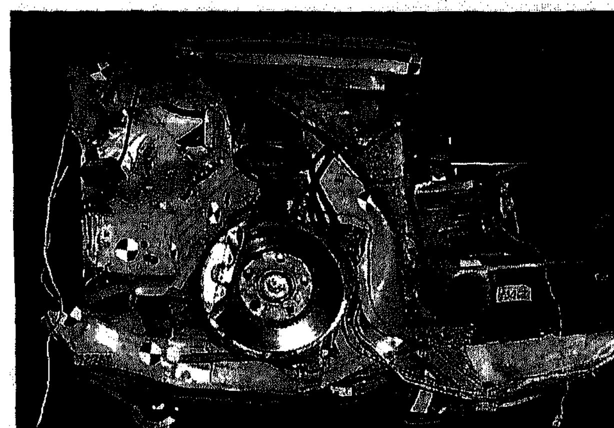
Another approach that was used to manage the upward displacement of the steering column involved the fundamental design of the front structure and the crash energy management of the vehicle front end system. This approach, however, is difficult and involves the complex behavior of the primary structural members and their influence on the kinematics of the steering column during vehicle frontal crashes. Consequently, for the purpose of implementing this approach and providing design guidance to the vehicle crash engineers, basic information on and understanding of the interrelationship between the deformation of the primary structural members, the dashpanel, and steering system are required. Toward this goal and because of the lack of information about this topic in the research literature, an experimental study was conducted in which several vehicle's front ends were crushed by using Ford Energy Management System (crusher) methodology [6].

In addition to providing basic information that fills up the void in the intrusion phenomenon, one of the objectives of the study was to develop a methodology for identifying critical behavior of the structure and determining the strength of the steering system's design to resist dashpanel intrusion. Furthermore, it was of extreme importance to determine which mode of intrusion has the most significant effect on the upward displacement of the steering column.

Remember, this study was conducted for only one type of vehicle design: A mid-size vehicle that was driven at the front wheels by a powertrain, which was installed along the transverse direction of the vehicle (as opposed to a rear-wheel drive vehicle type with a powertrain installed along the longitudinal direction of the vehicle). The body design of this vehicle was a unitized construction type. The powertrain was fully mounted on a longitudinal type subframe that was bolted to the body structural members. Also in this vehicle, the steering column was supported by a bracket which was bolted to the cowl structure.

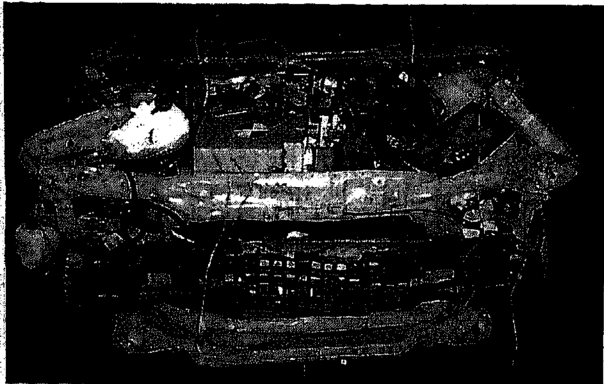
For the experimental study, a test structure, which consisted of a vehicle body equipped with few components (including the cowl-mounted steering column and surrounding parts), was crushed from the front at different places to simulate different types of intrusion. The tested structure was limited to the structure near the dashpanel and front part of the passenger compartment. The test structures were extensively instrumented to measure loads and displacements while testing, particularly the intrusion and steering column displacements.

This report describes the experimental study of the intrusion modes into the passenger compartment. The results showing the effect of each of these modes on the upward movement of the steering column are explained. Then, the intrusion mode that is most critical to column movement is discussed. These sections are followed by an example depicting the implication of the findings in developing a simplified experimental procedure that can be easily extended into analytical methods for assisting vehicle design. But first, a section is presented explaining the intrusion modes during vehicle frontal impact tests.



INTRUSION MODES

The way the primary front structure near the passenger compartment, and the panels such as dashpanel, cowl top and front floor deform during crash influences the intrusion mode of that vehicle. In fact, the vehicle's intrusion mode during frontal impact is highly dependent on the structural design concept of that vehicle. Therefore, to determine the possible intrusion modes in the vehicle type used in this study, films, photos and test data of crashed vehicles were reviewed and resulted in the following findings:



DEFORMATION AND COLLAPSE MODE OF PRIMARY STRUCTURE - A review of photos of a crashed vehicle (Figure 1a and Figure 1b below) shows that the mode of intrusion into the front space of the passenger compartment is influenced by the relative displacement of powertrain and deformation of primary structural members as follows:

- Crushing of powertrain crush into dashpanel and toe-board
- Bending of the aft-rail
- Crushing of the subframe into dash crossmember
- Bending of the sled runner
- Bending of the shotgun, twisting of the shocktower, and pushing at the cowl.

The final intrusion profile after impact is a result of the combined effects of crushing the above members. This profile was easily determined by implementing an intrusion mapping technique.

a: Side view showing collapse of aft-rail, subframe and sled runner

b: Front view showing collapse of shotgun

Figure 1: Collapse mode of the primary structural members after frontal barrier impact test

INTRUSION PROFILES OF CRASHED VEHICLES- As a way to determine the intrusion as well as the collapse mode of the vehicle structure near the dashpanel of a crashed vehicle, mapping plots are constructed using techniques developed at Ford. By these techniques, the deformed surface of the dashpanel and final position of the powertrain relative to the dashpanel are plotted and superimposed on the original position. Also shown on those plots are the initial and final relative positions of the steering column, brake pedal bracket, and other components that change the driver's space environment. Examples of these plots are shown in Figure 2.

The intrusion maps (also referred to as intrusion profiles) depict very detailed and reasonably accurate information about the behavior of the structure and components during crash. This high quality results are achieved because the plots are constructed by: (1) compiling information from design layout drawings, (2) measuring positions of several points on the tested vehicle before and after crash, (3) analyzing the motion of several points marked by targets using the crashed films, and (4) analyzing the kinematics of some selected points where accelerations were measured during crash. Intrusion profile plots show a section taken in a vertical plane that passes through the driver's center, front passenger's center or the vehicle's center.

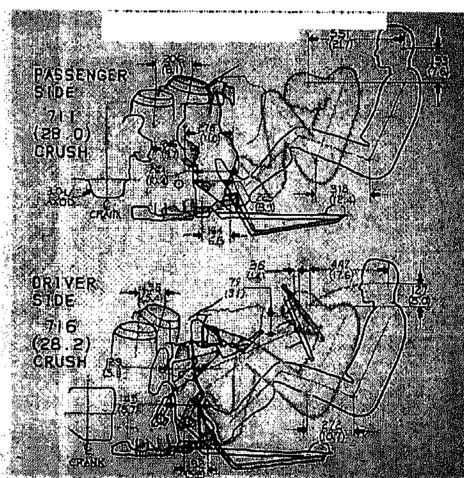


Figure 2: Intrusion profile and relative position of powertrain, shock-tower, steering column after frontal barrier impact test of a midsize front wheel drive vehicle

INTRUSION MODES AND STEERING COLUMN MOVEMENTS - By examining the intrusion profile plots shown in Figure 2, it can be easily seen that the deformed structures and panels move whatever components are mounted on them. For example, the brake pedal bracket moves as a rigid body and follows the motion of the dashpanel as it deforms. Similarly, when the cowl moves, the steering column support that is attached to it also moves. Profile plots also reveal that gaps between different components packaged under the instrument's panel and near the lower end of the column (the end that is near the dashpanel) may be closed and the components may be pushed by intrusion forces.

In fact, to determine the components that may be stacked between the dashpanel and steering column which can force it to move during intrusion, the packaging layout drawings of the vehicle interior and exterior near the steering column were examined. A compiled list of these components is shown in Table 1.

Table 1: List of component's packages that may offset steering column movement during vehicle frontal crashes

Item	Description
1	steering column and wheel installed on the vehicle structure
2	steering shaft
3	steering gear installed in the vehicle
4	brake pedal and bracket installed in the vehicle
5	other rigid components, which were not listed as secondary contributors to column movement are listed here because they influence the intrusion at cowl and upper dashpanel: windshield wiper motors, brake booster &housing, air conditioning evaporator core (inside instrument panel)

INTRUSION EXPERIMENT

The above brief introduction of the intrusion phenomenon and the column movements during frontal vehicle crashes is used as a background to explain the experimental study presented in this paper. The parameters of the experiment and the structural testing are described next.

FACTORS CAUSING STEERING COLUMN MOVEMENTS - A list of the factors that could have an effect on the movement of the steering column inside the vehicle was easily compiled from the background information given above such as: (1) the factors which may influence the shape of the intrusion mode while crushing the vehicle primary structure during frontal barrier impacts, and (2) the effects of the intrusion mode on the stacking of the components near the steering column and make it move during crash. Figure 3 shows this list of factors. The figure shows two major groups. The first group is on the outside of the ellipse and involves the vehicle's primary front structure and powertrain. Therefore they are referred in this report as primary factors or intrusion factors since they influence the intrusion mode shape in the vehicle.

The second group in the figure is given on inner ellipse, and the factors in this group are referred to as secondary factors. Some of these factors must exist to cause steering column

movement, but they are originally driven by the primary factors. Of course, various combinations and interactions between the various factors are additional possible causes of steering column movement during frontal crashes.

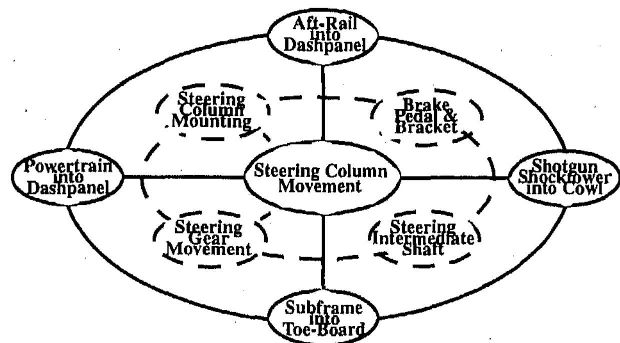

Figure 3: Primary and secondary factors causing steering column movement during vehicle frontal crashes

TEST MATRIX - Since the major objective of this study is to determine the effect of the different intrusion modes on the upward movement of the steering column, only the primary factors identified earlier were investigated. However, to actually see the effects on the column, all the secondary factors must be present. In other words, all the components listed in Table 1 were mounted on the tested structures.

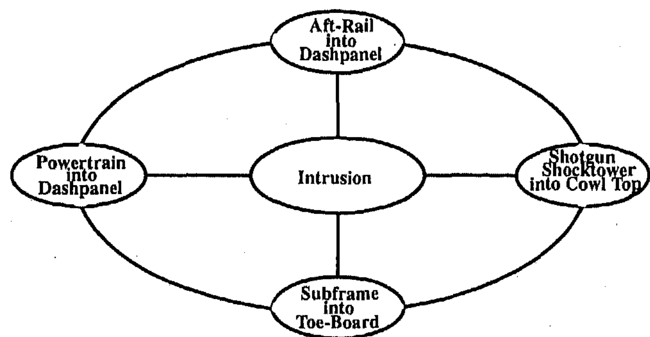

Figure 4a: Primary factors causing intrusion into passenger compartment front closure panels

Primary (Single) Factors	Combined Two Factors	Combined Three Factors
1 Rail into Dashpanel	1 + 2 Rail into Dashpanel + Subframe into Toe-Board	1 + 2 + 3 Complete aft-frame Structural System
2 Subframe into Toe-Board	1 + 3 Rail into Dashpanel + Shotgun/Shock into Cowl	
3 Shotgun/Shock Tower into Cowl	2 + 4 Subframe into Toe-Board + Powertrain into Dashpanel	
4 Powertrain into Dashpanel		

Figure 4b: Matrix of intrusion tests

Four primary (or main) factors were selected in order to study their effects separately. These are shown in Figure 4a and are also shown on Figure 4b as single factors. The interactions between these primary factors were selected by conducting tests which have the combined effects of two factors. Three cases were studied and shown in Figure4b (combined two factors). Finally, a test case was set up to study the effects of combining three factors, also shown in Figure 4b.

RESPONSES PLANNED FOR ANALYSIS - To analyze the effects of the primary factors mentioned above, the amount of intrusion in every test mode and the resulting steering column upward movement would constitute the most important responses to be measured during testing. However, for the needed understanding of the intrusion phenomenon as well as the mechanics of the steering column movement during intrusion, several key responses were also measured for additional analysis. These responses are discussed further in the experiment's instrumentation section which is discussed next.

TEST STRUCTURE- Literally, a passenger compartment was cut off a complete car. The body was cut off at the center of the shocktower from the front, and slightly rear of the B-pillar from the back end. Parts that had no effect on the test were removed. But primarily, the compartment left with the needed components for the test. These components are the parts listed in Table I. Additional modifications were made to this structure as described at the section on preparation of test structure and intrusion testing.

INSTRUMENTATION- Several unique measurements were taken while conducting the intrusion tests. Highlights of the more important ones include:

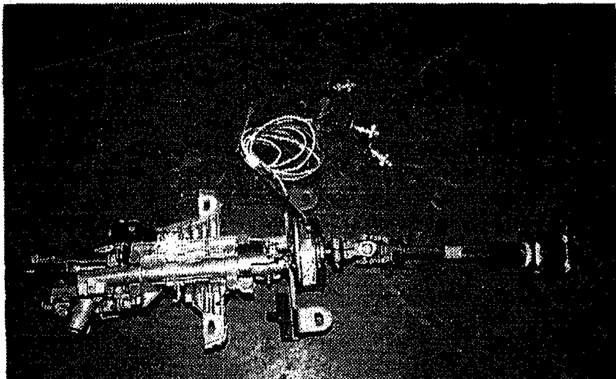

Figure 5: Loadcell at lower end of steering column to measure intrusion loads on steering column support system

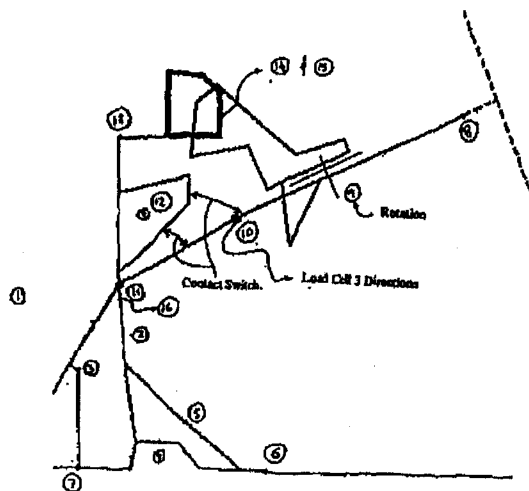

Figure 6: Instrumentation for intrusion tests

1. Steering Column Loads from Intrusion: One of the clever instrumentations used in the intrusion tests was the measurement of the loads imposed by the intrusion on the lower (also forward) end of the steering column (marked #10 in Figure 6). A 3-axis load cell, specially designed to be short, was attached (as shown in Figure 5), to the lower end of a modified steering column. The column modifications involved simple adjustments in the length of the column shaft to maintain the clearance space with the brake pedal bracket. Also, to signal the contact of the parts located under the instrument panel as they move with the dashpanel, an electrical switch was used (Figure 6). The signal from the switch helps in determining the intrusion that can occur without any effect on the column. The measured loads proved, as will be shown later, to be invaluable in explaining the interaction between the intrusion at the deformed dash panel and the moving steering column.

2. Steering Column's Displacements & Rotations - For capturing the kinematics of the column during crush, both ends (points marked # 8 and #10 in Figure 6) were instrumented by string pots to measure displacements in at least two directions. Additionally, an inclinometer was used as a check on the column rotation (point #9 in Figure 6) in a vertical plane.

3. Stack-up Between Dashpanel and Column - To monitor the progress of the contact between components and their stackup near the lower end of the column, string pots were used on some components under the cowl. These components were: brake pedal bracket, steering intermediate shaft, and steering gear. The measurements were taken at points marked by numbers 10, 11, 12, and 3 in Figure 6.

4. Intrusion Profile - To analyze the intrusion mode during crush, string pots were used at the cowl, toe-board, front floor, and dashpanel to record the deformation history. Measurements were taken at several points on these parts as shown in Figure 6. The results will allow plotting the intrusion profile (or mode) for each intrusion test.

5. Load- Crush Distance of Primary Structure - While conducting the crush tests, load cells were used to measure structural crush loads in addition to the crush distance (Figure 7). These load measurements were necessary to monitor the collapse of the structural members. The significance of knowing the collapse load is that its occurrence indicates the phase at which a large displacement and possibly of tear and fracture occurred in the test structure.

PREPARATION OF TEST STRUCTURE AND INTRUSION TESTING - At least one or more tests were conducted for each of the cases listed in the test matrix table shown in Figure 4b. Before each test, the structure in front of the dashpanel was modified by cutting the parts that are not used for loading. For example, in the case of crushing the aft-rail, the part of the apron, shotgun, shocktower and subframe were removed ahead the dashpanel's plane. This leaves only a small part of the structural member (406 mm to 508mm long) protruding at the dashpanel (see figure 7a). A steel tubular structure, approximately 1.5 meter long, was attached at one end of the member where the crush is desired. A steel end plate, 18 mm thick, was welded at the front of the member for that purpose. The other end of the loading structure was set to contact the crusher loading ram. The loading ram was equipped with load cells for measuring the intrusion loads during crush. Schematic of the set up for the four tests on primary (single) intrusion factors are shown in Figure 7a to 10. Additional schematic of set ups for tests on the two and three combined factors are shown in Figure 11 and 12. Actual photos of these test setups are given in Appendix A for reference.

In addition to modifying the front of the partial passenger compartment for proper loading, some welding was performed to restrain the body from moving during crush (Figure 7b). This was achieved by welding the rear edge of roof rails, roof panels, rockers, and floor panels to the test fixture. Also welded to the test fixture were plates that restrain the rocker at hinge pillar from moving. The hinge pillar, too, was held from moving rearward by welding two tubes, as shown in Figure 7b.

The intrusion tests were conducted by moving the ram toward the stationary test structure at a rate of approximately 50 mm per minute. The ram was stopped every two inches for observing the intrusion profile, the contact between stacked up components, the steering column, as well as for taking photographs. Another important reason for frequently stopping the test was to observe the crush mode of the primary structural member being crushed. To ensure a satisfactory test, this mode must be like the mode occurring in the actual crash test of the vehicle under investigation. To illustrate this point, the collapse mode of the shotgun during intrusion testing shown in Figure 13 was triggered to be the same as the mode shown in Figure 1b, the mode occurring in the vehicle crash test. A similar example can also be shown for the collapse mode of the sledrunner, particularly in the case of intrusion by subframe loading.

All test data from instruments were recorded electronically and stored on disc files for processing after the test. However, while running the test, data from four channels (crush loads, crush distance, and steering column displacements) were monitored on a screen to observe any unusual behavior and ensure satisfactory progression of the test.

Most of the conducted tests were stopped between 305 mm to 406 mm of intrusion or of deformation at the dashpanel, depending on the extent of damage or tear occurring at the thin walled panels and the spotwelds. Photographs were taken of the test structure and column before and after completion of the test. These photographs are shown in Appendix-A.

TEST RESULTS

The data collected from more than ten intrusion tests conducted during the course of this investigation were used to calculate the effects of the different factors on the upward movement of the steering column as follows:

EFFECT OF PRIMARY FACTORS -Results of the intrusion tests conducted to study the effects of the primary (single) factors (listed in Figure 4b, and shown in Figures 7 to 10) were analyzed. The various displacements as well as load data measured during each test were cross plotted or combined in a way to determine any unusual or strong effects. Also, as a part of this analysis, some responses were cross plotted against a displacement of a common reference point as a way to normalize the data. For instance, the results on the steering column movements from various tests were plotted against the corresponding displacement of dashpanel near rail (point #2 in Figure 6) as a common variable. In addition, the results of these tests on the displacement of closure panels (dashpanel, cowl top, toe-board, front floor), were used to plot the deformation mode.

In this section, some results from only the structural intrusion tests will be presented. As for the powertrain intrusion test, no data will be provided because of the difficulties which were found in controlling its motion as well as achieving a representative dashpanel deformation while testing. Explanation is given later on, and an alternative test on powertrain intrusion is described under the section of combined factors.

Structural Intrusion Tests -In each of the three intrusion tests on the structural primary factors, the steering column moved differently. During the aft-rail crush into the dashpanel, the column was steadily rotating as well as moving upward while crushing the aft-rail into the dashpanel. The appreciable sensitivity in the column movement for each small increment of aft-rail crush was a classic cause and effect behavior, especially after the first few inches of crush. Figure 15 shows clearly this effect in that the steering column was almost vertical after 406 mm of aft-rail crush.

Contrasted with this excessive upward displacement and rotation noted above was the downward movement of the column while crushing the shotgun and shocktower into the cowl and upper dashpanel (Figure 9). Yet, there was another behavior of the column that fell between the extreme upward and downward motions. The limited and slow upward movement of the steering column were the results of the intrusion test in which the subframe was crushed into the toe-board. All these three results are shown in Figure 14. The vertical movements of the steering column were plotted against the longitudinal displacements measured at a common point in the three tests, a point at the dashpanel near the joint with aft-rail. It may be noted from Figure 14 that a small rearward displacement of the dashpanel at the rail is an indication of the weak effect between that particular intrusion factor and the middle area of the dashpanel.

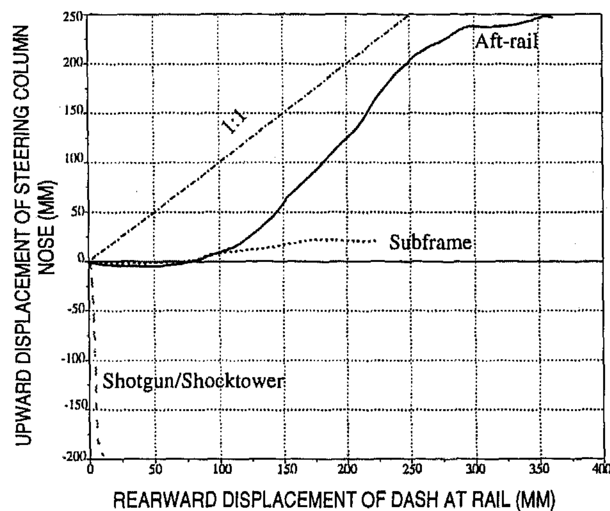

Figure 14: Effect of primary factors on the upward displacement of steering column

The crush mode (as the intrusion profile) for each of these three tests was plotted from the displacement results. The deformation (or mode) plots were found to be very effective in depicting the main characteristics of the behavior, as well as in explaining the intrusion effects on the steering column movements. Beginning with the aft-rail intrusion test, the intrusion mode is shown in Figure 16 after 200 mm and 400 mm of crush. Additional profile from that test was plotted from the results after 406 mm (Figure 17) illustrating the behavior of the column at an extreme intrusion condition. The important feature in this deformation mode is the membrane effect induced at the parts of the dashpanel alone and below the line of crush. The panel membrane forces pulled down the cowl from the top and pulled up the cross member reinforcing the toe-board from the bottom.

The next intrusion mode (shown in Figure 18) illustrated the effect of crushing the shotgun/shocktower into the cowl and upper dashpanel. This mode is distinguished by bending the upper dashpanel and cowl above the joint of aft-rail. It was observed from the shape of this deformation that there was not adequate stiffness in the upper cowl structure to pull the dashpanel below the joint with the aft-rail. The rearward displacement of the dashpanel at rail in this test was very small.

Continuing with the results on intrusion modes, the intrusion profile due to crushing the subframe into the toe-board was plotted and given in Figure 19. The effect of this primary factor was weak as is evident by the position of the steering column after 356 mm. Again the structural stiffness (in this case the toe-board cross member and underbody reinforcement sled runner), was not high enough to produce the necessary forces to push the column. The upward displacement of the steering column and the rearward displacement of the dashpanel at rail were small, as shown in Figure 14.

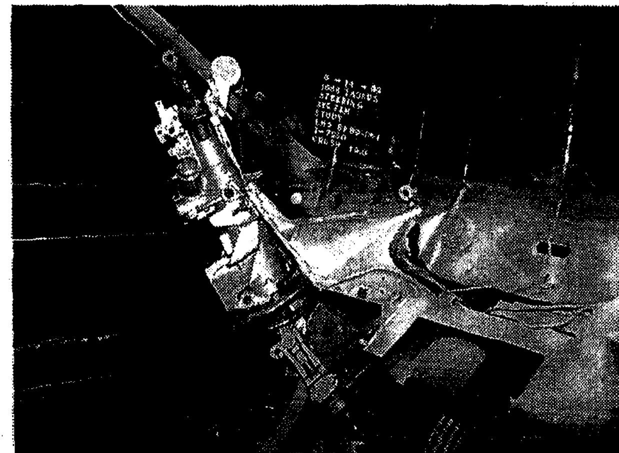

Figure 15: Excessive column upward displacement and rotation shown by the final position after 406 mm of crush of aft-rail into dash-panel

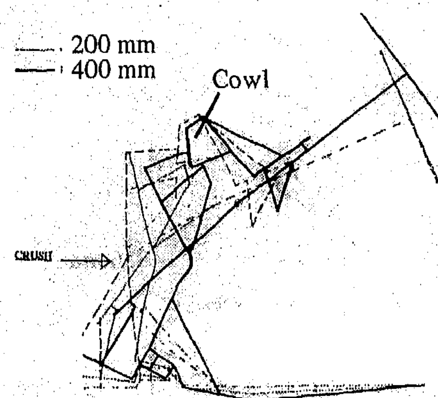

Figure 16: Deformation made after 100 mm and 200 mm of at-rail crush into the dashpanel intrusion test

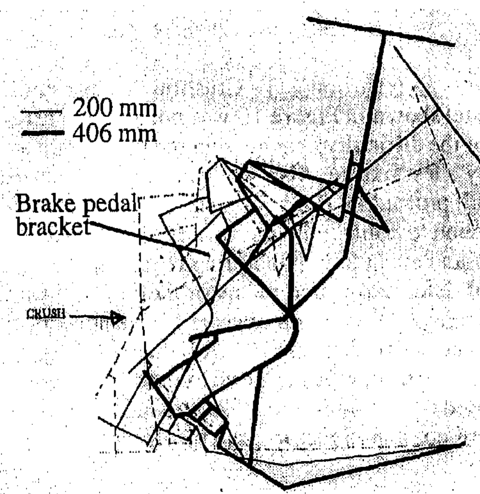

Figure 17: Intrusion profile and column position after 200 mm and 406 mm of aft-rail crush into the dashpanel intrusion test

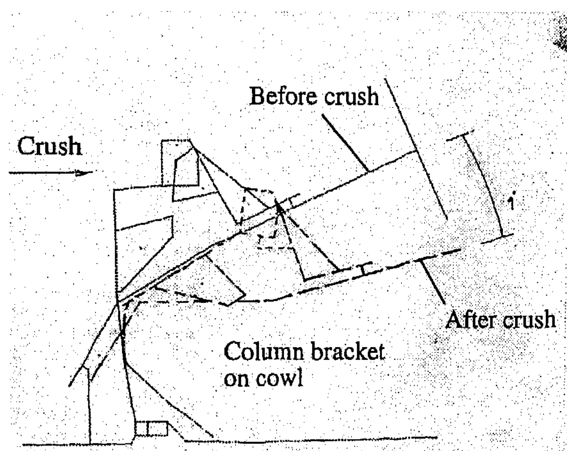

Figure 18: Effect of cowl and upper dashpanel intrusion on the steering column movement

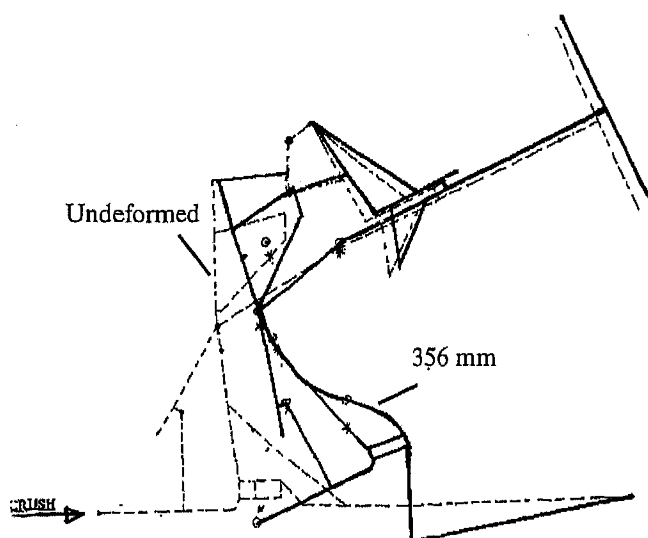

Figure 19: Deformation mode after 256 mm of subframe crush into toe-board intrusion test

Powertrain Intrusion test - Crushing the powertrain into the dashpanel shown in Figure 10 was not acceptable test set up because of the difficulty in achieving the powertrain motion by using only a test fixture. Also while conducting that test, some of the small protruding rigid parts on the engine and transmission were found to contact the dashpanel surface and caused local denting and eventually puncturing that surface. Because the mode of deformation and the tearing of the dashpanel were different from what has been observed in vehicle crash tests, this test was considered unrealistic. A better way of showing the effect of powertrain crush relative to dash is to push on it as it is positioned on the subframe. This alternative is discussed under effects of combined factors, and the set up is shown in Figure 21.

EFFECT OF COMBINED FACTORS - The results of intrusion tests to study the effects of two factors and three factors were analyzed similar to the primary (single) factor analysis. The effects are shown in Figure 20. It is very obvious from this figure that the strong effect of the primary aft-rail intrusion factor on the upward displacement of the steering column was also dominant in the combined effects that involve the aft-rail.

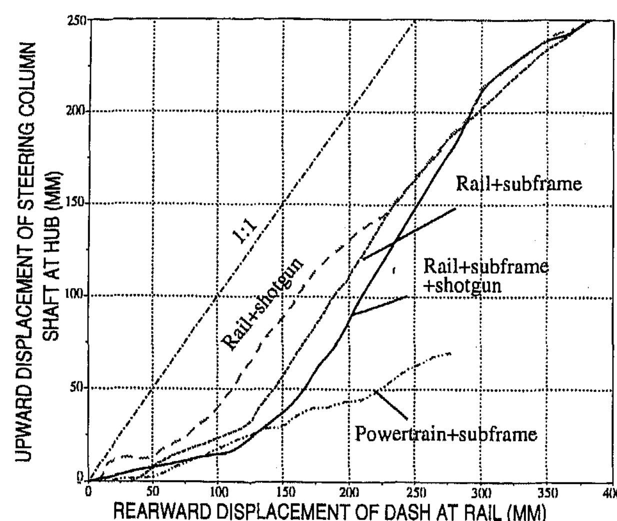

Figure 20: Effect of combined factors of intrusion on the upward displacement of steering column

However, the effect of crushing the powertrain which was mounted on the subframe, was not as strong as the structural intrusion on the upward displacement of the steering column (Figure 20). Appendix A shows the powertrain position relative to the dashpanel before and after crash. A significant rearward displacement of the dashpanel at rail, 275 mm but resulted only in a 70 mm upward displacement of the column (see Figure 20).

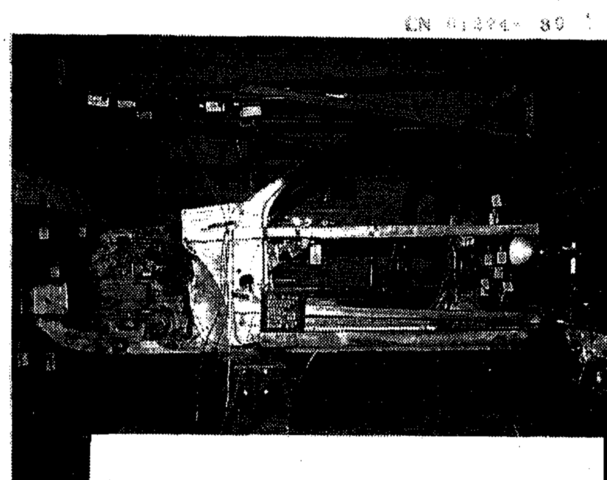

Figure 21: Powertrain intrusion into dashpanel new test setup

DISCUSSION

DOMINANT INTRUSION MODE - The intrusion tests discussed above showed very interesting and surprising results. For example, by investigating the effects of the primary factors, crushing at the aft-rail revealed a very strong effect on the upward displacement of the steering column. This was a surprise finding because of two reasons. First, this finding disproves the common perception among vehicle safety engineers that the

powertrain is the main reason of intrusion, in that it pushes on the dashpanel, and hence becomes the principal driver of the steering column movement. Figure 20 shows the weak effect of powertrain crush on the upward column displacement compared with aft-rail crush. Second, the strong effect when crushing at the aft-rail shows on Figure 14. The finding is a surprise because by crushing only at the aft-rail, the response of the steering column was magnified by the resulting intrusion mode. This finding was evidenced by the steering column's displacement results in this single case, which exceeded those occurred when crushing at all the structural factors simultaneously (Figure 20). In fact, when combined with other factors, the aft- rail crush dominated and overpowered the other effects (also shown on Figure 20).

The strong effect of the intrusion mode which was generated during aft-rail crush can be explained by a closer examination of the test results. Specifically, the mechanics of loading the steering column was analyzed to the extent of reaching a large displacement and loss of stability stage. Our methodology involved investigating the roll of the components' stack-up near the lower end of the column and its effect on the nature of loads as well as displacements at that end of the column. With this understanding as a background, the loads and deflections at the lower end of the column measured while testing with the different primary intrusion modes are presented and compared.

MECHANICS OF LOADING THE STEERING COLUMN DURING AFT-RAIL CRUSH - The reasons behind this strong effect can be explained by first investigating the effect of the intrusion mode on the stack up near the lower end of the column, i.e, secondary factor.

Roll of Secondary Factors on Loading the Column During Intrusion - To determine the effect of the secondary factors on the way the steering column is loaded during the aft- rail intrusion test, the intrusion profile plots shown on Figure 17 from the intrusion test and Figure 2 from the actual vehicle crash test are examined. In both plots, the position of the brake pedal bracket is rotated and moved as the upper part of the dashpanel rotates and moves. The similarity of the motion in both the vehicle crash test and crusher test indicates the validity of the simulation by the crusher method. This motion of the brake pedal bracket resulted in closing any gap that existed between it and the lower end of the steering column. Furthermore, as the crush and intrusion continued the brake pedal bracket and the steering intermediate shaft contacted and pushed the end of the column rearward. The events after the load on the column continued to build-up are divided into four stages as described below in this report. The photograph in Figure 22a shows good view of the brake pedal bracket pushed against the lower end of the steering column.

To validate the critical effect of the brake pedal bracket and the steering intermediate shaft on the upward displacement of the steering column, an aft-rail intrusion test was conducted after removing these two parts. The result of that test was compared with the results of a similar test before removing the parts and shown in Figure 22b. The figure shows a negligible upward displacement of the column after brake pedal bracket and the steering intermediate shaft were removed a definite proof of their effect in loading the column during an aft-rail intrusion test.

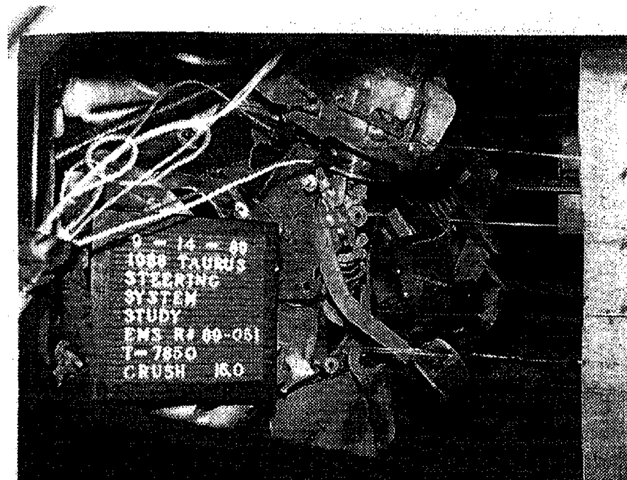

Figure 22a: The brake pedal bracket is pushed against the lower end of the steering column during an aft-rail intrusion test - shown at 406 mm crush

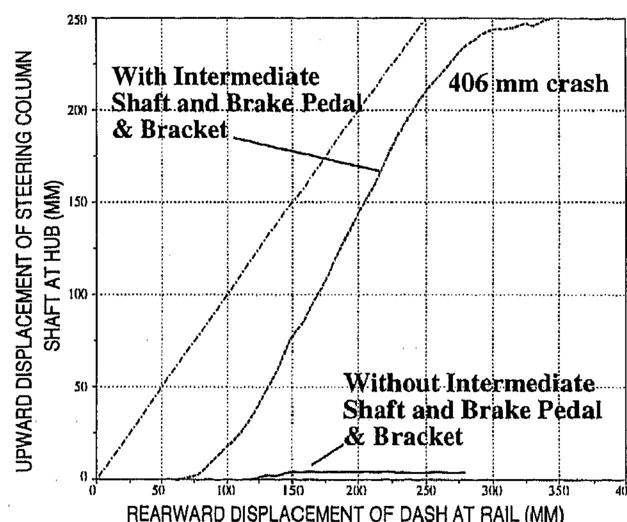

Figure 22b: Effect of brake pedal bracket on the upward column movement of the steering column

Stages of Loading Steering Column during Intrusion - We then examined the load deflection at the lower end of the column and identified the different stages in column loading. Referring to Figure 23, the loading and movement of the steering column can be divided into four stages described as follows:

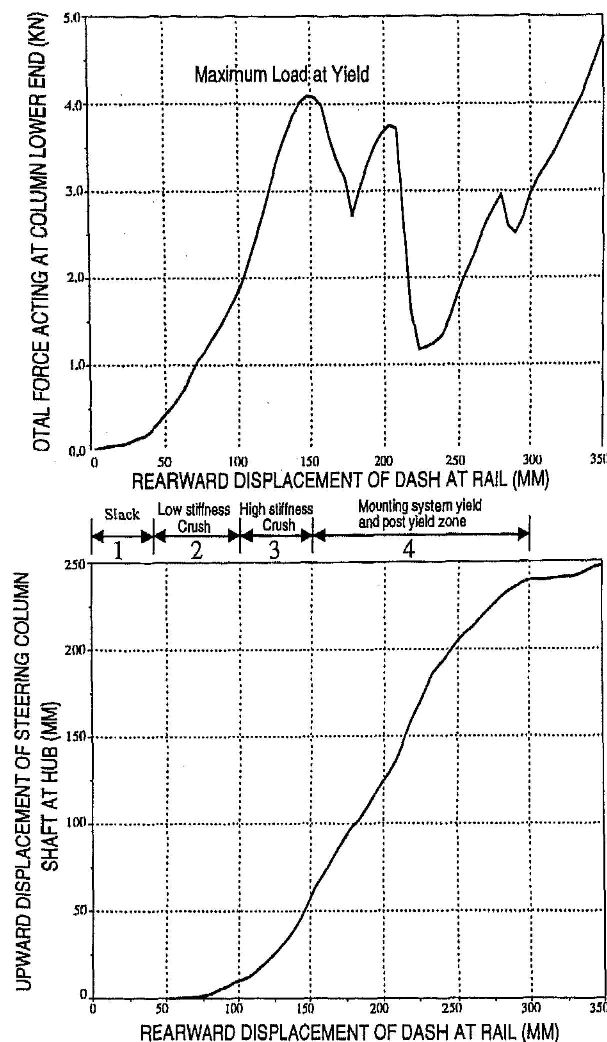

Figure 23: Different stages of column loading during crush

1. Slack- It is the rearward displacement of the dashpanel at rail during which the gaps or clearances in the package under the instrument panel are closed. During this motion there are no forces developed at the lower end of the column to cause any movement. For this investigation, the tested design showed 38 mm of slack.

2. Low stiffness crush - During this stage, as the dashpanel moves rearward from 38 mm to 89 mm, contact and local crush take place between soft edges of the components packaged between the dash and lower end of column. The load on the column builds up gradually (up to 1.33 KN), but the magnitude is still too small to cause any noticeable movement of the column.

3. High stiffness crush to peak load - Crushing the dashpanel from 89 mm to 152 mm causes the load at the lower end of the column to increase rapidly to 4.89 KN lbs with small increase in upward column displacement (0 to 50 mm)

4. Post peak load and large column displacement - crushing the dashpanel beyond 152 mm causes the column to move upward at a rate of approximately one-to-one.

EFFECT OF INTRUSION FACTORS ON THE STEERING COLUMN LOADS - The loads and displacements at the lower end of the column due to these different intrusion factors were examined and the results are given in Table 2. Shear loads are given in the table to show their effect on the moment acting on the support structure. A downward shear has the effect of adding the bending moment from the shear to the bending from the axial compression, while an upward shear has the effecting of substracting the bending due to shear from the bending due to the axial compression. The results clearly indicate that intrusion mode by the aft-rail has the capacity to load the lower end of steering column by a high load that exceeded the load capacity of the support system and made it yield. However, in the other cases, the loads generated at the lower end of the column were not high enough to weaken the support and move into the large displacement stage.

Table 2: Effect of intrusion factors on the resultant loads measured at the lower end of the steering column

Intrusion Factor	Initial peak load - KN		
	Axial	Shear[a]	Resultant[b]
aft-rail	4.67	1.82	5.01
powertrain & subframe	3.38	1.67	3.77
shotgun & shocktower	1.6	1.69	2.33

SUMMARY AND IMPORTANT FINDINGS

Based on these intrusion tests conducted on a partial passenger compartment structure of a medium size front wheel drive vehicle equipped with a cowl bracket type design to support the steering, the significant findings are summarized as follows:

1. The intrusion caused by crushing the aft-rail into the dashpanel had the strongest effect on the upward displacement of the steering column. Because of the stiffness and strength of the combined stretched dashpanel and aft-rail, this intrusion mode had the capacity to force the brake pedal bracket and steering intermediate shaft and consequently pushed the column to the point of yielding its support.

2. The intrusion caused by crushing a powertrain mounted on the subframe proved to have a significantly weaker effect than the effect of aft-rail intrusion on the upward displacement of the steering column.

3. The intrusion caused by simultaneously crushing at the aft-rail and at another primary structure (case of combined two actors shown in Figure 4b) was found to have stronger effect on the upward displacement of the steering column than the effect of the intrusion caused by the combined three structural factors.

4. The column support structure and the components packaged

under the cowl (near the lower end of the steering column) are critical factors in influencing the effects of intrusion.

APPLICATION EXAMPLE

To demonstrate the benefits and power of the key finding described above, an evaluation of alternative design concepts of steering column support was made. In other words, based on the finding that the intrusion mode from the aft-rail crush into the dashpanel is the most important factor causing the upward displacement and rotation of the steering column, this test case was used as a method for evaluating different designs of column support. These designs were: a cross-car beam that has a uniform cross-section, a cross-car beam that has a variable cross-section, and lastly a cantilevered half-car beam. The hardware representative of these designs was installed in the passenger compartment test structure as shown in Figures 24, 25 and 26 respectively. The base-line cowl mounted steering column system is shown in Figure 27 for reference.

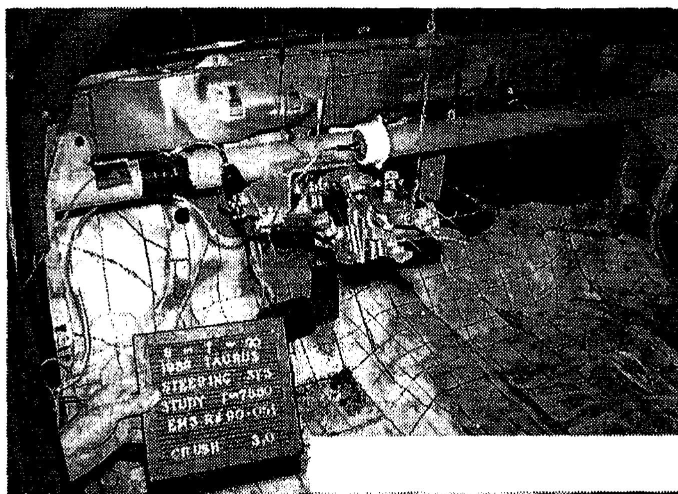

Figure 24: An experimental uniform section cross-car beam column support system

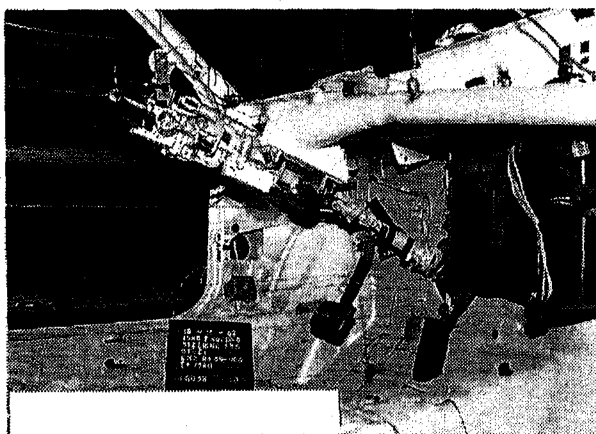

Figure 25: An experimental variable section cross-car beam column support system

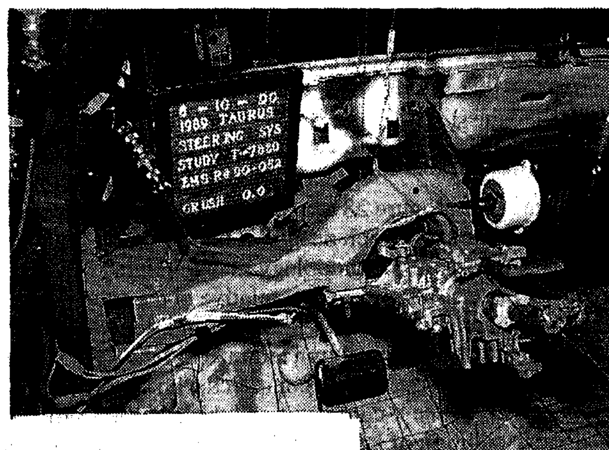

Figure 26: An experimental half-car beam column support system

Figure 27: An experimental cowl mounted column support system

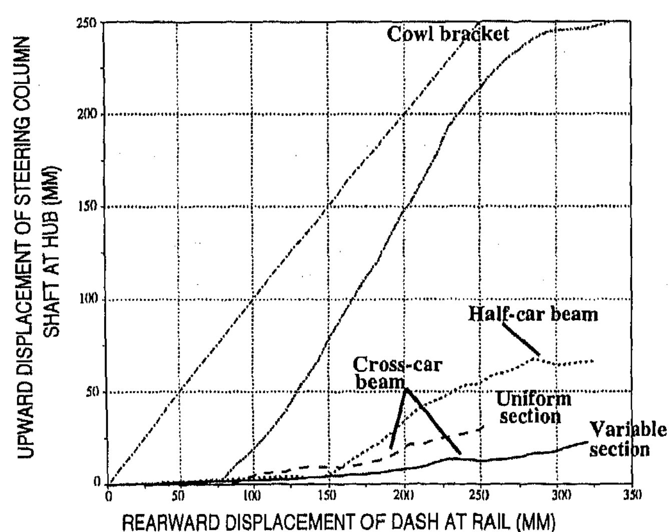

Figure 28: Comparison between the steering column upward displacement during the aft-rail intrusion testing of different column support designs

The test methodology of aft-rail crush into dashpanel was used for each of the three column support designs. The results of these tests showed the improvement in the sensitivity of these designs to the steering column's upward displacement as the intrusion at the dashpanel was increased (Figure 28).

The results in Figure 28 are very informative and provide the needed evaluation of each design. It illustrates the capability of aft-rail intrusion test methodology in highlighting the advantages of alternate column supports relative to the cowl mounted support. For example, at 254 mm of aft-rail longitudinal displacement the steering column mounted on the cowl moves upward approximately 200 mm compared with 12 mm and 38 mm for the cases off the x-car beams and the half-car beams respectively. In addition of knowing the column displacement at the expected intrusion in the vehicle, from the information in Figure 28 a guideline on the intrusion limit at which the column has a negligible upward movement can be established. For example, the alternative column support design can actually allow more intrusion without influencing the upward column displacement. Figure 28 shows that the benefit of the alternative column design can be translated into sustaining additional 100 mm of intrusion in that vehicle without seeing any effect on the upward column displacement. Historically, this consideration, (which can result in shortening the car's front end and making it more efficient) has traditionally not been included in studies that are conducted during early phases of vehicle development.

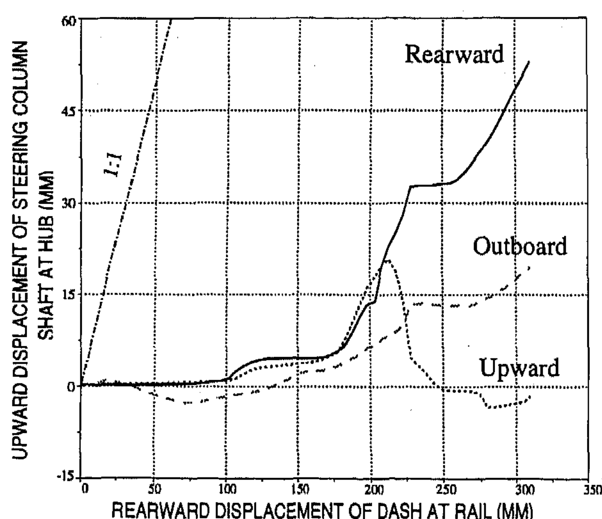

Figure 29: Steering column displacement at hub during aft-rail intrusion test of a partial passenger compartment equipped with cowl bracket column support

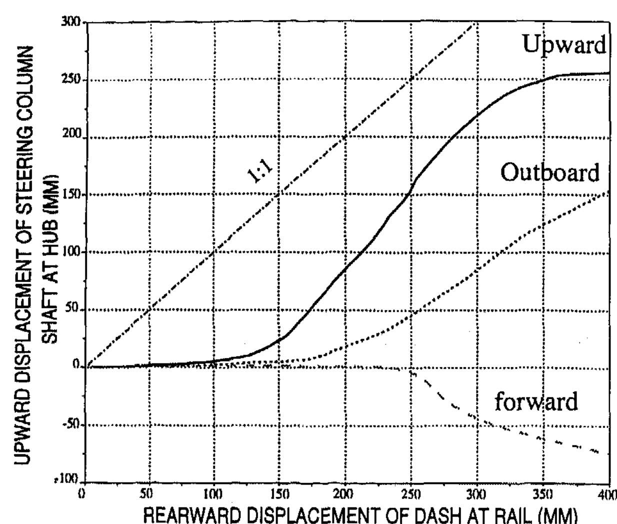

Figure 30: Steering column displacement at hub during aft-rail intrusion test of a partial passenger compartment equipped with cross-car beam support

Although the emphasis in this study is on the upward displacement of the steering column, the aft-rail intrusion testing proved to be valuable in showing the effectiveness of the alternative support designs in containing the movement of the column in other direction. Comparing the results (shown on Figures 29 and 30) of testing a cross-car beam support with the cowl mounted support column is clear indication of significant drop in the column movement in the longitudinal and lateral directions as well as the vertical direction mentioned earlier.

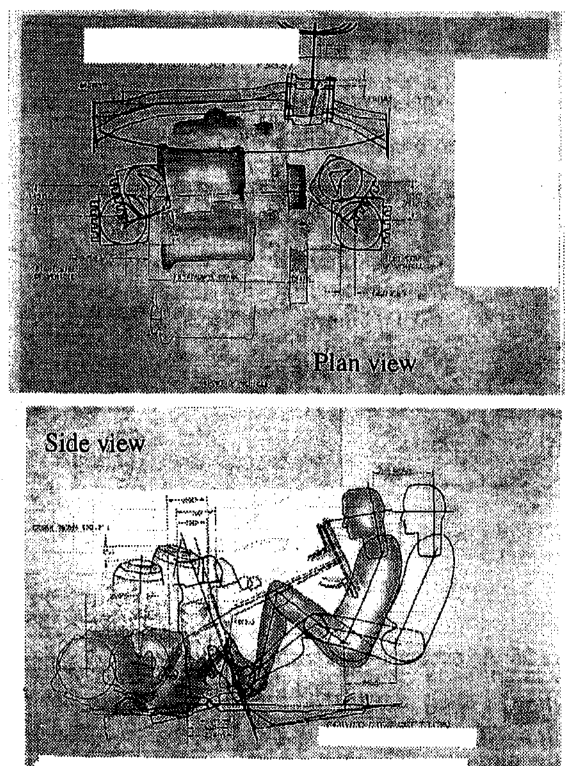

Figure 31: Intrusion profile and steering column displacement after frontal crash test of a midsize vehicle equipped with experimental cross-car beam column support

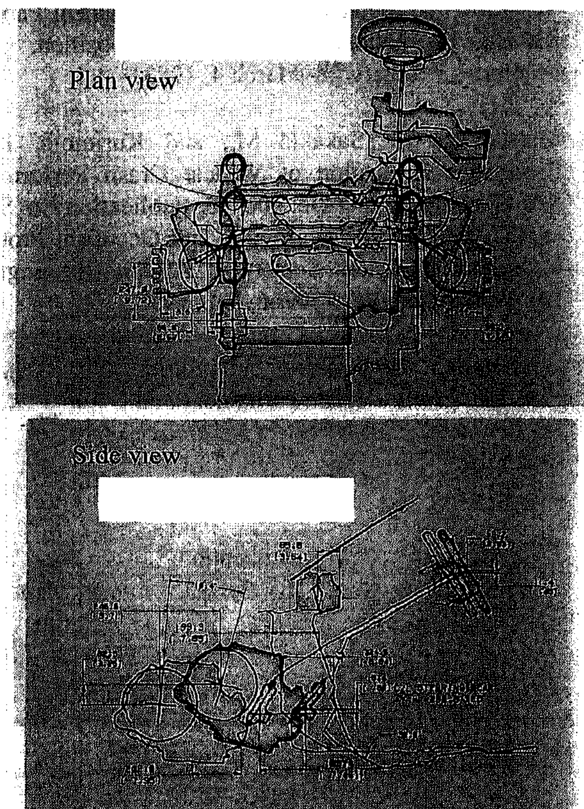

Figure 32: Intrusion profile and steering column displacement after frontal crash test of a midsize vehicle equipped with experimental half-car beam column support system

To validate the effectiveness of these proposed designs, the results of crash tests of vehicles that were equipped with a cross-car beam and a half-car beam were analyzed. The intrusion profiles and steering column displacements were plotted and shown in Figures 31 and 32. As expected from the results of the crusher testing methodology, the column was very stable, with approximately 25 mm of upward movement at a dashpanel intrusion of approximately 246 mm for the cross car beam design. Similarly, the behavior of the column with half-car beam was validated (Figure 28).

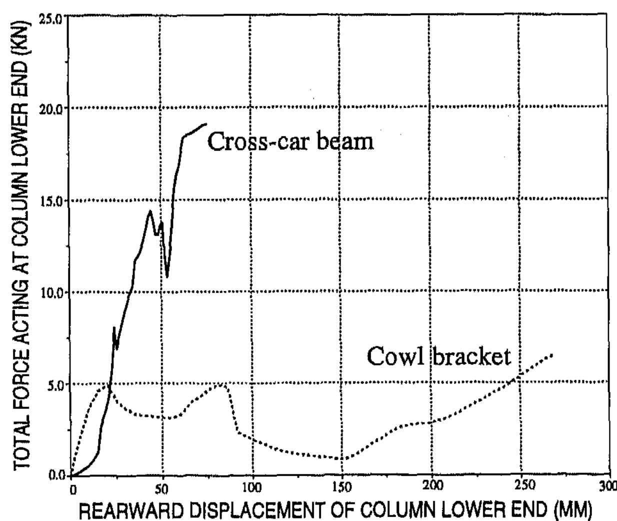

Figure 33: Steering column loads vs. deflection measured at lower end of column for two different support systems

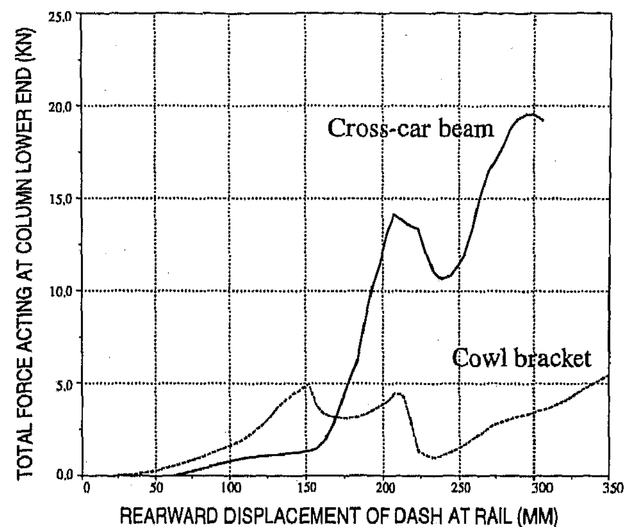

Figure 34: Steering column loads for two support systems

In addition to proving a design or helping to select a design, the aft-rail intrusion testing methodology provides information that can serve as a target to size and optimize the column support design. This unique tool as a design aid can be explained by reviewing the results of the loads produced at the lower end of the column given in Figures 33 and 34. The curves in Figure 33 present the load- deflection at the lower end of the column during the testing of cross-car beam and cowl bracket column support systems. Obviously, the higher load required to collapse the cross-car beam system (14.23 KN relative to 4.89 KN for the cowl bracket system), is the characteristic for the salient improvements in the column displacement. However, to reach the collapse load in each system, the amount of dashpanel intrusion is approximately 216 mm for the cross-car beam system, compared with only 152 mm for the cowl bracket system. That is a significant gain of 64 mm in intrusion potential that has no effect on the column displacement. The comparison in the performance characteristics can be shown in the form of the four different stages of column loading as shown in Table 3.

Table 3: Dashpanel intrusion at aft-rail and corresponding loads at different stages of column loading for two different support systems

Stage[a]	Cowl bracket		Cross-car beam	
	Intrusion mm	Column load-KN	Intrusion mm	Column load-KN
1	0-38		76

CONCLUSIONS

The primary intrusion modes and how they combine to form the final intrusion mode or profile (which occurs in frontal

crashes of vehicles) has been explained. Also the role of each of these modes on causing the movement of the steering column has been clearly illustrated. A simple crush test configuration, aft-rail crush into dashpanel, was shown to be a powerful simple methodology in guiding vehicle engineers in making decisions on intrusion limits and management of the steering column movement as well as energy absorption of the vehicle.

This simplified test methodology could actually eliminate the need to conduct a vehicle crash test regarding amount of intrusion and selection of steering system design concepts. The methodology was shown to evaluate alternative concept designs of steering columns and its support structure. Many meaningful as well as quantitative performance characteristics of these alternative design proposals became available by conducting this test. Important examples of these evaluative performances include the capacity of the design to resist or tolerate intrusion, and the amount of intrusion at the dashpanel that can occur with only negligible steering column movement. These evaluations can serve as input to vehicle engineering when making design decisions during early phases of vehicle development.

The simplified test does not have to be a physical hardware test, because the case of aft-rail crush into dashpanel can be easily simulated using CAE crash codes. It is certainly simple and more economical to run these tests on the computer than simulating the complete vehicle.

ACKNOWLEDGEMENTS

The authors wish to thank Dr. P. Prasad for sponsoring and supporting the research presented in this paper. Also, we acknowledged the contribution of the late Mr. Jerry Fritzler in planing of the experiments and in providing most of the hardware used in the testing. In addition, the authors are grateful to the crusher testing staff at Ford Motor Company for being so patient in accommodating our requests while conducting the experiments discussed in this report. In particular, we thank Mr. Steve Upmeyer, who helped in acquiring very valuable data by providing new and extensive instrumentation. Moreover, we wish to thank Mr. K. Presulmalli and Dr. Y. Lin for supervising several of these tests and conducting extensive analysis of the test data. Finally, we acknowledge Dr. E. Hara and Dr. C Chou for their editorial comments and advice.

ABSTRACT

Two sled systems capable of producing structural intrusion in the footwell region of an automobile have been developed. The first, System A, provides translational toepan intrusion using actuator pistons to drive the footwell structure of the test buck. These actuator pistons are coupled to the hydraulic decelerator of the test sled and are powered by hydraulic energy from the impact event. Resulting footwell intrusion is characterized using a toepan pulse analogous to the acceleration pulse used to characterize sled and vehicle decelerations.

Sled tests with System A indicate that it is capable of accurately and repeatably simulating toepan/floorpan intrusion into the occupant footwell. Test results, including a comparison of lower extremity response between intrusion sled tests and no intrusion sled tests, indicate that this system is capable of repeatable, controlled structural intrusion during a sled test impact. Test results also suggest that lower extremity forcing during footwell intrusion is significantly larger than such forcing with no intrusion and that response and risk of injury for occupants in frontal or frontal-offset crashes are more severe. To expand the available range of simulated footwell intrusion, the design of a second intrusion test system, System B, is presented. This system includes toepan translation, rotation and combined translation/rotation motions as well as an expanded range of toepan accelerations. System B also allows the independent motion of the left and right toepan thus enabling the simulation of yawing motions in the occupant footwell.

INTRODUCTION

Structural deformation of a vehicle into the occupant compartment, termed intrusion, occurs in very severe frontal crashes for which all of the energy absorbing capability of the front structure is exhausted. Such intrusion, however, may be especially significant in frontal-offset crashes in which less than the full frontal area of the vehicle is engaged in energy absorption. Reviews of accident database cases (Morgan *et. al.*, 1991) and computer simulations of crashes (Henson *et. al.*, 1983, *Pilkey et. al.*, 1994) have shown that this structural deformation greatly increases the severity of the impact response and the risk of injury for the occupant. In addition, case histories of lower extremity trauma in automobile collisions indicate frequent costly rehabilitation and significant rates of lifetime impairment (Dishinger *et. al.*, 1994). Although current vehicle safety standards in the United States require only testing of full-frontal vehicle collisions against rigid barriers, offset frontal testing is currently being evaluated by the U.S. National Highway Traffic Safety Administration (NHTSA) of the U.S. Department of Transportation (DOT), automobile manufacturers and foreign vehicle testing organizations (Grosch *et. al.*, 1989, Panath-Skogsmo and Nilsson, 1994).

Full-scale vehicle tests are expensive and time-consuming methods by which to conduct parametric studies of impact conditions, to estimate the likelihood of injury using anthropometric test dummies and to evaluate design changes intended to minimize the risk of injury resulting from intrusion. Ideally, a test procedure capable of reproducing the frontal-offset impact environment of the vehicle could be simulated in a laboratory setting where tighter control of test conditions and configurations is possible. At the University of Virginia, two systems for duplicating the structural intrusion of a vehicle have been developed using a modified sled system. The goal of this effort is to characterize the effects of structural intrusion on the occupant in a simplified and repeatable manner. This paper begins with the basic theory necessary to simulate the essential characteristics of vehicular intrusion in the footwell region and follows with the physical and procedural design of a first-generation translational intrusion simulation system, System A. The succeeding section presents intrusion experiments performed using System A; included is a description of structural and lower extremity response of the translational intrusion system at intrusion levels of 0 cm, 7 cm and 22 cm. The design of a second-generation intrusion system, System B, follows with a discussion of design criteria and the development of a system capable of toepan rotation, translation, and combined translation/rotation motions. We

finish with conclusions regarding System A test results and the System B design.

CHARACTERIZATION OF FOOTWELL INTRUSION

Few published studies exist that describe the displacement, collapse and buckling of a vehicle's thin metal structures during a crash. This lack of information is a result of both the complexity of the intrusion event and the mechanical response limitations of the instrumentation used to record the event. For frontal-offset vehicle tests, intrusion data of the footwell region has historically been obtained from a single uniaxial accelerometer mounted to the toepan along the longitudinal axis of the automobile. As the crash progresses, however, the toepan locally deforms in translation and rotation so that the actual orientation of the accelerometer axis becomes poorly defined (c.f. Prasad and Smorgonsky, 1995). To obtain more accurate intrusion data, many alternative methods of measurement have been attempted, but they also fail to fully characterize the toepan and floorboard deformation. Movement of the engine or structural members (e.g., the rails or subframe) relative to the occupant compartment has been recorded by both accelerometers and film analysis. Whereas this motion can provide estimates of the initiation and completion of the intrusion event, it does not provide a three-dimensional characterization of the collapse and buckling of the thin metal structures. Direct measurements of the displacement of the toepan have been attempted by affixing string potentiometers to the toepan. This instrumentation package has met with little success owing to the limited response characteristics of the spring-loaded potentiometers. Analysis of the structural intrusion during the crash event using high speed films often provides incomplete information owing to partial occlusion of views and to difficulty in obtaining orthogonal frames of reference. Post-crash measurements of the vehicle's occupant compartment provide cross-sections of the footwell region at only a single instant and cannot provide complete time histories or indicate the sequence of translations and rotations. In addition, no elastic effects occurring after the crash in the floorpan and toepan structure can be evaluated. Although the ability to measure the intrusion event in the footwell is currently limited, increased frontal-offset testing and advances in finite element models should provide more data and detailed descriptions of the structural deformation. Meanwhile, approximations based on available data must be made to characterize intrusion for reproduction in the laboratory sled test environment (Crandall, *et. al.*, 1995).

Sled systems have demonstrated their usefulness in reproducing a given vehicle deceleration pulse in a controlled, reproducible manner. In a similar way, a toepan or floorpan pulse can be used to define the intrusion event. Analogous to the crash pulse used to characterize vehicle and sled tests, Kuppa and Morgan (1993) have suggested the use of a toepan and floorpan acceleration time history to characterize the structural deformation of the footwell region. Kuppa and Morgan addressed the problem of limited experimental data by making several simplifying assumptions based on a 58 km/h (36 mph) frontal-offset test performed with a 1991 Ford Taurus 4-door sedan and a 1991 Honda Accord DX 4-door sedan. Toepan accelerations during the initial phases of vehicle deceleration were matched with those of the vehicle using the assumption that little rotation had taken place to that point in the event. They also used static post-test profiles to evaluate the overall level of intrusion and matched the second integral of the acceleration curve with the post-test measurements (c.f. post crash-test footwell profiles from Prasad and Smorgonsky). Using these approximations, Kuppa and Morgan produced an equivalent toepan pulse and brake pedal pulse in terms of the longitudinal and vertical motion. These pulses maintained the characteristics of the original data and were readily reproducible in the laboratory.

While these approximations are an excellent start at defining the structural intrusion issue, several issues still need to be addressed to fully characterize the complex motion of the toepan and floorpan intrusion. Examination of the static post-crash profiles for several automobile toepans indicates that both translational and rotational motion about the intersection of the floorpan and the toepan can occur during the crash events. Depending on the vehicle, these intrusion profiles may be described as predominantly translational, predominately rotational or a combination of translation and rotation. Thus, characterization of the toepan and floorpan intrusion as a sequence of finite longitudinal and vertical displacements is a rough approximation of the actual footwell deformation. As more data from computer models and vehicle crash tests becomes available, general motions about three axes will be able to be incorporated into the characteristic pulse description. Additionally, since the intrusion event is deformation of a structure, rigid body translations and rotations about the heel location may not sufficiently describe the intrusion event. Indeed, motion at the midpoint of the toepan may have little similarity with the intrusion at other regions of the footwell owing to the compliance and complexity of the footwell structure (e.g., wheel well asymmetry). In addition to improved instrumentation measuring more degrees of freedom, sensors must be mounted at multiple locations on the toepan and floorpan structures.

For the purposes of designing an intrusion system using a laboratory sled, however, the intrusion simulator sled system begins with a simple, easily characterized intrusion profile. This profile is translational intrusion of the toepan in the occupant footwell parallel to the ground. In the next section, the System A intrusion simulator is described that incorporates translational motions of 0 cm, 7 cm, or 22 cm total toepan displacement into the occupant compartment.

INTRUSION SYSTEM A - DESIGN CONSIDERATIONS

The System A intrusion simulator is the result of the application of several design criteria to enable accurate and reproducible investigation of occupant response, particularly lower extremity response, during a simulated crash event. These criteria are:

- **The system is designed for translational intrusion.** The intrusion simulator will generally be capable of rigid body translations into the footwell region.
- **The toepan produces approximately 20,000 N maximum force applied to both legs.** As the average tibial breaking strength in axial compression is approximately 10,000 N (Yamada and Evans, 1970), the maximum forcing of the intrusion simulator should be able to simulate conditions including the fracture of both tibias under axial load. This extreme condition should enable the simulation of other lower extremity injuries (for example, calcaneous or tibial pylon fractures) under lower loads.
- **The toepan is capable of approximately 25 cm maximum toepan displacement during a simulated crash event.** A recent study (Crandall *et. al.*, 1995) found that 85.6% of below-knee injuries sustained by the driver occur with less than 14 cm of intrusion. In addition, typical intrusions of ~20 cm are seen in full-frontal automobile crash testing.
- **Toepan translation is relatively independent of dynamic lower extremity load.** As the gross structural intrusion in an automobile is likely insensitive to the loading provided by occupant lower extremities, toepan motion should occur independently of this applied loading. Also, it is desirable to repeat intrusion conditions for occupants of various masses and lower extremity geometries.
- **The intrusion simulator is capable of toepan pulse tailoring and stroke selection.** To investigate various intrusion conditions and responses, flexibility is desired in the programming of the intrusion simulator.
- **The toepan mechanism is driven by the sled decelerator.** A substantial amount of fluid power is dissipated in the sled decelerator during an impact event. This energy is used to drive the intrusion simulator as discussed below.

Investigating crash-induced structural deformation of the vehicle footwell with a laboratory sled requires the capability to move the toepan and floorpan components into the footwell space in a programmed displacement versus time profile. One way to fulfill this requirement is to integrate the actuation of the floorboard components with the function of the hydraulic decelerator of the sled. The University of Virginia test sled (VIA Systems 713) functions by initially accelerating the test buck, carriage and payload to a predetermined velocity and then decelerating the payload along a programmed crash pulse. The deceleration profile is produced by a hydraulic decelerator (i.e., water brake) mounted on the sled carriage. The hydraulic decelerator is configured as a cylinder with an array of discrete orifices over its length. During the deceleration pulse, fluid flows through this array, dissipating energy from the test sled in a controlled manner. The individual orifices are sized to vary the amount and velocity of the fluid being forced through them and to regulate the energy absorption rate of the device. Since the decelerator is coupled to the sled carriage, it is possible to utilize the flows and pressures generated through the orifices to actuate the floor board components of the vehicle compartment mounted on the sled carriage.

Figure 1 shows a projected (flat pattern) view of the decelerator cylinder. The standard orifice rows for deceleration of the sled, referred to as program rows, have been supplemented by an output row used to provide hydraulic power to the intrusion simulator. The output ports are currently spaced at 7.6 cm intervals, whereas the two staggered rows of programming orifices provided for pulse tailoring are 1.9 cm apart. For finer control of the output pulse it is possible to add additional output ports to the decelerator between the current ports. When the decelerator cylinder is installed in the containment vessel, each port of the output row is adjacent to an opening provided in the containment vessel. This allows output pipes to connect directly to the ports and to be routed outside the containment vessel. Outside the containment vessel, flexible tubing connects the decelerator with pistons mounted on the buck. These actuator pistons, also referred to as slave cylinders, are used to displace the toepan and floorpan structure. During deceleration of the sled, the ports in the output row are used to transfer fluid from the hydraulic decelerator to the slave cylinders. Varying the size and location of the orifices in the output row permits detailed programming of the toepan/floorpan displacement time histories. **Figure 2** shows a basic circuit schematic investigated for the System A integrated hydraulic decelerator/floor board actuator system.

System A is comprised of a set of drive side hydraulic lines, a control side hydraulic line, an accumulator and a double-acting hydraulic slave cylinder with equal piston areas on both sides. The slave cylinder is driven from the output ports of the hydraulic decelerator discussed above. The system is initially fully filled with hydraulic fluid. Pressure develops in the sled hydraulic decelerator which results in pressure in the drive lines and control line and fluid flow into the hydraulic accumulator to be stored for the toepan actuation. As the impact event begins, the pressure in the hydraulic decelerator is transmitted to both sides of the slave cylinder. So, the toepan remains stationary with respect to the test buck.

At a certain point, the sled decelerator piston passes the control side output port on the sled decelerator. As this occurs, the control side pressure drops and the toepan begins moving under the force of the drive lines remaining in front of the sled piston and the pressure in the accumulator. The maximum attainable acceleration pulse of the actuator is a function of the instantaneous pressures and flows in the hydraulic decelerator and the hydraulic accumulator. Check valves prevent backflow down the drive lines when drive ports are passed by the sled decelerator piston. A constant force internal stop inside the slave cylinder at maximum mechanical stroke is used to terminate toepan travel at a location determined by the position of the hydraulic slave cylinder. The intrusion pulse is controlled by varying the orifice sizes on the drive or control side of the of the circuit. Further tailoring of the toepan force and displacement values is available using one or more 'tuning' circuits with control

orifices and check valves. Since the toepan actuator piston area is substantially smaller than the hydraulic decelerator piston area (typical values are 5 cm^2 for the former versus 20 cm^2 for the latter) minimal fluid drive volume is required from the decelerator.

The detailed physical arrangement of the System A intrusion simulator at the University of Virginia is shown in side view in **Figure 3** and in oblique view in **Figure 4.** The simulator consists of a toepan carriage with separate footrests for the left and right feet. This carriage travels in translation with respect to the ground into the occupant compartment on two rods mounted to the test buck. The limit of travel of the toepan carriage is 24.9 cm from the reference footwell location. The toepan carriage is driven by a 6.4 cm diameter hydraulic slave cylinder connected to the hydraulic decelerator on the test sled. The cylinder is a double rod/double acting hydraulic cylinder with equal piston areas on either side of the cylinder. The rear mounting position of the hydraulic cylinder may be adjusted to limit total toepan travel in increments of 2.5 cm.

The toepan carriage is instrumented with footplates mounted on the toepan carriage at 55 degrees from the horizontal, consistent with a typical midsize vehicle driver-side footrest as shown in **Figure 4.** The footplates are 30 cm in height by 17 cm in width and are instrumented with load cells at each corner oriented normal to the local direction of the footplate. In addition, accelerometers are mounted on the rear center of the plate to assist in mass compensation of the measured forces.

SYSTEM A - INTRUSION PULSE SELECTION AND PULSE PROGRAMMING

The pulses in both the hydraulic decelerator and the toepan actuator circuit are selected using hydraulic assumptions based on Bernoulli hydrodynamics. The volumetric flow rate, Q, from any orifice in the system is assumed to obey the relation:

$$Q = kA\sqrt{\frac{2}{\rho}(P_1 - P_2)}\,.$$

The quantity ρ is the density of the fluid, A is the orifice area, and P_1 and P_2 are pressures on the upstream and downstream sides of the orifice. Semi-empirical flow coefficients k are determined from experiments and from standard values of orifice coefficients (ASME, 1981).

To select the sled acceleration profile and the toepan acceleration profile simultaneously, the orifice array in the decelerator and the orifices leading from the decelerator to the toepan actuator must either be coordinated or the effect of the toepan actuation on the decelerator pulse must be negligible. In the first instance, toepan actuator flow and pressure requirements may contribute to the effect of the decelerator orifice array on the sled acceleration pulse. Thus, at any given instant, the volume of fluid for the operation of the actuator has to be a part of the volume of fluid being forced through the orifices of the decelerator to govern the test pulse. However, since considerable power is dissipated by the decelerator under a wide range of experimental conditions, the effect of toepan actuation on the deceleration pulse generated by the hydraulic decelerator may be negligible. For example, a 55 km/h, 1000 kg sled run dissipates over 1000 kW of power for a pulse length of 80 milliseconds. In contrast, the power required to move a floor/toeboard complex 15 cm at an average force of 10 kN over a 40 millisecond interval is approximately 37 kW, giving a power ratio from decelerator to toeboard actuator of over 25:1. However, for more extensive use of decelerator hydraulic power, the toepan intrusion actuation must be coordinated with the sled deceleration.

To model structural intrusion events, the toepan pulse should have certain acceleration, velocity and displacement characteristics. For instance, the toepan should experience a displacement relative to the vehicle center of mass in a direction opposite to the direction of sled travel. Ideally, this displacement is caused by a toepan actuator acceleration pulse. After some time, the toepan remains fixed in space with zero velocity relative to the ground while the sled continues to decelerate and move with respect to the toepan. The selected maximum toepan intrusion/deformation is the total distance of sled travel after the toepan velocity becomes zero relative to the ground. So, if a given toepan displacement, D, is selected, the toepan actuation should begin within a length of D from the end of the total sled travel.

Input requirements for programming this process are the desired acceleration on the sled, the force on the toepan and the degree of toepan intrusion. Each of these parameters is a function of the local pressure at various locations in the decelerator/toepan actuator hydraulic system. These parameters are adjusted specifying input/output orifice diameters and the port locations. An essential design characteristic for the intrusion system is the ability to adjust the dynamic intrusion parameters over a large range for a given sled pulse. In actual crashes, the level, duration and nature of the intrusion is highly dependent on vehicle characteristics (e.g., size, weight, engine mounting orientation and drive-train configuration) and crash configuration (e.g., vehicle offset distance and velocity). Thus, the degree of toepan intrusion for vehicles involved in a 55 km/h crash under various conditions may range from 0 cm to over 20 cm.

For System A, several toepan intrusion parameters can be controlled in the intrusion event:

- **Intrusion initiation.** Location of a control line in the hydraulic decelerator can be used to define intrusion initiation. The intrusion initiation of this intrusion drive circuit is accurate owing to the ability to control precisely a delayed initiation of the toepan actuator using the physical position of decelerator output ports.
- **Toepan stroke.** Stroke can be controlled by the cylinder mounting location and cylinder stop.
- **Toepan acceleration profile.** System A includes a combination of passive orifices in the drive lines and a

hydraulic accumulator so that the dynamic effects of the sled pulse can be used to tailor the toepan pulse. The simulator is capable of toepan forcing late in the sled deceleration stroke.

Spreadsheet-based computer software has been developed to identify the orifice array for a given pulse with the hydraulic decelerator while incorporating the essential pressure and flow information necessary to select the hardware configurations and operational conditions for the toepan actuator. The procedure requires the user to specify the toepan acceleration, velocity and position time histories. Conservation of energy and momentum are used to derive the flow rates and pressures required from the decelerator for the actuator pistons within limits. As the flow in the intrusion hydraulics has a significant effect on the sled decelerator, an iterative solution for the sled deceleration profile must be sought, constrained by the desired intrusion. An algorithm for performing this iteration is presented in **Figure 5**. For a given circuit configuration, the program outputs the location and size of orifices for the output rows (i.e., toepan actuator piston) and the program rows (i.e., sled pulse) of the hydraulic decelerator.

SYSTEM A - TEST RESULTS

To demonstrate the use of the intrusion simulator, sled impact tests were performed with zero intrusion, 7 cm intrusion and 22 cm intrusion using dummy and cadaveric subjects restrained by a knee bolster and a three-point seat belt. Sled tests were performed using the University of Virginia Automobile Safety Laboratory acceleration sled test system. The test buck was configured as a 1994 Ford Taurus vehicle and the deceleration pulse was selected to reproduce the crash pulse of a mid-size automobile measured using damped accelerometers. As discussed above, hydraulic power from the sled decelerator drives the intruding toepan. Instrumentation on the toepan includes force-sensing footplates, a toepan carriage accelerometer and a spring-loaded string potentiometer to measure toepan displacement relative to the sled.

Sled velocity at the initiation of the crash pulse is selected to be 58.2 km/h. The intrusion stroke is selected to be 7 cm or 22 cm relative to the sled. This intrusion is selected to coincide with the last 7 cm or 22 cm of sled travel respectively, late in the deceleration stroke. Intrusion acceleration is selected as approximately sinusoidal in the sled frame.

The dummy tests utilized the Advanced Lower Extremities (ALEX) developed by the NHTSA. The goals in developing the ALEX legs include increased biofidelity through such means as improved inertial distribution of the lower extremities and reduced stiffness using advanced composite materials. The ALEX lower extremities also offer an increased range of motion for ankles compared with the standard Hybrid III lower extremities. This is significant in intrusion tests where the standard Hybrid III lower extremities likely reach hard joint stops, disrupting testing. In addition, the ALEX legs incorporate improved instrumentation compared with the standard Hybrid III lower extremities. For the intrusion runs, a Hybrid III dummy with ALEX lower extremities and cadaveric subjects were used.

In **Figure 6**, a representative deceleration sled pulse and toepan intrusion pulse are plotted for a representative intrusion sled test of 7 cm intrusion. The toepan intrusion deceleration relative to the test sled is approximately sinusoidal with an approximately 80 g peak in the intrusion pulse (100 g relative to the ground). The oscillation at the end of the sled deceleration results from a single control orifice remaining in the hydraulic decelerator at that sled travel position. To eliminate this oscillation would require active control of decelerator orifices or an addition of passive control orifices in the decelerator. **Figure 6** illustrates that the toepan acceleration follows the sled acceleration until the actuation of toepan intrusion. The toepan then quickly stops relative to the ground while the sled continues to decelerate (i.e., the hydraulic decelerator continues to stroke). The net effect of the sled and toepan decelerations is movement of the toepan into the occupant compartment of the buck. As the initial peak and impulse most relevant for lower extremity injury, this toepan intrusion provides a potentially realistic translation intrusion pulse.

In **Figure 7**, the sled displacement relative to the ground and the toepan displacement relative to the sled are compared. The sled travel is derived as the double integration of the unfiltered sled deceleration signal in **Figure 6**. The toepan intrusion relative to the test buck, measured using a string pototentiometer attached to the toepan, is selected to approximate sled travel in the laboratory reference frame for the last 7 cm. This process imitates a crushing process wherein a rigid body engine stops in the laboratory reference frame and intrudes through the occupant footwell at the very end of the vehicle crash pulse. For exact replication of this process, the toepan displacement relative to the sled and the sled displacement relative to the ground would be the same. From the graph in **Figure 7**, it is seen that the variation between toepan displacement and sled displacement is less than 5% of full scale during the intrusion event.

Repeatability of the toepan acceleration relative to the test sled is shown in **Figure 8**. ATD-35 is a dummy run with ALEX lower extremities. Runs CAD-35-CAD-36 are tests with cadaveric subjects. The inertial loading varies widely between these runs with occupants ranging from 50 kg to 106 kg. However, the magnitude of the initial peaks and troughs varies less than 2% and the timings of the peaks are closer than 1% as a percentage of the 110 ms deceleration event. It is important to note that the initial sled velocity of the three events varied only from 58.2 km/h to 58.4 km/h.

Typical lower extremity response of a 7 cm translation intrusion sled test using System A is presented in **Figure 9**. Initially the lower extremities experience an inertial slap in tibia axial load, identified in high speed films taken of the sled test. This slap results from heel contact with the toepan following initiation of the deceleration crash pulse. It occurs in both intrusion and non-intrusion tests with peak axial force values comparable when intrusion initiation is late enough.

Computational simulations of this slap suggest that the magnitude of the initial force is relatively insensitive to the size of the gap but very sensitive to the existence of a gap. After this inertial loading, translational intrusion onset is approximately 65 ms. The effect of the translational intrusion on the tibia axial load is somewhat obscured by the seat belt/knee bolster interaction which occurs at the same time. However, the peak value of axial load in the tibia is nearly 70% larger than the peak axial load in sled tests without intrusion. For the 7 cm intrusion sled test, the tibia A/P moment clearly shows the impact of knees into the knee bolster at approximately 51 ms. During the intrusion event after 65 ms, the maximum bending moment is more than twice the value of a similar test with no intrusion.

A 22 cm intrusion test is shown in **Figure 10.** Again, the initial slap in axial force is seen in tibia axial load and A/P moment. As the intrusion occurs after this period, the peak load values and slap duration is comparable to that seen in the 7 cm intrusion sled test. In contrast with the 7 cm intrusion test, a clear intrusion peak is seen in the tibia axial load after intrusion initiation at approximately 47 ms; the intrusion is early enough to produce a force peak distinct from the knee bolster/belt interaction. In addition, the tibia A/P moment peaks at nearly 120 N-m during the intrusion event. Also, we again clearly see knee bolster contact in the femur axial load.

A comparison of the lower extremity response using a Hybrid III dummy between a 22 cm intrusion sled test using System A and a NHTSA full frontal crash test of a 1992 Ford Taurus is plotted in **Figure 11.** Qualitatively, we see the characteristic triple humped features in both outboard distal tibia axial forces. We identify the first peak as inertial slap, the second as onset of intrusion (can also see this in as an acceleration peak in Taurus vehicle acceleration) and the third peak as the knee bolster/ belt interaction. The magnitudes of these peaks are quite comparable though the Taurus crash test deceleration pulse is nearly 20 ms shorter than that of the sled test.

The behavior of the maximum forward location of the foot center of pressure, for tests with both dummy and cadaveric subjects, is shown in **Table 1** for various levels of intrusion. The foot center of pressure has been normalized by foot length and is an average of multiple cadaveric and dummy runs for each condition. The location of the furthest forward center of pressure increases with intrusion level for both cadaver and dummy since increasing dorsiflexion of a cadaver ankle tends to shift the center of pressure towards the toes. The timing of the maximum occurs earlier with increasing levels of intrusion for cadaveric lower extremities since earlier intrusion results in earlier dorsiflexion; the bending moment that can be applied about a cadaver ankle during a crash event increases as the cadaver ankle dorsiflexes. In contrast, Alex dummy ankles see relatively constant and low moment values until the joint stops are reached. The Alex joint stops are not reached in either 0 cm or 7 cm intrusion, only in 22 cm intrusion. So, the maximum center of pressure is obtained very early for 22 cm.

A comparison of dummy center of pressure maxima vs. cadaver maxima again shows the differences between moment/angle properties of dummy ankles vs. cadaveric ankles. Center of pressure forward extent is always greater for cadavers for a given intrusion condition since cadaveric ankles can offer significant moment resistance across the ankle before reaching natural joint stops. This tends to shift the center of pressure forward, towards the toes. Other intrusion subject sled test data from these tests, including cadaveric ankle injuries, are reported elsewhere (Crandall *et. al.*, 1996).

Level of Intrusion	Subject	Center of Pressure Maximum	@Time (ms)
0 cm	Dummy	45.5%	58.8
	Cadaver	52.4%	81.4
7 cm	Dummy	49.9%	73.1
	Cadaver	61.1%	66.6
22 cm	Dummy	55.5%	46.3
	Cadaver	66.6%	62.8

Table 1: Longitudinal Center of Pressure Maxima for Cadaveric and Dummy Left Feet vs. Level of Intrusion, Normalized by Foot Length, Multiple Run Average.

INTRUSION SYSTEM B

Intrusion System B was developed to address limitations of System A. These include a limitation on the maximum acceleration developed in the toepan and certain 'quantization' limits on travel. Assuming reasonable intrusion behavior, toepan travel was limited in System A to discrete 7.6 cm segments owing to decelerator output port locations. In addition, since sled hydraulic cylinder orifice spacing is constant, the toepan and the sled deceleration pulses were sensitive to the last 7.6 cm of sled travel. Late in the sled deceleration event, the sled hydraulic decelerator piston travels relatively slowly over the last few orifices at the end of sled travel. The lack of control orifices significantly reduces control of toepan and sled pulses at end of travel. Also, a finite element analysis of System A footplates/toepan indicated substantial dynamic deflections during the impact event. The existence of these deformations was confirmed by observing the permanent deformations of several structural components over the series of tests using System A.

A second-generation design, System B, was developed incorporating the experience gained operating System A. An augmented set of design criteria successfully addresses significant limitations of System A. These modified design criteria are:

- **The system is designed for translational, rotational and combined translational/rotational intrusion.** The intrusion simulator will generally describe rigid body motions into the footwell region. Each footplate is

capable of independent motions and is thus capable of 'yawing' motions between the left and right feet.

- **The toepan produces approximately 20,000 N maximum force applied to both legs.**
- **The toepan acceleration may be prescribed in excess of 150 g's.** Maximum available acceleration with System A using a typical Ford Taurus crash pulse at 58 km/hr is approximately 100 g's.
- **The toepan is capable of approximately 25 cm maximum toepan displacement during a simulated crash event and approximately 55^0 of rotation.**
- **Toepan translation is relatively independent of dynamic lower extremity load.**
- **The intrusion simulator is capable of toepan pulse tailoring and stroke selection.**
- **The occupant footplate is more rigid and includes enhanced instrumentation.** The System A toepan instrumentation was capable of measuring forces normal to the plane of the footplate. Additional measurement capability was desired in System B.
- **The toepan mechanism is driven by independent contact with stationary reaction mass.** A disadvantage of System A is the dependence of the sled pulse on hydraulic power derived from the sled decelerator very late in the impact event. With the existing hydraulic cylinder design, this reduces the ability to control either the sled or the intrusion deceleration pulses near the spatial end of the impact event.

System B operation is based on the impact of three separate hydraulic decelerators into a fixed reaction mass: a sled decelerator, a left toepan decelerator and a right toepan decelerator. These decelerators must be coordinated to produce appropriate sled crash and toepan intrusion pulses. For pure rotational motion the base of the carriage is locked and the intrusion decelerator actuates the toepan only. For pure translation, the toepan is locked with respect to the footplate carriage which is allowed to slide along a carriage guide rod. Combined rotational/translational motions can be achieved using the cam follower on the Rotational Guide Bar shown in **Figure 12.** The Rotational Guide Bar is adjustable to allow different combinations of translations and rotations. Forces on each footplate are measured using a six-axis load cell measuring local shears, moments and normal force.

For System B, several toepan intrusion parameters can be controlled in the intrusion event:

- **Intrusion initiation.** Intrusion initiation occurs when the intrusion hydraulic decelerator contacts the intrusion impact cushion. This intrusion impact cushion is generally located in a different spatial location from the sled impact cushion.
- **Toepan stroke.** Stroke can be controlled by the cylinder mounting location and cylinder stop. The left and the right toepans can be controlled independently.
- **Toepan rotation.** May be controlled independently or in a combined motion with translation.
- **Toepan acceleration profile.** Acceleration profile tailoring is available using orifice arrays in the intrusion hydraulic decelerators. Again, can be independently adjusted for each footplate.

System B is diagrammed in **Figure 13.** Individual toepan carriages allow independent toepan motions, and cylindrical hydraulic toepan decelerators provide toepan actuation. There are two attachment points behind each toepan for the toepan hydraulic decelerators. The first is aligned with toepan carriage translational motion to actuate translation and combined translation/rotation. The second is located at the top of the toepan to actuate purely rotational motions.

For intrusion pulse programming, the desired sled crash pulse is selected initially. Then, an intrusion profile is selected. This profile is subject to certain admissibility constraints. For example, no acceleration and displacement may be selected that results in the toepan intrusion cylinders reaching limits of travel. The rest of a typical iterative algorithm is shown in **Figure 14.** One primary difference between the procedure followed using System A and that for System B is in the use of simulation to select a toepan orifice profile. Applied force on the footplates affects the pulse derived from the toepan hydraulic decelerators. So, the test must be simulated prior to the run to allow appropriate selection of orifice parameters for the toepan decelerators. A lumped mass model of the test system will be used to perform these simulations.

An ideal triangular toepan intrusion pulse, comparable to translational pulses produced using System A, is shown for System B in **Figure 15.** This triangular pulse has equal rise and drop times after which it drops rapidly to zero in the laboratory reference frame. This pulse produces zero toepan translation thereafter in the laboratory frame while the sled continues to translate resulting in motion of the footplate into the occupant compartment. The calculation procedure is adaptable to complicated toepan motions.

There are several advantages and disadvantages of System B as compared to System A. The primary advantage of System B is that it can describe more complicated motions including combined translational/rotational motions. In addtion, System B allows increased toepan acceleration as compared with System A. The primary disadvantage of System B is a potentially complicated pulse programming calculation. This may be eased somewhat if the energy associated with the toepan motion is a small percentage of the sled energy over the entire range of motion.

CONCLUSIONS

Structural intrusion into automobiles is a complex process involving deformation, translation and rotation of automobile structural components. However, two test systems, one capable of simulating translational toepan intrusion, the other capable of simulating translational, rotational and a combined translational/rotational motion, have been developed to simulate the structural deformation

seen in car crashes. Although current data on intrusion is limited, System A is capable of reproducing available toepan and floorpan intrusion time histories in translational motion. This intrusion simulator adapts an extensively tested and documented technology developed to tailor deceleration pulses for sleds using hydraulic decelerators. Similar to the sled pulse tailoring, the intrusion profiles can be programmed in a precise manner with relative ease. Parameters affecting the intrusion pulse that can be adjusted include orifice sizes, orifice locations and hydraulic circuit layout. A computer program has been developed to iteratively determine these parameters for both the sled hydraulic decelerator and the intrusion actuator pistons simultaneously.

Using this intrusion simulator, the significant effects of a 7 cm and a 22 cm structural intrusion on dummy and cadaver lower extremity force and moment values have been demonstrated. The displacement of this structural intrusion is selectable to within 5% of the selected displacement condition. The peak forcing of the demonstrated intrusion pulse is repeatable in both timing and magnitude to within 5% under widely differing inertial lower extremity loads. Also, using rigid body toepan and floorpan structures, the system requires minimal energy from the hydraulic decelerator and does not significantly affect the sled pulse.

Building on experience gained operating System A, an enhanced second-generation system, System B, was developed. This intrusion system incorporates pure translation, pure rotation and combined translational/ rotational motion. The system may be actuated independently for each foot. It includes increased translational acceleration limits as compared with System A. With more options for system control, however, comes a more complicated pulse programming procedure. Tests with System B will proceed in the future to explore various aspects of occupant footwell intrusion.

ABSTRACT

The University of Virginia is investigating the use of a magnetohydrodynamic (MHD) angular rate sensor to measure head angular acceleration in impact testing. Output from the sensor, which measures angular velocity, must be differentiated to produce angular acceleration. As a precursor to their use in actual testing, a torsional pendulum was developed to analyze an MHD sensor's effectiveness in operating under impact conditions. Differentiated and digitally filtered sensor data provided a good match with the vibratory response of the pendulum for various magnitudes of angular acceleration. Subsequent head drop tests verified that MHD sensors are suitable for measuring head angular acceleration in impact testing.

INTRODUCTION

Head Injuries Due To Angular Acceleration

Brain injuries occurring in automobile accidents fall generally into two categories: focal brain injuries and diffuse brain injuries. Focal brain injuries occur as a result of head contact, or impact loading. Diffuse brain injuries occur as a result of sudden head motion, or inertial loading. Translation and rotation, independently or in combination, convey inertial loading. Diffuse Axonal Injury (DAI), in particular, has been linked to the presence of non-impact rotational acceleration during impact collisions (Gennarelli, 1993). Margulies, et al. (1990) subjected models of the skull-brain tissue structure to rotational accelerations of varying magnitudes. Results indicated that DAI, which manifests itself immediately after injury as a prolonged state of coma, may be experienced when the head encounters rotational accelerations on the order of 20,000 rad/s^2.

Although brain injuries usually result from a combination of contact loads and inertial loads, they can be produced by a single event such as pure head rotation. As such, measuring angular head acceleration is an important means of identifying injury potential. However, the current standard for measuring head injury potential in automobile collisions is the Head Injury Criterion (HIC), a value based upon the vector sum of translational accelerations in anthropomorphic dummy headparts. Angular accelerations alone have no affect on the HIC value.

Determining HIC in Cadaver Tests

Aside from its importance in assessing brain injury risk, angular head acceleration can be used in cadaver tests to find the HIC value. This is accomplished by attaching sensors to the outer surface of the cadaver's skull. The sensors measure the skull's angular velocity and acceleration (assuming the skull acts as a rigid body) and the linear acceleration of a point on the skull. This information is required to determine the acceleration of the cadaver head's center-of-gravity, which is then used to find the HIC value. In this manner, it is possible to compare HIC values derived in cadaver tests with those obtained in dummy tests.

MEASURING ANGULAR RATE

The angular velocity and acceleration of a rigid body can be measured using accelerometers arranged in an array, or with angular rate sensors. Several methods have been reported, such as a 3-2-2-2 accelerometer array described by Padgaonkar et al. (1975), a 3-3-3 accelerometer array described by Nusholtz (1993), and the use of three angular rate sensors described by Laughlin (1989).

The 3-2-2-2 Array

Padgoankar describes a method of measuring angular acceleration of a rigid body using nine accelerometers positioned in a 3-2-2-2 pattern. This configuration consists of a tri-axial accelerometer group at the body origin, and three pairs of accelerometers positioned at some distance on the three mutually orthogonal body axes. The appeal of this scheme lies in the parallelism of the three matched pairs of accelerometers which allows cancellation of the Coriolis components of angular acceleration. This leaves only the differences between the various pairs of accelerometer signals and their separations along the axes as the direct determinators of the angular acceleration components at each point in time.

The 3-3-3 Array

Nusholtz describes a measurement system of nine accelerometers arranged in a 3-3-3 array. This scheme applies spherical geometric analysis which exploits the topology of the sphere in its approach. Three tri-axial accelerometer groups are positioned in a circular pattern in manner that allows both angular acceleration and angular velocity to be obtained by manipulating the output from the linear accelerometers.

Nine accelerometer array schemes can be used to measure HIC and angular head acceleration. DiMasi (1995) illustrates how Padgoankar's 3-2-2-2 accelerometer array can be mounted within a Hybrid III head, and Nusholtz et al. (1985) has demonstrated how a 3-3-3 accelerometer array can be mounted to a cadaver head.

MHD Angular Rate Sensors

The recent development of a magnetohydrodynamic (MHD) angular rate sensor has generated new possibilities for measuring angular acceleration. MHD sensors, which measure angular velocity, have four components: the permanent magnet, the electrode areas, the conductive fluid, and the case. The conductive fluid lies in a constrained annular region within the field of the permanent magnet, which is attached to the case. The sensitive axis of the unit runs through the center of the annular region, perpendicular to the plane of the annulus. As the instrument rotates about the sensitive axis, the case, permanent magnet, and magnetic field rotate producing a magnetic field, ***B***. The conductive fluid, however remains stationary with respect to its own reference frame producing a relative motion, ***U***, between a magnetic field and a conductor. This motion produces a voltage, ***E***, governed by the relationship:

$$\boldsymbol{E} = \boldsymbol{U} \times \boldsymbol{B} \qquad [1]$$

Laughlin demonstrated that MHD sensor output (angular velocity) may be numerically differentiated to obtain accurate angular acceleration data. In his tests, data was collected from impacts of a Hybrid III dummy head fitted with both an MHD angular rate sensor and a 3-2-2-2 accelerometer array. Angular acceleration obtained by differentiating MHD sensor output was a close match to that obtained from the 3-2-2-2 array.

The MHD sensors used in Laughlin's tests were developed by Applied Technology Associates, Inc. (ATA) of Albuquerque, NM and are marketed as model number ARS-01. ATA has since developed an orthogonal set of three MHD sensors housed in a single 3.18 cm x 3.18 cm x 4.06 cm aluminum cube. This cube, referred to as the Dynacube, weighs 86 grams and furnishes separate measurements of angular velocity about three orthogonal axes. Furthermore, accelerometers can be mounted on the aluminum case to provide a 6-degree-of-freedom system. However, the Dynacube has only about half the dynamic range and half the resolution of the ARS-01.

Using Dynacubes to find angular acceleration

At the University of Virginia (UVa), an effort is being made to incorporate head response measurements using Dynacubes into dummy and cadaver impact tests. UVa already uses Dynacubes to measure foot and ankle rotation of dummies and cadavers in dynamic sled tests (Hall et al., 1996). Dynacubes have also been used by Klopp et al. (1995) at UVa to record whole-body rotation in tests involving the Side Impact Dummy (SID).

Rather than using a nine accelerometer array, UVa is considering extending the use of the Dynacube to determine angular head acceleration. A Dynacube is easy to mount and handle, it is light-weight and compact, and it does not greatly influence the movement of the body part upon which it is attached. Moreover, the HIC value and angular head acceleration can be evaluated using three accelerometers mounted to one Dynacube for a total of just six data channels.

VALIDATION OF MEASUREMENT METHODOLOGY

Notwithstanding Laughlin's reported success using the ATA model ARS-01 MHD sensor to determine angular acceleration in an impact environment, the effectiveness of the Dynacube, given its lower resolution and lower dynamic range, is not as certain. Therefore, UVa has developed a test fixture that generates predictable angular velocities and accelerations of similar magnitude to those seen in head impact tests against which sensor output may be compared. The test fixture consists of a torsional pendulum that is capable of handling various angular rate measuring instruments, including a Dynacube.

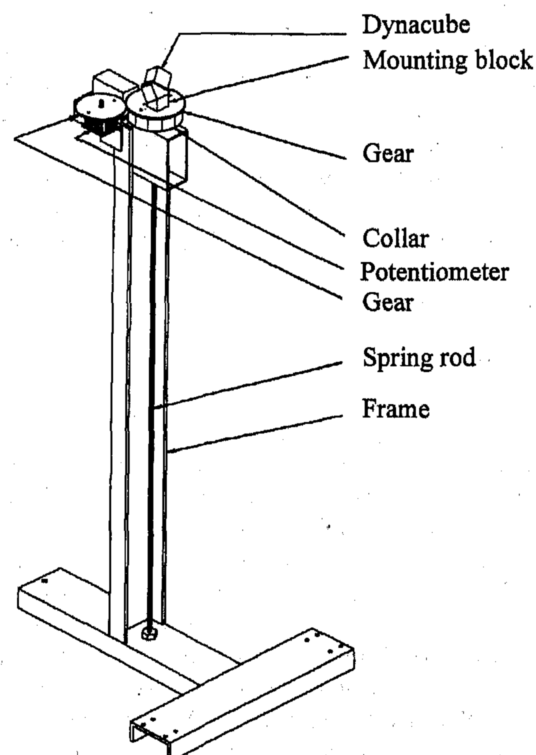

Figure 1. Torsional pendulum.

Torsional Pendulum

The torsional pendulum is a single-degree-of-freedom system constrained to rotate about its axis. When the pendulum disk is rotated and released suddenly, it undergoes free vibration that follows a simple damped harmonic motion. The device is used to compare the output of a three-axis Dynacube (or other rate sensors) with the theoretical response of the harmonic system. The pendulum also serves as a means to check sensor outputs for any signal irregularities.

Description of the pendulum

The pendulum is a very simple mechanical structure consisting of the following components:

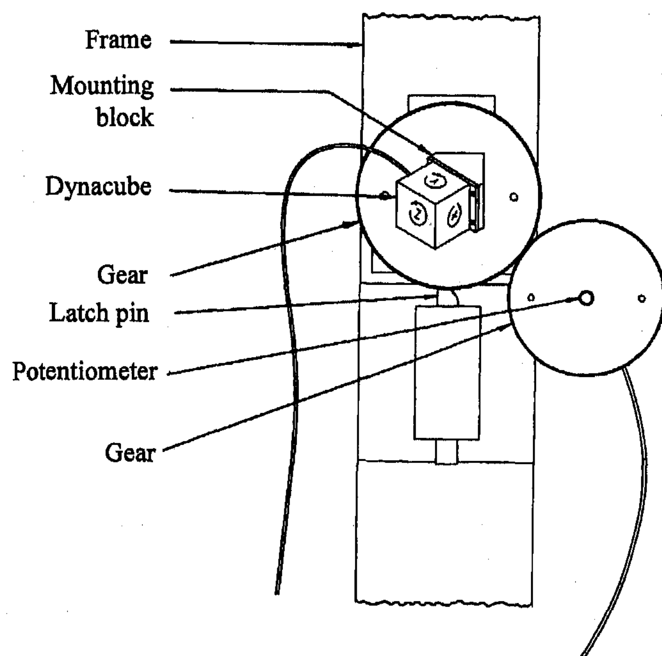

Figure 2. Top View of Pendulum.

Frame - Constructed of steel channels, the rigid frame houses the pendulum spring. Radial bearings built into the frame constrain motion of the spring to rotation about its axis only. The size and weight of the frame assure that it will not vibrate significantly as energy is released by the oscillating pendulum.

Spring Rod - A 3-meter long steel rod provides the system with enough stiffness to produce angular accelerations up to 20,000 rad/sec². Rods of various diameters may be interchanged to produce different frequencies.

Collar - The collar, or pendulum disk, is bolted directly to the top end of the spring rod. Markings on the collar allow the amplitudes of the pendulum to be easily tracked by a high speed video camera positioned above the apparatus. The collar also provides a surface onto which the Dynacube (or other instrumentation) may be mounted.

Potentiometer - The collar is connected by gears to a rotary potentiometer. Potentiometer measures the position of the collar and serves as a check against the theoretical predictions and Dynacube data.

Mounting block - The block enables the Dynacube to be mounted so that all three of its axes form an equal angle with the pendulum's axis of rotation. When mounted as such, each Dynacube axis should produce the same response. Thus, the pendulum serves as a means to check the Dynacube's sensitivity factors, and enables them to be adjusted if needed.

Latch pin - Upon setting the collar at an initial angle of twist, the collar is released suddenly by disengaging the latch pin. This sends the pendulum immediately into a state of free vibration.

Theoretical response

The movement of the pendulum is assumed to obey simple harmonic motion subjected to viscous damping. The equation for the angular position as a function of time for the free vibration of such a system is:

$$\theta(t) = \mathrm{Exp}(-\zeta\,\omega_n\,t)\cdot\{\theta_0\,\mathrm{Cos}[\omega_d\,t] + ((\zeta\,\theta_0\omega_n + \dot{\theta}_0)/\omega_d)\,\mathrm{Sin}[\omega_d\,t]\} \quad [2]$$

where:

ω_n = Natural frequency of the pendulum
ω_d = Damped natural frequency
θ_0 = Initial angular position (angle of twist)
$\dot{\theta}_0$ = Initial angular velocity
ζ = Damping factor

The damped natural frequency is related to the undamped natural frequency by:

$$\omega_d = \sqrt{1-\zeta}\;\omega_n \quad [3]$$

and the initial position, θ_0, is set by adjusting the position of the latch pin. The initial velocity, $\dot{\theta}_0$, is zero since the pendulum is released from rest. Moreover, it is possible to calculate the natural frequency of the pendulum from the spring constant, mass, and moment of inertial of its components. These values can be obtained either experimentally or from published material property lists.

Unfortunately, damping arises in a manner that does not allow the damping factor to be determined directly. Damping in the pendulum results from looseness of joints, internal damping in the spring rod, friction within the bearings, and does not result from some viscous dashpot. It is not possible to treat all of these forms of damping. However, since the amplitude of the vibration follows an approximately exponential decay, viscous damping is used in the mathematical model of the system.

The angular velocity and angular acceleration is determined by taking the time derivative of the position:

angular velocity - $$\dot{\theta}(t) = \frac{d}{dt}\theta(t) \quad [4]$$

angular acceleration - $$\ddot{\theta}(t) = \frac{d^2}{dt^2}\theta(t) \quad [5]$$

Pendulum Operation

Operation of the pendulum is simple. A Dynacube is affixed to the mounting block and the block is attached to the pendulum collar. The collar is rotated to a given angle and held in place by the latch pin. The collar may be rotated to any angle up to 45°, and variations in the angle of rotation may be used to control the amplitude. The latch pin is then quickly disengaged, sending the pendulum into a state of free vibration. As the pendulum oscillates, the rotary potentiometer tracks its position. Meantime, a high-speed camera (Kodak Ektapro model 1012) operating at 10000 frames per second captures the event on video tape.

Data Analysis

Data analysis is performed on three levels: displacement, velocity, and acceleration. Displacement analysis is performed first, with the validity of the potentiometer data verified against the high-speed video data. Since the pendulum displacement is measured directly by two independent sources, it is on this level that the parameter constants for the equation of motion of the pendulum are determined. Parameter constants are initially estimated from the material properties of the pendulum, and then adjusted so that the theoretical response fits the potentiometer/camera data. These same constants are subsequently used in analyses at the velocity and acceleration levels.

At the velocity level, Dynacube data is compared with potentiometer data and the theoretical response. First, the potentiometer data is differentiated using a 3-point differentiation scheme, and then digitally filtered using a 2-pass second order Butterworth algorithm evaluated at 200 Hz. Then, the Dynacube data is analyzed for consistency. All three Dynacube channels should have identical output. If they do not, it indicates one or more calibration factors need to be adjusted. In this fashion, the pendulum serves as a means to check angular rate sensors for any signal irregularities and determine correction factors.

After the calibration factors are adjusted, all three Dynacube outputs should be nearly identical to each other and to the differentiated potentiometer data scaled by $\sqrt{3}$. Finally, the corrected Dynacube data must be transformed from the local Dynacube reference frame to the collar reference frame using the following transformation:

$$\begin{bmatrix} X_{COL} \\ Y_{COL} \\ Z_{COL} \end{bmatrix} = \begin{bmatrix} X_{MHD} & Y_{MHD} & Z_{MHD} \end{bmatrix} \cdot \begin{bmatrix} Cos(\alpha) & Sin(\alpha)\cdot Sin(\beta) & Sin(\alpha)\cdot Cos(\beta) \\ 0 & -Cos(\beta) & Sin(\beta) \\ -Sin(\alpha) & Cos(\alpha)\cdot Sin(\beta) & Cos(\alpha)\cdot Cos(\beta) \end{bmatrix} \quad [6]$$

where α and β define the orientation of the Dynacube with respect to the collar. The rotation angles formed by attaching the Dynacube to the mounting block are:

α = rotation about the y-axis = 45°
β = rotation about the x-axis = 35.26°

When using the mounting block, X_{COLLAR} and Y_{COLLAR} should approach zero after the transformation is complete.

At the acceleration level Dynacube data is again compared with the theoretical response and potentiometer data. The potentiometer output is differentiated and filtered a second time. The three corrected Dynacube outputs are first differentiated using a 3-point differentiation scheme, then digitally filtered using a 2-pass second order Butterworth algorithm, and finally transformed to the collar reference frame.

RESULTS

Results for a typical test are shown in Figures 3 - 6. Figure 3 shows the pendulum displacement time-history. The potentiometer data and the fitted theoretical data are close, but not a perfect match due mainly to the fact that the damping is not purely viscous.

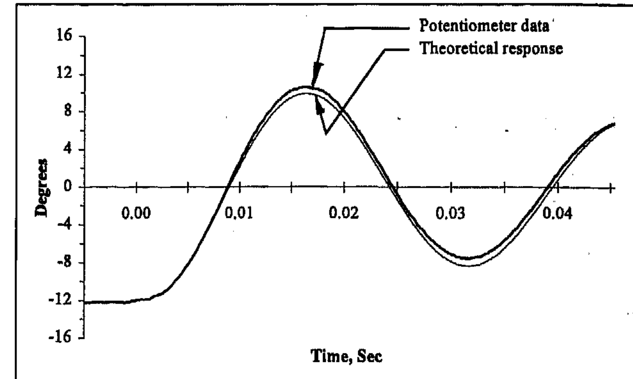

Figure 3. Angular displacement.

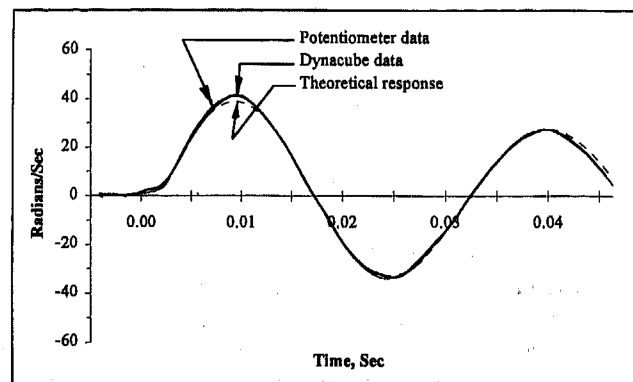

Figure 4. Angular Velocity

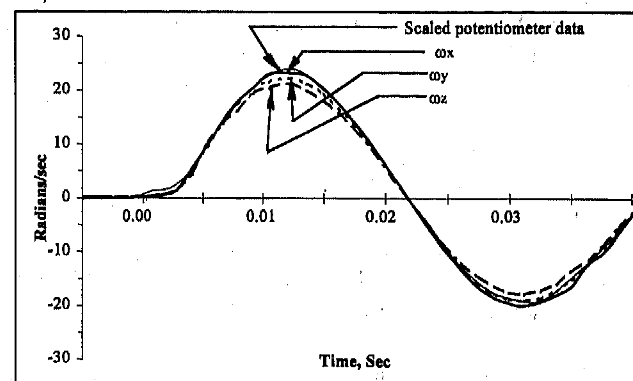

Figure 5. Dynacube output.

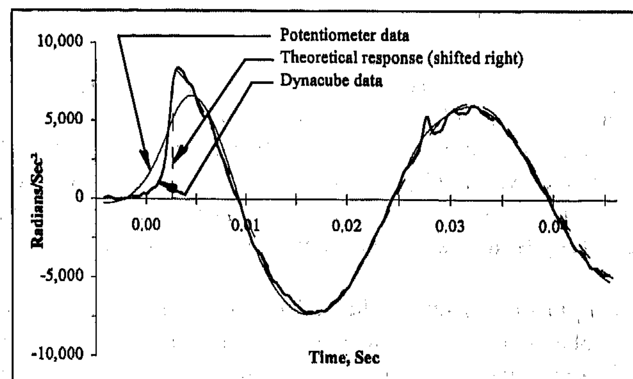

Figure 6. Angular acceleration.

Figure 4 shows the Dynacube output for the test and illustrates a slight variance in the amplitudes of each channel. Changing the position of the Dynacube on the mount and re-running the test at different speeds and frequencies verified that the inconsistent output was caused by inaccurate Dynacube sensitivity factors, and not a consequence of out-of-plane movement in the pendulum due to looseness in bearings and joints. The output was adjusted so that all three outputs most closely matched each other and the potentiometer data.

Figure 5 shows the pendulum velocity time-histories obtained from three sources: Dynacube data corrected and transformed to the collar reference frame; potentiometer data differentiated and filtered at 200 Hz; and the theoretical response. There is almost a complete overlap of Dynacube and potentiometer data indicating that the Dynacube works very well in measuring angular velocity.

Figure 6 shows the pendulum acceleration time-history of the three sources: Dynacube data corrected, differentiated, filtered at 600 Hz, and transformed to the collar reference frame; potentiometer data differentiated twice and filtered at 100 Hz; and the theoretical response. The theoretical response has been shifted manually to the right to be in phase with the Dynacube and potentiometer data. The out-of-phase condition occurs during the brief moment when the latch pin disengages from the collar.

The data match is not as precise as that seen on the velocity level, but it is still very close, particulary between the Dynacube and the theoretical response at the initial peak. The initial acceleration peak is oftentimes the highest in actual head impacts. This peak has been lost in the potentiometer data due to the heavy filtering.

Other tests were performed using the same Dynacube at higher and lower pendulum frequencies and amplitudes. In all cases, Dynacube data differentiated and filtered at 600 Hz produced a good correlation with the theoretical angular acceleration, like that seen in Figure 6.

Dynacube Application

A dummy head drop test was conducted to determine if the pendulum response is representative of an actual impact. The behavior of a Dynacube in an actual head impact was also examined. The test was configured so that angular motion was constrained to the head's y-axis. A Dynacube was placed inside the dummy head, and three linear accelerometers were affixed to the Dynacube to produce a 6-degree-of-freedom measurement system.

In Figure 7, the unfiltered vs. filtered (600 Hz) Dynacube output is shown. The frequency and amplitude are similar to those that can be produced by the pendulum, confirming that the pendulum can provide an impulse comparable to an actual head impact. As in the pendulum tests, the 600 Hz filter is seen to remove only the very high-frequency components. The actual angular acceleration of the head is unknown, but an analogy with the pendulum test would indicate that it is very close to the filtered Dynacube data. As a final note, this head impact was considered moderate by the current head injury standard: the calculated HIC value was 570.

CONCLUSIONS

The measurement of angular acceleration in head impact studies has gained recognition as an important indicator of head injury potential. Although there are several methods of measuring angular acceleration in a rigid body, no standard measurement protocol has yet been recognized by all testing agencies.

Differentiated output from a Dynacube, an angular rate sensor marketed by ATA, Inc., simplifies the measurement of angular head acceleration in impact tests because it is compact, easy to handle, and requires only three data channels. However, limited information was available on the reliability of differentiated Dynacube output. UVa therefore constructed a torsional pendulum to study Dynacube output and to develop a measurement protocol to determine angular acceleration. Two important findings came out of this study:

1. Dynacube output filtered at 600 Hz provides a good measure of angular acceleration for head impacts in automobile crashes.

2. Although the three orthogonal Dynacube outputs are not always consistent with one another, the pendulum can be used to determine appropriate correction factors.

Future analyses of head, limb, and torso kinematics in crash tests may be expanded by using angular acceleration measurements determined with Dynacubes.

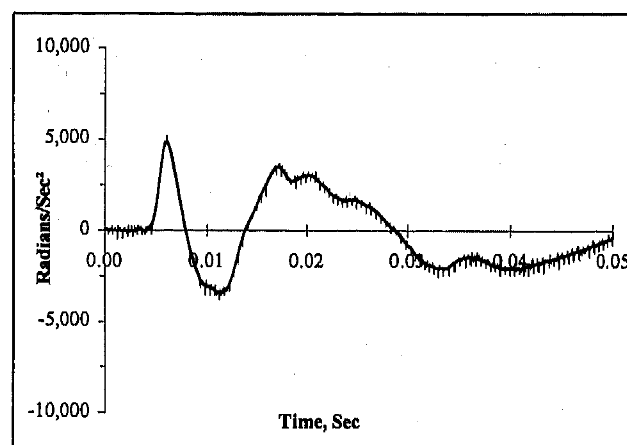

Figure 7. Dynacube output from head drop test. Filtered vs. unfiltered data.

ACKNOWLEDGMENTS

The angular rate sensor analysis and measurement methodology was supported in part by the Ford Motor Company and the University of Virginia School of Engineering and Applied Science. Angular rate sensors were provided by ATA, Inc.

ABSTRACT

The application of aluminum Body-In-White has several technical barriers in press forming, joining, and chemical conversion treatment processes. Among them, the optimization of joining processes with which structural stiffness and durability will be assured might have the key role for the success of aluminum applications to BIW.

In this study, stiffness, strength and fatigue strength of BIW joints with aluminum sheets were evaluated as a function of joining methods, such as resistance spot welding and weld bonding, via both experimental and analytical routes(FEM). For the evaluation, single-lap joint and T-shaped joint were made, with each joining method, as variation of pitch, sheet thickness and even materials - steel sheets.

Based on the experimental and FEM analysis results, the optimum joining method for the aluminum BIW which is suitable for weight saving and has equivalent stiffness and strength to steel is suggested. In addition, for obtaining optimum processes with improved stiffness and strength of the joining method, design parameter, such as the influence of the spot pitch on the structural joint stiffness and the minimum wall thickness of aluminum which is able to maintain the equivalent stiffness and strength to steel are discussed.

INTRODUCTION

The automotive body which maintains the shape of a vehicle and has to endure the interior and exterior load is comprised of many joints. Since the structural joint stiffness, especially between pillar and rocker, pillar and roof rail affects not only the body stiffness(such as bending or torsional stiffness) but also body strength, vibration, and crash characteristics, it is an important factor to be considered carefully in designing of a vehicle.[1,2]

In the case of aluminum body, the structural joint stiffness should be looked over more carefully, because of its difficulties in joining.

To get the equivalent structural joint stiffness of aluminum body with conventional steel body, it is the purpose of this study to investigate the relationship in the simple specimens between joint properties and process, such as spot pitch, sheet thickness, even adding adhesives(weld bonding) replacing conventional spot welding, via experimental and FEM. Weld bonding offers increased joint stiffness, more even load distribution, and improved fatigue performance. [3,4,5] In addition, because of insufficient open data for analyzing whole structural stiffness of real automotive body, FEM simulation for BIW with above mentioned process is performed.

SINGLE-LAP JOINT

First of all, parameter was evaluated with very simple model or specimens, such as single-lap joint as shown in Fig. 1. Aluminum 5xxx alloy for automotive body and mild steel sheets were used. (See Table 1) According to the plate theory, the stiffness of sheets are proportional to the cube of the thickness multiplied by the modulus of elasticity. Therefore, in order to achieve the same stiffness, the aluminum sheets would have to be about 1.4 times as thick as the steel one, making

it about half the weight.[2] The thickness of steel and aluminum sheets used for the evaluation of single lap joint were 0.7 mm, 1.0 mm respectively. The number of spot weld in aluminum sheets were two(spot pitch =80 mm), three (spot pitch = 40 mm) and five (spot pitch = 20 mm), and the number of spot weld in steel sheets were two and three.

Table 1 : Mechanical Properties of Aluminum and Steel

Property / Material	Elastic modulus (MPa)	Poissons ratio	density (kg/m³)	Yield strength (MPa)	U.T.S (MPa)	elongation (%)
Aluminum	7×10^4	0.33	2700	130	280	35
Steel	20.5×10^4	0.33	7800	180	320	45

SHEAR STIFFNESS - Fig. 2 shows analytical and experimental results of shear stiffness as a function of spot pitch in case of aluminum single-lap joint. As expected, for each spot pitch, weld bonded joint shows higher stiffness, while the difference in stiffness between weld bonded and spot welded joint increase with increasing spot pitch. This reason can be explained as : the local stress concentration in spot welded joint is able to be released by distributing the stress uniformly in weld bonded joint with adhesive layer. Because spot welded part is unbonded area in weld bonded joint, the part of local stress concentration decrease with the increase of the spot pitch, therefore, stiffness and strength will become higher.[3,4]

To confirm the experimental results, FEM analysis was developed, as shown in Fig. 3. A linear static analysis was performed using MSC/NASTRAN software. Various FE modeling have been used for the spot welded and adhesive bonded parts.[3,6,7] Among them, the adopted modeling method was as follows : In the spot welded structural model, 3-D linear quadrilateral shell element was applied for adherend sheet, and spot welded part was connected with rigid element, respectively. Then, bar element was inserted at the ends of the rigid element, In the weld bonded structural model, spring element that has three directional stiffness was adopted for adhesive layer.

As shown in Fig. 2, FEM analysis agrees well with experimental result. Therefore, this FE modeling method was also applied to T-shaped joint and structural joint of real automotive body, mentioned in next section.

STATIC STRENGTH - Table 2 gives the optimized welding conditions. An adhesive used in weld bonding was single component, heat cured epoxy type. Its curing was completed at 170℃ for

30 minutes. Table 3 shows the general properties of the adhesive.

Fig. 4 exhibits lap-shear strengths of single lap joint vs. spot pitch, in a similar manner as showed in Fig. 2. For comparison, data for steel sheets were also plotted.

Table 2 : Welding Parameters

parameter / material	Welding current(kA)	Welding time(cycle)	Electrode force(kN)
Aluminum	28.0	9.0	3.43
Steel	8.5	15.0	2.45

Table 3 : Properties of Adhesive

Viscosity (cps/20 °C)	Specific gravity (20 °C)	Shear stress (MPa)	Young's modulus (MPa)	Poissons ratio
10^6	1.62	27.0	4.83×10^3	0.33

FATIGUE - Results of fatigue strength of single-lap joint performed under the condition of R = 0(where, R = min/max load) and 70Hz frequency were shown in Fig. 5. Increasing number of spot weld caused improved fatigue performance, while a little moderate decreased fatigue strength was obtained in weld bonded aluminum sheets. This phenomenon might be quite consistent with the results of shear stiffness and strength.

The superior fatigue strength of weld bonding was proved quite well even in aluminum sheets when compared with the results of conventional spot welded steel sheets. (even 3 times higher)

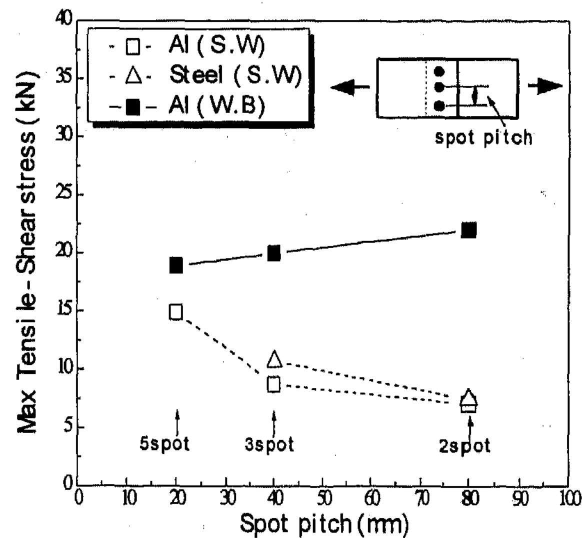

Fig. 4 : Static Lap - Shear Strength of Single Lap Joint

T-SHAPED JOINT

Automotive body structures are comprised of structural joints of various shapes. The configuration of the structural joints connecting structural members are classified into three typical shapes, such as L-shaped joint as Rocker Panel to

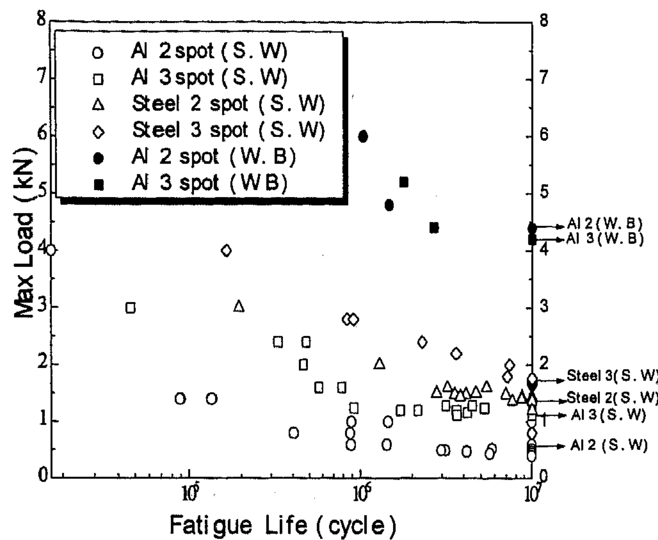

Fig. 5 : Fatigue Test Results of Single-Lap Joint

Front Pillar, T-shaped joint as Rocker Panel to Center Pillars, and Y-shaped joint as Front Pillar to Roof Rail. Among them, T-shaped joint was selected, for the joint requires higher stiffness and strength than the other two shapes. The structural joint stiffness was obtained analytically (FEM) and experimentally as variation of joining parameters : spot pitch, sheet thickness and joining method as summarized in Table 4.

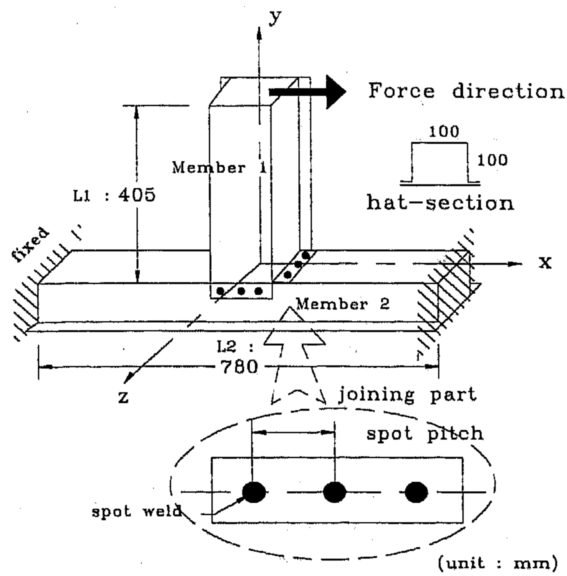
35 ● ● ●	S. W W. B	S. W	S. W
70 ● ● ●	S. W		

THE METHOD OF FEM ANALYSIS AND STRUCTURAL JOINT STIFFNESS TEST - The shape of T-shaped joint and boundary condition are shown in Fig. 6 and FE model of T-shaped joint is shown in Fig. 7. The shape of T-shaped joint was simplified to be handled easily. FE model shown in Fig. 7 describes T-shaped joint of spot welded aluminum. FE model of spot welded part and weld bonded part was equal to the model applied to single lap joint described already.

Structural joint stiffness is classified into three values : In-plane bending stiffness, Out-plane bending stiffness and Torsional stiffness. In this paper, however, only In-plane bending stiffness was measured in order to compare analytical results with experimental ones easily. According to the previous research[8], structural joint stiffness(K_j) was defined as follows.

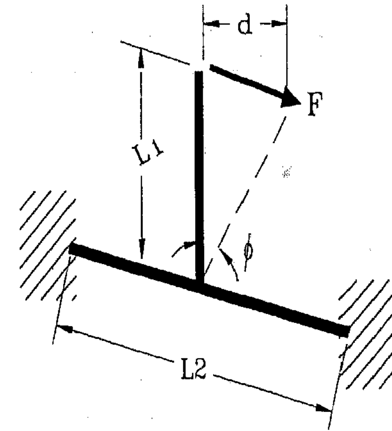
$$\frac{1}{K_t} = \frac{1}{K_j} + \frac{1}{K_1} + \frac{1}{K_2} \qquad (1)$$

$$K_t = \frac{F \cdot L_1}{\Phi} \quad \text{at tip : Global stiffness}$$



$$K_1 = \frac{EI}{L_1} \quad \text{: rotational stiffness of member1}$$

$$K_2 = \frac{8EI}{L_2} \quad \text{: rotational stiffness of member2}$$



In Eq.(1), 1, 2, and j denotes member 1, 2 and joining part respectively. Eq.(1) represents that the work done by external force is equal to the sum of energy stored in member 1, 2 and joining part. Therefore, the structural joint stiffness of T-shaped joint, K_j, in Eq.(1) was calculated by FEM analysis as a function of joining parameters in Table 4.

To check the validity of the FEM analysis result, structural joint stiffness test was performed under the same joining parameters as with analytical method. The schematic drawing of the stiffness test apparatus are shown in Fig. 8. Spot welded and weld bonded portions of T-shaped joint specimens were made under the same condition as described for single lap joint.

RESULTS AND DISCUSSION - Results of structural joint stiffness from analytical and experimental method in T-shaped joint are shown in Fig. 9 and 10 with various spot number and sheet thickness. Fig. 11(a) shows global deformation of T-shaped joint as a result of analysis and Fig. 11(b) shows local buckling that happens in joining part as a result of experimental test. It is seen from Fig. 9 and Fig. 10 that structural stiffness of T-shaped joint is proportional to sheet thickness and spot number, and joint

(a) geometry and dimension
(in case of 3 spot welding)

(b) boundary condition

Fig. 6 : The Geometry and Dimension of T-shaped Joint

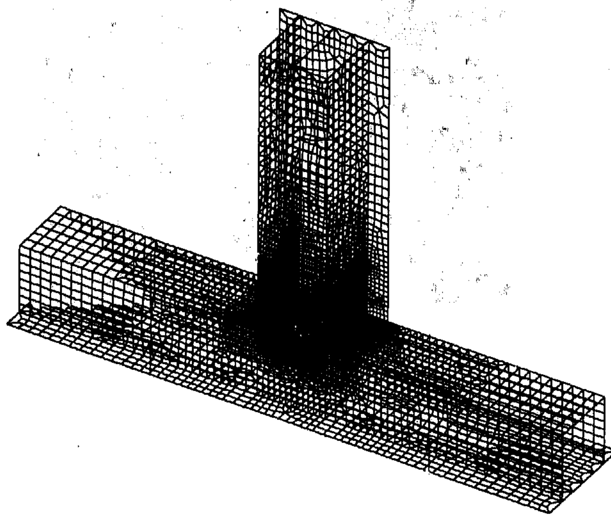


Fig. 7 : FE model of T-shaped Joint

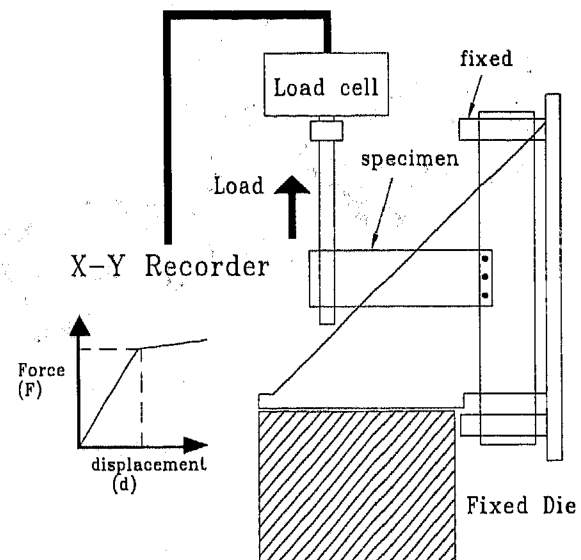

Fig. 8 : Equipment of Structural Joint Stiffness Test

stiffness was more affected by sheet thickness, which is contributed to strengthening base material, than spot number in spot welding. In other words, joint stiffness is more affected by strengthening of base material than increase of spot number. Fig. 11(b) shows base material fractured near spot welded part, and make the phenomenon clear. Therefore, the increase of sheet thickness is more effective to enhance joint stiffness than the increase of spot number in spot welding.

Comparing the joint stiffness of 1.0 mm thick aluminum with that of 0.7 mm thick steel under three welded spot from Fig. 9, it can be noticed that the stiffness of spot welded aluminum and

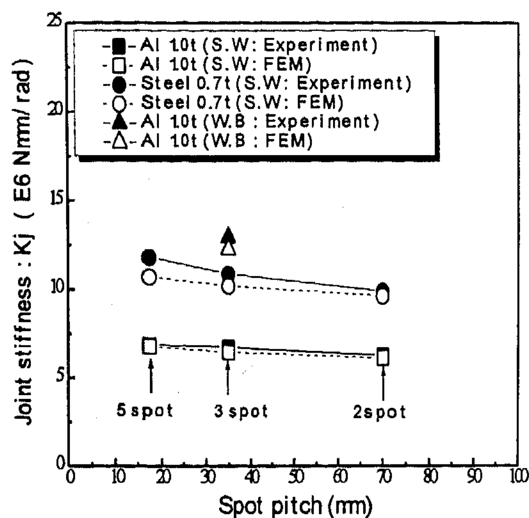

Fig. 9 : Effect of Spot Pitch on the T-shaped Joint Stiffness

(a) overall deformed shape (FEM)

(b) local deformed shape (Experiment)

Fig. 11 : Deformed Configuration of T-shaped Joint

weld bonded aluminum amount to 62% and 119% of steel, respectively. This indicates that, stiffness of weld bonding is about two times higher than that of spot welding, as in the case of single lap joint. This result is in accordance with FEM analysis.

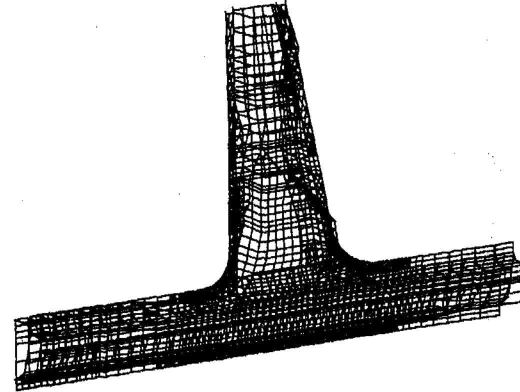
In spot welded aluminum, the thickness of aluminum with equivalent stiffness to steel(at 0.7 mm gauge) should be 1.4 mm, not 1.0 mm predicted in plate theory as shown in Fig. 10. These results are compatible with the results obtained by analytical and experimental methods.

Table 5 shows the results of analysis and experiment with T-shaped joint. It can be seen that the difference between the two results is within 10%, thus we can confirm the compatibility of FEM analysis.

APPLICATION TO BIW STRUCTURAL JOINTS

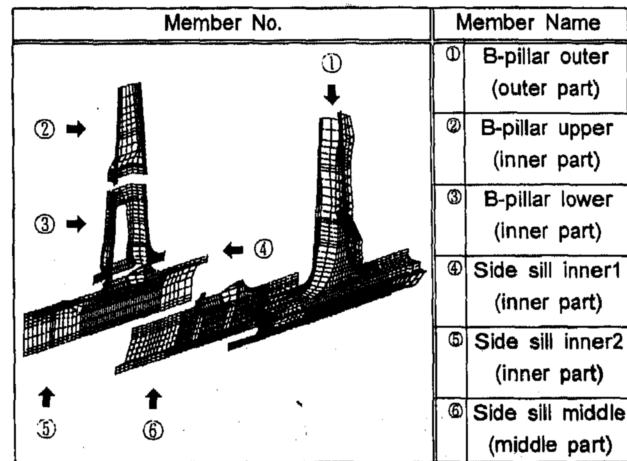
The study for simple specimens such as single lap joint and T-shaped joint is unpractical for real BIW, so we need to study real body joint of BIW. In this section, structural stiffness of real body joint

Table 5 : Comparison between FEM and Experiment (in case of spot pitch = 35 mm)



Joining Parameters \ Stiffness			Structural Joint Stiffness ($\times 10^6$ N·mm/rad) FEM (A)	Experiment (B)	difference(%) (A-B)
Al	1.0t	W.B	12.2465	12.9224	-5.23
		S.W	6.4455	6.7380	-4.34
	1.5t	S.W	11.4705	10.8519	+5.70
	2.0t	S.W	16.6530	15.6509	+6.40
Steel	0.7	S.W	10.1887	10.8599	-6.18

and BIW was obtained by FEM analysis as functions of sheet thickness, spot number and joining method. Based on the results, the optimized joint design for aluminum BIW with minimum weight to obtain the equivalent value of stiffness to steel is suggested.



STRUCTURAL JOINT STIFFNESS OF B-PILLAR - As a structural joining part of real automotive body, Center pillar to Rocker Joint(B-pillar Joint) was considered in the present investigation for a real model of T-shaped joint. FE model and the construction of B-pillar joint were shown in Fig.12. As shown in Fig 12(b), B-pillar joint is made of six part members.

For designing sheet thickness, four types of B-pillar joint with various part thickness were analyzed. The first and second type were designed to increase uniformly the thickness of inner part and outer part, respectively. For the third type, the thickness of both parts increased uniformly and for the fourth type, based on theresult of analysis, the thickness of parts which have lower stiffness than other parts increased locally.(Fig. 12 : member no. ①, ③)

Fig. 13 and Fig. 14 show the results of FEM analysis. Joint stiffness of B-pillar joint with various spot pitch is plotted in Fig. 13, in which stiffness equivalent sheet thickness is considered for aluminum and steel sheets.(t_{Al} = 1.4 t_{steel}) It can be seen that the decrease in joint stiffness of spot welded B-pillar and the increase in weld bonded B-pillar are found as increasing spot pitch. The stiffness of spot welded aluminum amounts to 57% of steel at 25 mm spot pitch even though aluminum is 1.4 times thicker than steel. On the contracy, weld bonded aluminum shows higher stiffness than steel as shown in Fig. 13, which is also consistent with the results of T-shaped joint.

(a) FE model

(b) construction of B-pillar joint

Fig. 12 : FE model of B-pillar Joint

The plate theory assumes that the section is constant throughout the whole region and that joining part does not exist. The local deformation and the effects of joining would, therefore, be neglected. A real automotive body, however, has various section and joining part, so the local deformation in the area of low stiffness and the effects of joining are not negligible and sometimes substantial.

In Fig. 14, relative joint stiffness of aluminum to steel sheets is plotted as a function of relative mass to investigate the stiffness equivalent sheet thickness of various aluminum sheets. In this figure, weight reduction can be notified quickly depending on joining method and thickness variation of inner and outer parts.

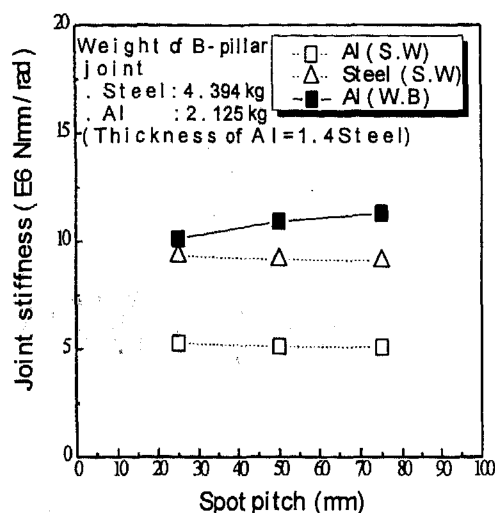


Fig. 13 : Effect of Spot Pitch on the B-pillar Joint Stiffness

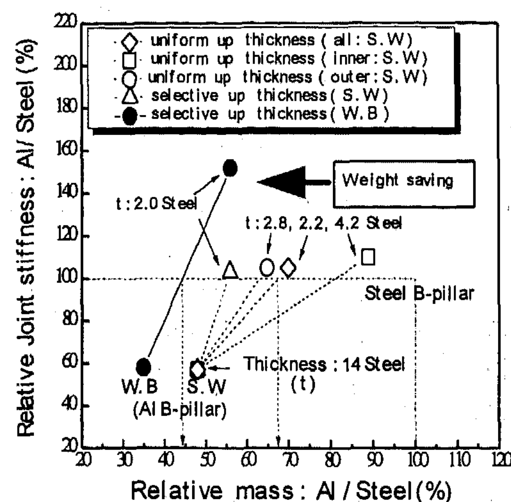

Fig. 14 : Effect of Sheet Thickness on the B-pillar Joint Stiffness (spot pitch = 25 mm)

In spot welding, thickness variation of inner parts(—□—) is the least effective, and thickness variation of local parts(—△—) is the most effective in terms of weight reduction and performance.

In weld bonding, increasing thickness of sheets improves the structural joint stiffness of aluminum B-pillar remarkably, thus, stiffness equivalent sheet thickness of aluminum would be 1.2 times of steel one.

Consequently, local reinforcement of sheets thickness is desirable for both conditions of joining method. And weld bonding would be strongly recommended, if optimum process for the increasing productivity is developed.

STRUCTURAL STIFFNESS OF BIW - Overall stiffness of BIW as a whole, depends on whether it is mainly a frame assembly or a monocoque construction, but even so, in all types of structure, the contribution of the individual joint stiffness to the overall stiffness varies widely. Individual joint stiffness is affected again by process, such as sheet thickness, joining method. It is, therefore, beneficial to investigate the relationship between overall stiffness of BIW and process in such a way as to attain maximum stiffness, via FEM analysis.

For the analysis of BIW stiffness, joint scheme is assured as shown in Fig. 15 to simplify the model.

First of all, FEM analysis was performed in which thickness of aluminum parts increased uniformly up to 1.4 times of thickness of steel. The result of the FE analysis indicated weak joining parts, such as rocker panel to center pillar joint, front pillar to roof rail joint and rocker panel to front pillar joint. After correction of sheet thickness of these weak joining parts, subsequent FE analysis was performed. It is, however, our restriction of this study that thickness should be maintained within 1 mm to 3 mm.

For the summary of the present investigation, Fig. 16 shows the relative bending stiffness of aluminum to steel BIW as a function of relative mass. Fig. 17 shows FE model and simulated deformed shape of aluminum BIW. In Fig. 16, weight reduction can be notified quickly depending on joining method and thickness variation as in the case of B-pillar joint. It is noticeable that for spot welded aluminum with uniform increase of thickness(—△—), the stiffness equivalent to steel is obtained with 70% of the weight of the steel, while for the weld bonded aluminum with selective increase of thickness(—■—), the stiffness equivalent to steel is obtained with 52% of the weight of the steel. Additional weight reduction of 18% is achieved when the spot welded BIW joint is replaced by weld bonding process. For the intensive weight reduction, extension of weld bonded region which mentioned in this investigation will be quite strongly recommended.

Fig. 17 : FE Model of Aluminum BIW

SUMMARY

1) Structural joint stiffness of aluminum sheet is more affected by sheet thickness than spot pitch, and it is more effectively increased by reinforcing the thickness of an individual sheet which was turn out to be a bit weak, via the analysis.

2) For the joining method, compared to the spot welding, weld bonding has more excellent property in stiffness and strength, especially in fatigue strength, because it enables the uniform stress distribution. The fatigue strength of weld bonded specimens is about seven times higher than that of spot welded ones.

3) Our FEM analysis showed that by optimizing sheet thickness of the part which has lower stiffness and applying weld bonding, the weight of aluminum with equivalent stiffness to steel is reduced to 44% of the weight of steel for B-pillar joint and 52% for BIW.

It is our concluding remarks that local reinforcement of an individual sheet thickness and application of weld bonding would be the most

effective way to improve stiffness, strength and durability of aluminum BIW if optimum process for the increasing productivity is developed.

ABSTRACT

The backlite molding squeak noise is caused by the stick-slip type of friction between the window molding and the body panel. To predict if the molding would squeak, a finite element analysis technique which uses the nonlinear explicit code LS-DYNA3D has been developed. The three dimensional finite element simulation technique is based on the threshold displacement, velocity spectrum and the relative movement of the window glass with respect to the body panel. Comparisons between FEA analysis and tests are also presented in this paper.

INTRODUCTION

The backlite molding noise is generated by the friction between the window molding and the body shell. The nonstationary and transient nature of the squeak noise makes it very difficult to be predicted.

To reduce and eventually eliminate the squeak noise, a simplest squeak generation mechanism model (plate-molding model) has been studied. In this model (figure 1), a plate oscillates in a specified frequency and amplitude to generate squeak noise. The model is used to calculate the threshold displacement which is defined as the critical plate displacement beyond which the relative movement at the contact point will occur. Secondly, the vibration frequencies of the molding which are excited by the stick-slip type of friction are calculated and compared with the critical radiation frequency of the backlite. Finally, the full vehicle analysis is employed to provide the excitation information for the squeak noise. The analysis procedure is outlined below:

1. Build a plate-molding model for the backlite molding and calculate the spectrum of the noise and the threshold displacement.
2. Calculate the critical radiation frequency of the backlite.
3. If the peaks in the frequency spectrum of the molding velocity are sufficiently offset from the critical frequency of the glass, the design will be accepted.
4. If sufficient offset does not exist, build a full vehicle model and calculate the relative displacement between the glass and the body shell.
5. If the relative displacement is less than the threshold, the probability that the molding will squeak is minimized. The design will be accepted. Otherwise, modify the design and calculate again.

PLATE-MOLDING MODEL ANALYSIS

A typical plate-molding model is shown in figure 1. It includes a 25 to 50 mm long molding strip and a plate which is used to push the molding and to generate the squeak noise. The molding is modeled using solid elements. The material properties of the PVCs, which include the Young's modulus, shear modulus, density and coefficient of friction are from material tests. The aluminum foil between the PVC and the rigid PVC is modeled with shell elements. The molding is fixed at the channel. The total number of elements is approximately 7000-8000. The size of the elements depends on the purpose of the analysis. For response analysis, the smallest element size is around 0.4 mm and for tip pressure analysis the element size around the tip of the molding strip is around 0.06 mm.

In the simulation process, the plate (either rigid or deformable) is first moved up toward the molding strip, so that the contact between the plate and the molding can be created. The plate is then vibrated horizontally to generate the squeak noise. The input of the analysis is the interference distance, amplitude and frequency of the vibration. The output of the analysis is the contact forces and the response of the molding.

1). CONTACT FORCE CALCULATION - Figure 2 and figure 3 show the contact forces in x (tangential) and z (normal) directions. At the first 10 milliseconds, the plate pushes the molding up and then vibrates horizontally with frequency of 15 Hz. After 10 milliseconds, the curve has peaks which represent the evidence that the molding and the plate stick together and plateaus which represent the friction slip. The

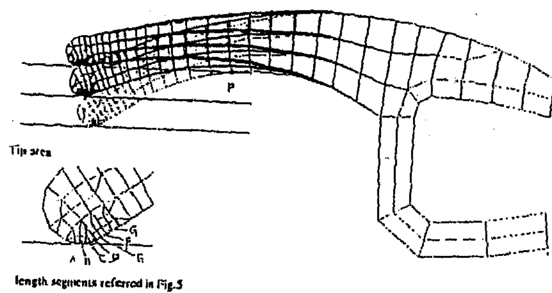

Figure 1: Plate-molding model

comparison of the average forces between FEA and a plate-molding test are shown in table 1. Although there are still differences in extension stroke, the contact forces generally agrees with the tests, which validate the FEA model.

Table 1: Comparison of FEA analysis and bench test

	Freq. (Hz)	Compression Stroke			Extension Stroke		
		Anal	Test	Dif.	Anal	Test	Dif.
Normal force (N)	15	4.0	3.8	5%	1.85	1.25	48%
	10	4.05	4.1	1%	1.95	1.6	22%
Tangential force (N)	15	6.4	6.5	2%	3.28	3.0	9%
	10	6.4	6.5	2%	3.2	3.0	7%

2). LIP PRESSURE ANALYSIS - Since the coefficient of friction is the function of contact pressure, it is suggested to conduct the friction tests at the pressure which is as close as possible to the reality. The FEA analysis shows that for a specified molding design, the contact length on a profile of the molding is around

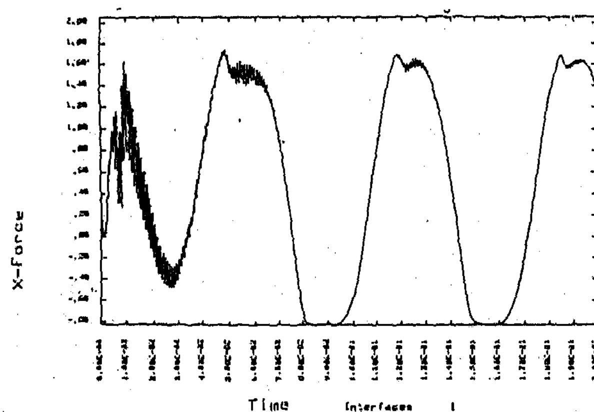

Figure 2: Contact force in x direction

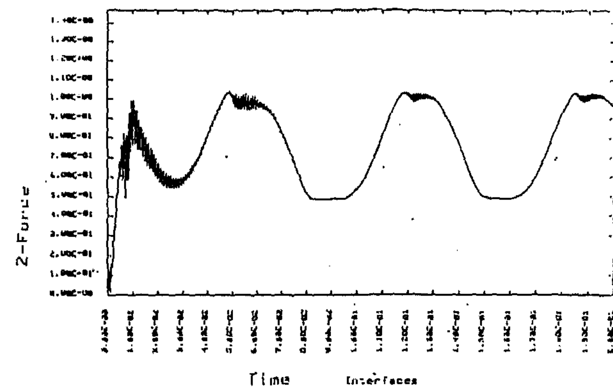

Figure 3: Contact force in z direction

0.2 mm. Figure 4 shows the pressure in the tip area vs. vertical displacement. A specific curve represents a specific length segment. The curve gives a full pressure time history for the segment. The maximum pressure can reach 0.413 MPa if the interference is 2 mm.

3). ANALYSIS OF THE RESPONSE OF THE MOLDING - Figure 5 shows the nodal displacement in x direction, where curve A represents the displacement of the plate which is actually the input and curve B is the nodal displacement at the tip point of the molding. The transition point from 'stick-state' to 'slip-state' are marked with 'T'. The displacement between the compression and extension transition point gives the analytical threshold value of the squeak noise for a particular frequency. If the full amplitude of the excitation, which in reality is the relative displacement of backlite and body shell, is less than the threshold value, there will be no transition from stick stage to slip stage or, in other words, there will be no squeak noise. In the design process, the configuration and the material employed should make the threshold value as large as possible, so that the excitation amplitude could be less

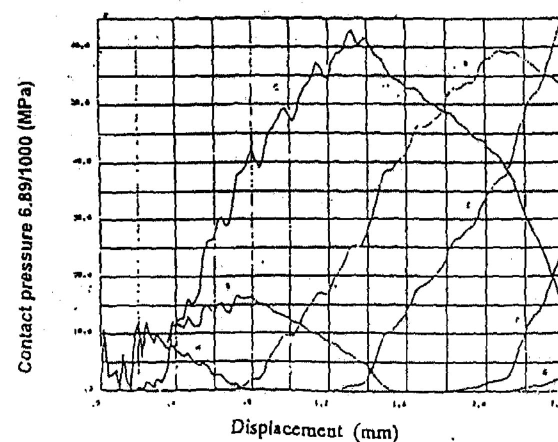

Figure 4: Pressure time history

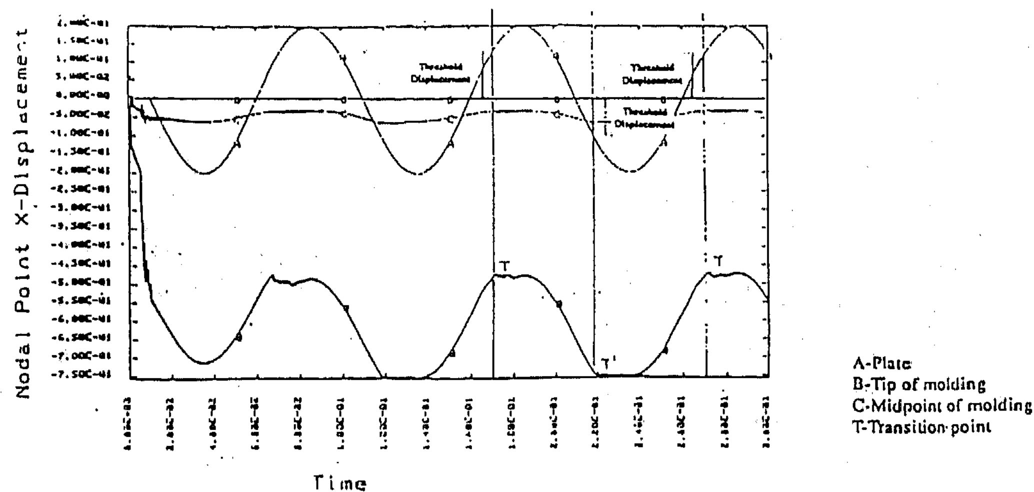

Figure 5: Nodal displacement in x direction

than the threshold. Theoretically, it is a sufficient condition by keeping the excitation amplitude under the threshold to avoid the backlite squeak noise. Table 2 gives a comparison of threshold between the analysis and test. In the table, the threshold of the test is defined as the current excitation amplitude of the plate when the molding begins to squeak. It shows that the analysis agrees with the test well.

Table 2: Comparison of the threshold between the analysis and test

Compression Stroke (mm)			Extension Stroke		
Anal.	Test	Dif.	Anal.	Test	Dif.
0.128	0.120	6.6%	0.11	0.106	3.7%

4). SPECTRUM ANALYSIS OF THE BACKLITE NOISE - In most of the cases, it may not be practical to control the relative displacement under the threshold value. Therefore, an alternative approach has to be found to control the noise. Since the squeak noise which a passenger could hear are mainly emitted from the backlite, reducing the noise intensity to the background noise level could be achieved either by eliminating the source of the noise or by controlling the transmission of the noise. For the backlite, or a curved panel, the noise radiation ratio varies according to the noise frequency. If

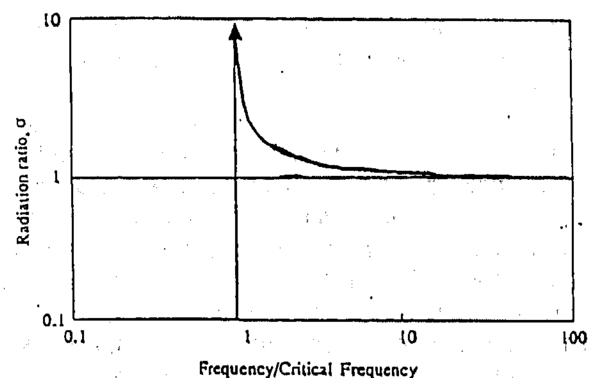

Figure 6: Radiation ratio vs. frequency for an infinite plate

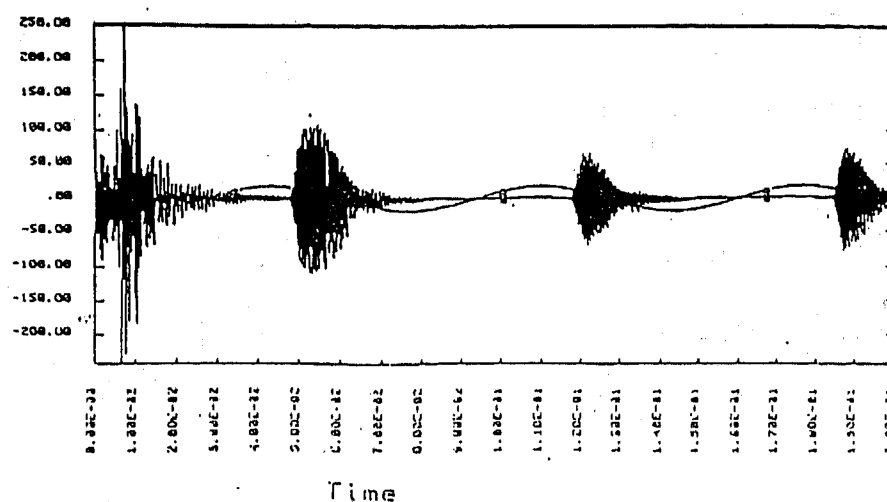

Figure 7: X-velocity of a point at the middle of the molding profile

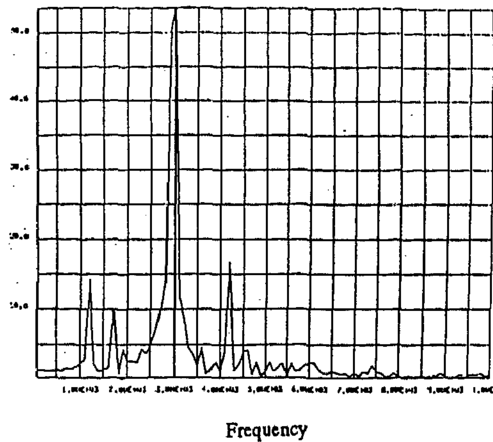

Figure 8: Spectrum of nodal velocity of design proposal 1

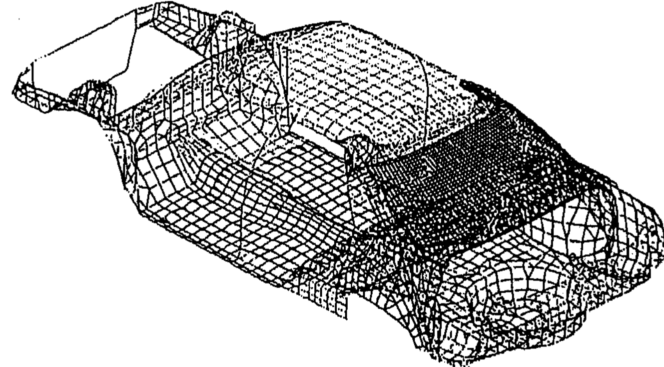

Figure 10: Simplified body in white model

it is an infinite plate, the critical frequency can be determined as:

$$f = \frac{c^2}{1.8t}\sqrt{\frac{\rho(1-\nu^2)}{E}} \qquad (1)$$

where c is the sound speed in air; ρ, E and t are the density, Young's modulus and the gage of the plate, respectively.

Figure 6 shows the relation of radiation ratio vs. frequency for an infinite plate. It is clearly depicted that if the frequency of noise is lower than the critical frequency, there is no sound radiation from the plate to the air. If the noise frequency is equal to the critical frequency, the radiation ratio becomes infinite. When the noise frequency is higher than the critical frequency, the radiation ratio becomes constant. Although the backlite, as a curved panel, does not behave that extremely, it still radiates sound very efficiently in a certain frequency range and relatively inefficiently out of certain frequency range. Considering the size of the backlite and the distance between a passenger and backlite, it is reasonable to first estimate the critical frequency by expression (1).

For a example, suppose the Young's modulus is taken as 61300 MPa, and the gage is 3.8 mm for a specific vehicle, the critical radiation frequency is 3065 Hz. Therefore, if the excited vibration of the molding has a central frequency which is close to 3065 Hz, the noise level will be very high. In other words, if the vibration frequency of the molding is far from 3065 Hz, the noise level could be low enough that it may not be able to be recognized from the background noise.

Figure 7 shows the velocity of the molding at point P (Fig.1). When there is a transition from stick-state to slip-state, there will be excited noises. Figure 8 and figure 9 show the spectrums of the noise for different molding design proposals. From Fig. 8, the spectrum curve of proposal 1 has a very high peak at 3000 Hz which is very close to the critical frequency of 3065 Hz. That means the noise could be radiated to air very

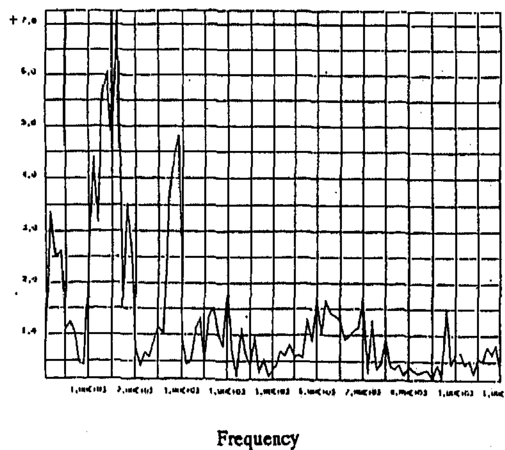

Figure 9: Spectrum of nodal velocity of design proposal 2

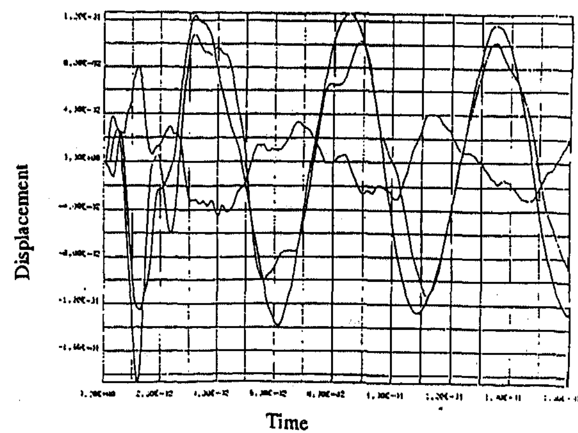

Figure 11: Relative disp. between body shell and backlite

efficiently. Another peak of the spectrum of proposal 1 is around 4200 Hz, which will also be radiated to air, although it is not as efficient as the 3000 Hz peak. Compared to proposal 1, the highest peak of proposal 2 is at 1600 Hz, which is far below the critical frequency. Therefore, the noise level will be greatly reduced since the radiation ratio is very low at that frequency range. There is another peak which is around 2900 Hz. But the amplitude is only 1/8 of proposal 1. Test results support this theory as there is no audible squeak noise for design proposal 2 while there is significant squeak noise for design proposal 1.

FULL VEHICLE ANALYSIS

The simplified Body-in-White Model has been modified to evaluate the body structure influence on the relative glass movement. The model is shown in figure 10. The model contains 10,000 elements. Among them, there are nearly 800 beam elements. To maker the analysis more accurate, the backlite is modeled with fine mesh and the urethane which connects the backlite and the body shell is modeled with solid elements. The input is a twisting displacement at the front shock tower. The amplitude of the input is 2 mm and the frequency is 20 Hz. Figure 11 shows the relative displacement between the body shell and the backlite at the left hand upper corner. From figure 11, the maximum relative displacement between the backlite and body shell is 0.12 mm. This data, together with the threshold displacement, can then be used to determine whether the molding will squeak or not.

CONCLUSION

1). A finite element analysis technique can be used to simulate and predict the backlite molding squeak. The method is based on the threshold displacement prediction, the velocity spectrum and the relative movement of the window glass to the body shell.

2). The explicit nonlinear dynamic code LS-DYNA3D and the software created in house are suitable for the study of the backlite squeak noise.

3). The analysis of the plate-molding model agrees with the test data for both the contact forces and the threshold displacements.

ABSTRACT

Current work develops and presents a clear methodology for all stages of adaptive structure design using a commercially available FE program. A procedure for replacing the induced strain actuation of the piezo-elements by mechanical forces is developed and validated numerically using the ANSYS^R coupled field piezoelectric 3-D solid elements, as well as experimentally. The use of reduced FE analysis as a spatial discretization tool for controller design is addressed and shown to be advantageous in many cases. Balanced order reduction schemes are applied to the discrete structural model in state space in order to ensure controllability and observability, as well as to maintain a low number of states for the controller design and implementation. Linear quadratic (LQ) and $\mathcal{H}_\infty$ controller designs are presented and implemented using computer simulations of the controlled structure. The methodology is applied to a simply supported beam as a bench-mark case, and is shown to effectively control the beam vibrations.

INTRODUCTION

A common form of intelligent or adaptive structures is a thin shell equipped with piezoelectric laminae. These laminae are made of piezoelectric materials such as Lead Zirconate Titanate (PZT), and are capable of transducing electric fields into mechanical strains, and mechanical strains into electric charges. These 'active' laminae are used to actuate the shell by inducing strains in the non-piezoelectric 'passive' laminae, and to sense deflections in the shell by measuring the local strain fields. The active laminae can be continuous over the entire domain of the structure, or discontinuous as in the case of piezoceramic 'patches'. Sufficiently accurate models for induced strain actuation are essential for the design of intelligent structures and their use for vibration suppression and steering.

Finite Elements Analysis (FEA) has been the method of choice for the analysis of structures which do not yield to closed-form solutions for some time now. It is widely used in the automotive industry, among others. In the context of smart structures, however, its role must be reassessed. The applicability of FEA to the adaptive structure design process should be investigated with respect to its capability of modelling the piezoelectric effects, and through them, piezoelectric actuation and sensing. In addition, the method's possible use as a structural discretization scheme for controller design should be addressed. In this work the piezoelectric modelling capability of the ANSYS^R commercial FE program was investigated and shown to be in excellent agreement with both analytical and experimental results.

In recent years the developers of commercial Finite Element (FE) software packages have anticipated demand and developed coupled-field piezoelectric elements. In general, these elements include electrical parameters such as voltage, as an additional degree of freedom at each node. The coupled-field elements can be incorporated into the FE model of the structure, yielding the structural response to the application of electric fields as part of the general output. A summary of these elements and their capabilities was given by Lin *et al.* [1]. The ANSYS^R FE program [2], which was used in this work posesses two coupled-field piezoelectric elements, an eight-node three dimensional solid, and a four node two dimensional solid.

While these elements can be very useful for the analysis of intelligent structures, they make the model much more expensive numerically [3]. The increased numeric cost stems from the additional degrees of freedom in the model (volts), as well as the lack of piezoelectric beam and shell elements, which can be very useful for the modeling of planar structures. This can be avoided by replacing the piezoelectric elements with the appropriate mechanical loads found using the extended pin-force model as presented in this work.

Discrete models of continuous structures tend to be very large, making the implementation and simu-

lation of the controlled structure extremely difficult [4]. This difficulty can be circumvented by bringing the system to a balanced representation and truncating the lightly controllable/observable states [5]. As a result of balanced truncation the structure is presented in state-space as a stable controllable and observable linear system of a relatively low order. This permits the application of state-space controller design tools to the controller and state estimator design [6].

The advantage of the proposed methodology is in its generality. It is applicable to any structure that can be modeled with FE, and is linearly elastic. In addition, it takes advantage of the state-of-the-art capabilities of commercial FE packages, and permits the application of the latest developments in state-space MIMO controller design techniques to continuous flexible structures.

METHODOLOGY OF ADAPTIVE STRUCTURE DESIGN WITH FEM

The objective of this work is to develop a methodology for the design and implementation of an active controller for the attenuation of vibrations in thin shells of general geometric and material properties. Since in general the vibrational modes cannot be predicted analytically, modal analysis is not applicable to this problem.

The design methodology therefore uses finite elements programs with coupled-field capabilities to discretize the structure and to identify undesirable modes, as well as to model piezoelectric sensing and excitation. Once the undesirable modes are identified, actuators and sensors are placed in a way that will ensure that these modes are observable and controllable. When sensors/actuators mass and stiffness contributions become significant, they should be included in the FEM.

Master degrees of freedom are then chosen and included in the model. The reduced model is run to obtain the mass and stiffness matrices and load vectors, which are processed to construct the matrices of the state-space model. A cost function quantifying the energy content of the vibration is found as a quadratic form of the system states, and a LQ controller is designed.

PIEZOELECTRIC ACTUATION AND SENSING

In this section existing models for piezoelectric actuation and sensing are briefly presented. The general results are modified to provide the scaling factors for converting piezoelectric actuation to mechanical loads.

PIEZOELECTRIC ACTUATION — When piezoelectric actuators such as PZT patches are used to control flexible structures, we need to know the scaling factor between the voltages applied to the actuators and the forces and moments which are applied by the actuators to the structure. This factor can be found using the extended pin-force models as reported in the literature, as well as coupled-field piezoelectric finite elements and experimental techniques. Here we present results for piezoelectric actuation of shells equipped with pizoceramic patches bonded to either one or both of the shell's surfaces.

The induced-strain load vector for a shell equipped with a symmetrically bonded actuator pair assuming that the poling axes are aligned with the coordinate system (see Figure 1) is [7]

$$\begin{Bmatrix} N_{11} \\ N_{22} \\ N_{12} \\ M_{11} \\ M_{22} \\ M_{12} \end{Bmatrix} = \frac{E_a}{1-\nu_a} \begin{Bmatrix} d_{31}V^+ \\ d_{32}V^+ \\ 0 \\ \frac{h_s}{2}\left(\frac{1}{T}+1\right) d_{31}V^- \\ \frac{h_s}{2}\left(\frac{1}{T}+1\right) d_{32}V^- \\ 0 \end{Bmatrix} \qquad (1)$$

where V^+ and V^- are the sum and the difference of the voltages applied to the upper and lower actuators, respectively. In case of only one actuator we get $V^- = V^+ = V$, and in case of two $V^- = 2V$. The thickness ratio between the actuators and the structure is defined as $T \triangleq h_s/h_a$.

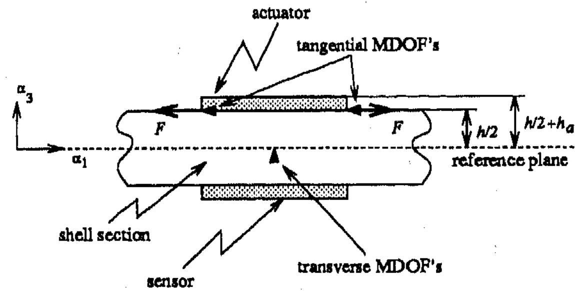

Figure 1: Section of actuated structure

In most cases we are interested only in the bending moments, since they can actuate transverese displacements. The moments are generated by the line-forces F, which act at the boundaries of the piezoelectric actuator. We can express these forces per unit width as

$$F = \frac{M_{ii}}{h_s} = \frac{E_a d_{3i}}{2(1-\nu_a)}\left(\frac{1}{T}+1\right) V \triangleq \xi_i V,\ i=1,2 \qquad (2)$$

where ξ_i is the volt-to-force scaling factor in the i-th direction. Alternatively, the scaling factors can be expressed through the induced curvatures as

$$\xi_i = \frac{M_{ii}}{h_s V} = \frac{EI\kappa_{ii}}{h_s V},\ \ i=1,2 \qquad (3)$$

where the curvatures are given by [3, 8]

$$\kappa_i = \frac{6\left(\frac{1}{T}+1\right)\left(\frac{1}{h_s}\right)}{\psi_\nu \frac{1+\nu_s}{1+\nu_a} + \tau}\left(\frac{d_{3i}}{h_a}\right) V \qquad (4)$$

The stiffness ratio ψ_ν between the actuators and the structure is defined by

$$\psi_\nu \triangleq T\frac{E_S}{E_a} \qquad (5)$$

and the non-dimensional coefficient τ as

$$\tau \triangleq 6 + \frac{12}{T} + \frac{8}{T^2} \quad (6)$$

The scaling factors can be easily incorporated into the formulation of the adaptive structure as a controlled system.

PIEZOELECTRIC SENSING — As shown by Pletner and Abramovich [3], the voltage measured across a piezoelectric sensor is proportional to the difference in the slope of the neutral axis deflection function $w(\alpha_1)$ evaluated at the sensor edges, as follows

$$\tilde{V}_l = \frac{h}{C_l}\int_{\alpha_1^l}^{\alpha_1^r} e_{31}^l \kappa(\alpha_1)dx = -\frac{he_{31}^l}{C_l}\int_{\alpha_1^l}^{\alpha_1^r} w''(\alpha_1)dx = -\eta_l\left[w'(\alpha_1^r) - w'(\alpha_1^l)\right] \quad (7)$$

where h is half the shell thickness, e_{31}^l is a piezoelectric constitutive parameter, and C_l is the l-th sensor capacitance. This model of piezoelectric sensing can be discretized and realized in state space, as is shown in the following sections.

CONTROL ORIENTED FINITE ELEMENT MODELING

A well established and validated technique for the discretization of continuous flexible structures is the Finite Element Method (FEM). In this method the structural continuum is divided (meshed) into a finite number of elements. Each element posesses a finite number of nodes, for each node a finite number of degrees of freedom (DOF's) are defined by the element type. These DOF's are most often mechanical displacements and rotations, but can also be thermal and electrical properties. In this manner a continuous structure is represented by a finite number of DOF's. The forces acting on the structure are applied at the nodes in the directions of the DOF's that are relevant for the node in question. For instance, at a node posessing the (U_x, U_y) translational DOF's, only forces in the (x, y) directions may be applied. The FEM uses energetic principles to assemble the global mass and stiffness matrices for the structure, and constructs the load vectors for each load case. The general form of the discretized equations of motion for the shell can be stated as

$$\boldsymbol{M}\ddot{\vec{d}} + \boldsymbol{C}_d\dot{\vec{d}} + \boldsymbol{K}\vec{d} = \vec{F}f(t) \quad (8)$$

where $\boldsymbol{M}, \boldsymbol{C}_d, \boldsymbol{K}$ are the global mass, damping and stiffness matrices, respectively, and $\vec{d}$ is the nodal displacement vector. $\vec{F}$ is the nodal load vector, and $f(t)$ is a time-dependent load.

REDUCED FINITE ELEMENT MODELS

In many cases a subset of all the DOF's in the FE mesh are of more interset to the structural analyst. For example, the vibrational analysis of thin shells and plates often requires the solution for the transverse DOF's located on the reference plane of the shell. In these cases the size of the model can be reduced by defining 'master' DOF's (MDOF's) along the reference plane, and solving the structure for these MDOF's only. This reduced analysis is a feature of many commercial FE programs, and is particularly useful if the FE representation of the structure is to be used in control applications. This is due to the fact that even 'modestly' sized FE models are far too large for many controller design tools. The number and location of the MDOF's should be chosen in such a way that the solutions obtained by the full and reduced models for a pre-specified number of vibrational modes coincide within a given tolerance.

Reduced FE Models of Piezolaminated Shells — A reduced FE model of a piezolaminated thin shell consists of three types of MDOF's. The transverse motion of the shell is described by MDOF's denoted by MDOF_3's. These MDOF's are located on the reference plane of the shell, and are aligned in the transverse direction α_3. Since the piezo-sensors are scaled to yield the structural deflection at their centers, the nodes located at the centers of all sensors should be defined as MDOF_3's.

The MDOF's needed for the application of piezoelectric loads are located on the upper and lower surfaces of the shell, and are aligned in the tangential directions (α_1, α_2). These MDOF's are denoted as MDOF_a's. Finally, the MDOF's used for the application of the external forces in the FE model are located on the reference plane of the shell, and aligned in the transverse direction (α_3). These MDOF's are denoted as MDOF_e's.

The shell is equipped with a number of sensors and actuators, and may be excited by a number of external forces. It should be noted that the MDOF_3's located at the sensors' centers are a subset of the total number of MDOF_3's, so that $N_s \leq N_3$. In addition, the excitation forces, which are usually normal to the shell, can be applied at the locations of the MDOF_3's, so that $N_e \leq N_3$.

STATE SPACE MODELOING OF ADAPTIVE STRUCTURES — The equations of motion for a piezolaminated shell excited by N_e forces, and controlled by N_a piezoceramic actuators are

$$\boldsymbol{M}\ddot{\vec{d}} + \boldsymbol{C}_d\dot{\vec{d}} + \boldsymbol{K}\vec{d} = \sum_{i=1}^{N_e}\vec{F}_e^i f^i(t) + \sum_{j=1}^{N_a}\vec{F}_a^j V^j(t) \quad (9)$$

where $\vec{F}_e^i$ is the load vector given by the FE model for the i-th excitation force, and $\vec{F}_a^j$ is the load vector for the j-th actuator. The excitation forces and controlling voltages are given by $f^i(t)$ and $V^j(t)$, respectively. To obtain a state-space representation of Equation (9) a state vector is defined as

$$\vec{x} \triangleq \left\{ \begin{array}{c} \vec{d} \\ \dot{\vec{d}} \end{array} \right\} \quad (10)$$

The equations of motion in state-space are then

$$\dot{\vec{x}} = A\vec{x} + B\left\{\begin{array}{c}\vec{f}\\ \vec{V}\end{array}\right\} \qquad (11)$$

$$\vec{y} = C\vec{x} \qquad (12)$$

where $\vec{y}$ is the measurements vector, and the vectors $\vec{f}$ and $\vec{V}$ contain the excitation forces and control voltages, respectively. The dynamics matrix A is given by

$$A = \left[\begin{array}{c|c} 0 & I \\ \hline -M^{-1}K & -M^{-1}C_d \end{array}\right] \qquad (13)$$

and the input matrix B is constructed as

$$B = \left[\begin{array}{c} 0 \\ \hline M^{-1}\left[\; \vec{F}_e^1 \,\middle|\, \cdots \,\middle|\, \vec{F}_e^{N_e} \,\middle|\, \vec{F}_a^1 \,\middle|\, \cdots \,\middle|\, \vec{F}_a^{N_a} \;\right] \end{array}\right] \qquad (14)$$

Assuming that the $MDOF_3$ located at the left edge of the l-th sensor is numbered k_l^l, and the one at the right edge is numbered k_r^l, Equation (7) can be approximated by

$$\begin{aligned}\tilde{V}_l = \\ -\frac{\eta_l}{\Delta_{\alpha_1}}\left[\left(x_{k_r^l+1} - x_{k_r^l-1}\right) - \left(x_{k_l^l+1} - x_{k_l^l-1}\right)\right] = \\ \frac{\eta_l}{\Delta_{\alpha_1}}\left[\left(x_{k_l^l+1} + x_{k_r^l-1}\right) - \left(x_{k_l^l-1} + x_{k_r^l+1}\right)\right]\end{aligned} \qquad (15)$$

where Δ_{α_1} is the distance between k_r^l and k_l^l, which may be assumed to be constant for all l without loss of generality. The measurement matrix C is constructed as

$$C = [\;\tilde{C} \mid 0\;] \qquad (16)$$

where the (l, m) components of $\tilde{C}$, $\tilde{C}_{lm}$ are given by

$$\tilde{C}_{lm} = \left\{\begin{array}{ll} \eta_l/\Delta_{\alpha_1}, & m = k_l^l + 1, \quad m = k_r^l - 1 \\ -\eta_l/\Delta_{\alpha_1}, & m = k_l^l - 1, \quad m = k_r^l + 1 \\ 0, & \text{otherwise} \end{array}\right. \qquad (17)$$

ACTIVE CONTROL OF STRUCTURAL VIBRATIONS

MODEL REDUCTION — The state space realization of the discrete structural model as given by the FEM is in all likelihood not minimal, since a number of MDOF's are aligned in the tangential directions. There are, however, no sensors that can sense displacements in these directions. This will cause the tangential or axial modes to be unobservable. In addition, in order to get a reliable approximation of the radiated acoustic power, an accurate representation of the spatial velocity field is needed, which in turn requires a large number of $MDOF_3$'s. However, due to the relatively small number of actuators, some of the discretized system modes will be uncontrollable.

The application of many controller design techniques to non-minimal systems can be numerically difficult. In addition, for reasons of computational efficiency and practical implementation considerations, systems with a low number of states are desirable. Low order systems can be obtained by using the balanced truncation technique. In this technique the system is transformed into coordinates where the controllability and observability gramians are diagonal and equal. This can be interpreted as if the states in the new coordinates are equally controllable and observable. Following the transformation, the states with Henkel singular values lower than a pre-specified tolerance ϵ are truncated. This may lead to a very substantial reduction in the number of states. Care has to be taken, however, that the lightly observable and controllable states do not include states we wish to control, since these states will be truncated, and will not be controlled. Careful placing of the actuators and sensors should overcome this problem. In general, sensors and actuators should be placed in areas of maximal bending moments, however, the optimal placement and sizing of sensors and actuators is the subject of ongoing research.

The Henkel singular values of the balanced system arranged in descending order are partitioned such that

$$\Sigma = \left[\begin{array}{cc} \Sigma_1 & 0 \\ 0 & \Sigma_2 \end{array}\right] \qquad (18)$$

where

$$\begin{array}{rcl} \Sigma_1 & = & \text{diag}\{\sigma_i\}, \; i = 1, \cdots, N_r \\ \Sigma_2 & = & \text{diag}\{\sigma_j\}, \; j = N_r + 1, \cdots, N_{states} \end{array} \qquad (19)$$

and $\sigma_j \leq \epsilon$. The balanced system is partitioned as follows

$$G_B(s) = \left[\begin{array}{cc|c} A_{11} & A_{12} & B_1 \\ A_{21} & A_{22} & B_2 \\ \hline C_1 & C_2 & D \end{array}\right]; \dim(A_{11}) = N_r \times N_r \qquad (20)$$

where the following transfer matrix notation is used

$$\left[\begin{array}{c|c} A & B \\ \hline C & D \end{array}\right] \triangleq C\,(sI - A)^{-1}\,B + D \qquad (21)$$

Since the original system is stable, the truncated system

$$G_T(s) = \left[\begin{array}{c|c} A_{11} & B_1 \\ \hline C_1 & D \end{array}\right] \qquad (22)$$

is balanced, asymptotically stable, and approximates the original system with a finite (known) accuracy [4, 5].

CONTROLLER DESIGN

The choice of a controller naturally depends on the control objective. When the control objective is to regulate the state response of an unforced structure to initial conditions or impulse excitation to zero, while minimizing the total vibrational energy in the structure, linear quadratic (LQ) controllers are used. In cases of persistent external disturbance to the structure, a better approach is $\mathcal{H}_\infty$ control, which minimizes the infinity norm of the output/input ratio for power bounded inputs.

Linear Quadratic (LQ) CONTROL — The LQ controller is designed to minimize a quadratic cost function

$$J = \int_0^\infty \left[\vec{x}(t)^T \boldsymbol{Q}\vec{x}(t)dt + \vec{u}(t)^T \boldsymbol{R}\vec{u}(t)\right] dt \quad (23)$$

where $\boldsymbol{R}$ is an input weighting matrix introduced to penalize the use of large control inputs. It is a well known result that the solution of Equation (23) is given by a linear constant gain feedback controller [9]

$$\vec{u}(t) = \boldsymbol{F}\vec{x}(t) \quad (24)$$

where the gain matrix $\boldsymbol{F} = -\boldsymbol{R}^{-1}\boldsymbol{B}^T\boldsymbol{S}_c$, and $\boldsymbol{S}_c$ is the solution of the controller Ricatti equation [4,9].

Linear quadratic regulation (LQR) assumes all states are measured. Since this is not the case here, a state estimator is needed. In this work a Luenberger observer is incorporated, where the observer gain matrix $\boldsymbol{L}$ is determined by pole placement [10]. This approach is valid when measurement and process noises are neglected. In the presence of noise, a stochastic estimator such as the Kalman filter should be employed.

Having placed the sensors and actuators so that the modes we are most interested in controlling are also the most observable/controllable, the state weighting matrix $\boldsymbol{Q}$ is chosen so that each state is penalized reciprocally to its controllability as [4]

$$\boldsymbol{Q} = 2\boldsymbol{\Sigma}^{-1}\boldsymbol{B}\boldsymbol{B}^T\boldsymbol{\Sigma}^{-1} \quad (25)$$

where $\boldsymbol{\Sigma}$ is a diagonal matrix with the Henkel singular values of the truncted system in Equation (22). The closed-loop system architecture is shown in Figure 2.

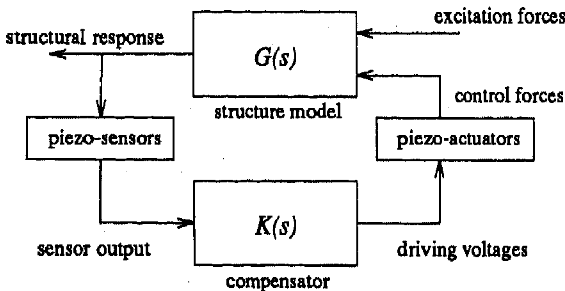

Figure 2: Schematic representation of controlled structure

$\mathcal{H}_\infty$ CONTROL — Steady state vibration can be stated as a problem of rejecting persistent disturbances in steady state. $\mathcal{H}_2$ control methods such as LQR are not ideally suited for this problem, since they minimize the "infinite horizon" $\mathcal{L}_2$ norm of the system response

$$||\vec{y}||_2 = \left[\int_0^\infty \vec{y}^T\vec{y}dt\right]^{\frac{1}{2}}$$

For persistently disturbed systems vibrating in steady state it is obvious that the $\mathcal{L}_2$ does not exist. A different approach is therefore needed to directly address the problem of persistent disturbance rejection.

Consider a linear dynamic system described by a generalized closed-loop transfer matrix $\boldsymbol{T}(s)$ as

$$\tilde{\vec{e}}(s) = \boldsymbol{T}(s)\tilde{\vec{d}}(s) \quad (26)$$

where $\tilde{\vec{d}}(s)$ and $\tilde{\vec{e}}(s)$ are power bounded scaled inputs and outputs, respectively as they appear in Figure 3. $\boldsymbol{P}(s)$ is the transfer matrix of the augmented open-loop plant, as explained in the following paragraphs. In this case the $\mathcal{H}_\infty$ norm of the closed-loop transfer matrix $\boldsymbol{T}(\jmath\omega)$ is defined as

$$||\boldsymbol{T}||_\infty = \sup_{\omega\in\boldsymbol{R}}\bar{\sigma}\left[\boldsymbol{T}(\jmath\omega)\right] \quad (27)$$

where $\bar{\sigma}(\jmath\omega)$ are the maximum singular values of $\boldsymbol{T}$. The $\mathcal{H}_\infty$ problem for power bounded input problems can be stated as: Find an internally stabilizing dynamic controller $\boldsymbol{K}(s)$, such that $||\boldsymbol{T}||_\infty \leq \gamma$, where γ = const [11]. The inputs to the system are assumed to be random zero mean processes, power bounded and scaled so that their power equals unity. Such scalng is denoted by $\tilde{(\cdot)}$. When such scaling is used, γ can without loss of generality be set to one.

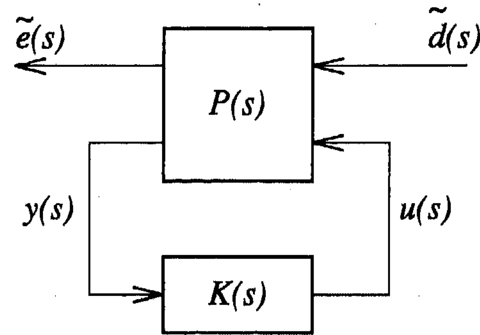

Figure 3: Closed-loop interconnection of controlled structure

In ASAC problems the external inputs $\vec{d}(s)$ may consist of mechanical or acoustic surface loads, as well as sensor or measurement noise. The output $\vec{e}(s)$ from the system is usually the displacement and/or velocity field of the vibrating structure.

Controller Design Setup — The control design objective is to obtain a constant gain controller of the sound radiation from a flexible plate. The interconnection model used for the controller design is presented in Figure 4. It incorporates the model of the plate dynamics (as given by finite element discretization), piezoceramic actuator dynamics, and various frequency weighting functions.

As can be seen, the inputs vector $\vec{d}$ to the augmented plant $\boldsymbol{P}(s)$ consists of two external and one control inputs: the external forces $f(s)$, measurement noise $n(s)$, and control inputs $u(s)$. The outputs vector of the closed-loop system $\vec{e}$ has two weighted components: controls $\vec{u}(s)$ and displacement field $d(s)$. The measurements $\vec{y}(s)$ are used as input to the compensator $\boldsymbol{K}(s)$.

The external force weighting parameter $\boldsymbol{W}_d(s)$ is a bandpass filter admitting only the frequencies of the

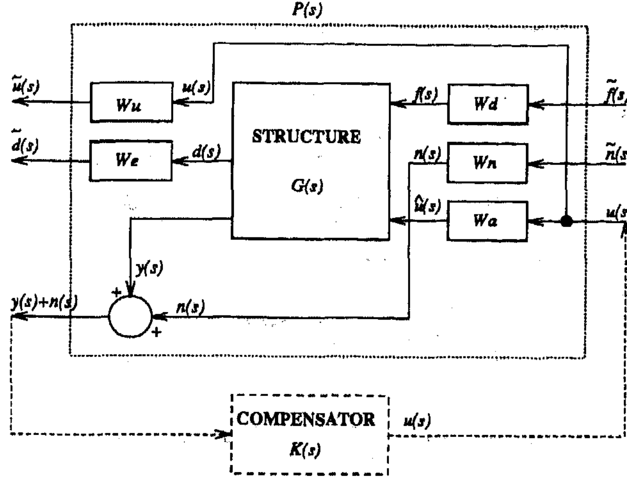

Figure 4: Open-loop architecture of generalized plant

external forces, and scaling them by their respective magnitudes. In the case of single frequency excitation $f(t) = F_a e^{j\omega_a t}$, a notch filter is used, as follows

$$W_d = \left(\frac{F_a}{2\zeta_a\sqrt{1-\zeta_a^2}}\right)\frac{\omega_a s}{s^2 + 2\zeta_a\omega_a s + \omega_a^2} \tag{28}$$

The measurement noise of the piezoelectric sensors is assumed to have a maximum amplitude of $\nu_{max} =$ 0.01[Volt], $\forall\omega$, and so the noise weighting factor is given by $W_n = \nu_{max} \boldsymbol{I}_{N_s}$. Piezoceramic actuators dynamic response can be obtained from the manufacturer, and is usually represented by a highpass filter, since they have a very limited DC capability. In this work, however no DC or low frequency actuation is required, and all performance requirements are limited to frequencies well within the actuators operating range. No generality is lost therefore by taking $W_a = \boldsymbol{I}_{N_a}$.

The voltage input to piezoceramic actuators is limited by the maximum allowable driving voltage, which may decrease with frequency. In some cases this voltage can be limited by the available power source, and not by the actuators themselves. In any case the controller design must take into account the limits on the control inputs. This is achieved by setting the weight W_u to $1/V_{max}\boldsymbol{I}_{N_a}$, where $V_{max} =$ 100[Volt] is the maximum allowable driving voltage.

The performance weighting parameter W_e determines the maximum displacements of the structure which can be tolerated after the application of control. It it thus set to $W_e = 1/d_{max}\boldsymbol{I}_{N_3}$, where d_{max} is the maximum allowable displacement.

EXAMPLES

Two examples are presented. In order to demonstrate the capapabilities of the coupled-field piezoelectric elements and the equivalent mechanical loading models proposed in this paper, a cantilever plate equipped with one actuator pair was used.

Demonstration of the controller design methodology was performed using a slender simply supported beam excited by one point force and controlled by three PZT actuator pairs. The beam was selected as a benchmark case because its vibrational modes are well known, and the results can be evaluated intuitively. The methodology is general and can be applied to any linear thin-walled structure.

THIN CANTILEVER PLATE — The experimental investigation was performed using a thin cantilever steel plate actuated by a single actuator pair as shown in Figure 5. The purpose of the experiment was to validate the coupled-field FE modeling technique, as well as the extended pin-force model presented previously. This was done by determining the first fundamental frequency of the plate, exciting it on-resonance using the piezoelectric actuators, and obtaining the steady-state response. As a measure of this response, the strain at the root of the plate was measured using a strain gauge couple at the clamp (see Figure 5). This strain was then compared to the strains found by the coupled-field FE model of the plate using the ANSYS[R] harmonic analysis capability. This was done both for electrical loads, and for the equivalent mechanical loads, found using the pin-force model. The process was repeated for several amplitudes of excitation, and the results are shown in Figure 6. Excellent agreement was found between the experimental results (denoted by (*)), and the results yielded by the coupled-field FEM (demoted by (o)). The equivalent mechanical loading used with a purely structural FEM (denoted by (+)), yielded an upper limit for the strain values.

SIMPLY SUPPORTED SLENDER BEAM — In this example we used an aluminum beam with three colocated sensor-actuator pairs, as shown in Figure 7. The beam was meshed into 480 SOLID42 two dimensional solid elements with 657 active DOF's, and a total of 33 MDOF's. The total number of states in this case was 66, and it was truncated to 6, so that the first three modes were represented in the truncated model. The truncation can be justified by looking at the natural frequencies and the frequency response of the beam. The frequencies yielded by the full FE (unreduced) model, the reduced and truncated model, and the idealized analytical expression which neglects the actuators and sensors and uses the Euler-Bernoulli model, i.e.

$$\omega_n = \left(\frac{n\pi}{L}\right)^2\sqrt{\frac{EI}{\bar{\rho}A}} \tag{29}$$

are grouped together in Table 1. As can be seen, the sensors/actuators mass and stiffness affect the natural frequencies of the beam. The truncated frequencies, however, are quite close to the values yielded by the full analysis. The actuators and sensors were placed so that their centers coincided with the maximum displacements in the third vibrational mode. Thus this mode was designed to be the most controllable/observable. Since the state weighting matrix $\boldsymbol{Q}$ was designed to favor the most controllable modes,

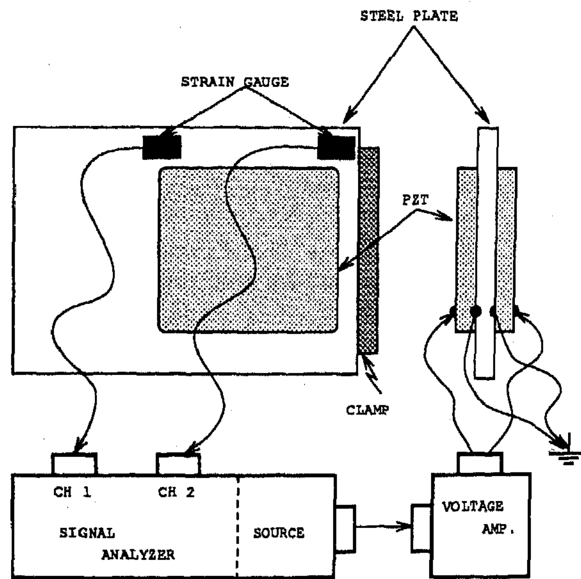

Figure 5: Experimental set-up

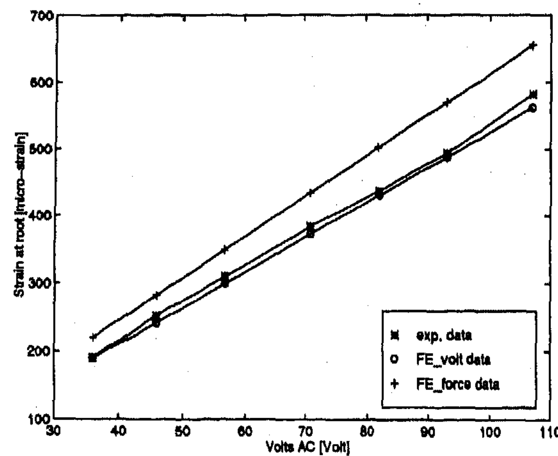

Figure 6: Strain at root of plate @ 40 [Hz]

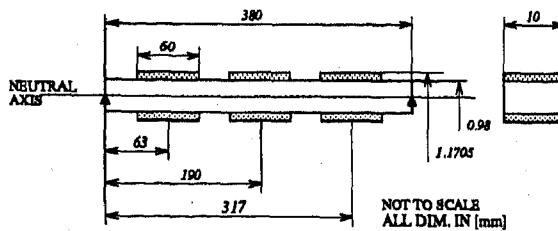

Figure 7: Simply supported beam with three actuator pairs

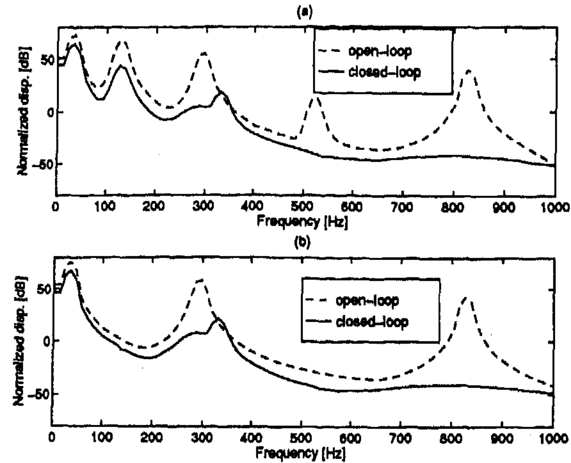

Figure 8: Normalized beam displacement

it is expected that the third mode vibrations will be attenuated the most. The matrix $\boldsymbol{R}$ was chosen so that the driving voltages never exceed 100 volts AC.

Table 1: Natural frequencies of simply supported actuated beam [Hz]

	analytical	FE full	truncated
f_1	31.34	32.45	32.45
f_2	125.36	130.10	130.13
f_3	282.05	294.11	297.05

Results — Figure 8 examines the spectral conetnt of the transient response of the beam to impulse excitation, as measured by the left (a), and middle (b), sensors. The measurement is scaled to a specified sensitivity of 10^{-6} meters, and presented in [dB]'s. Both sensors clearly show that the greatest reduction in displacement was achieved for the third mode, which was the mode we have designed for maximum attenuation through actuator placement and choice of $\boldsymbol{Q}$. The second mode is not measured by the second sensor, which is located at that mode's nodal location. In addition, we see that the third natural frequency was shifted upwards by the active control.

Tables 2, 3 present the open and closed-loop natural frequencies and damping ratios for the first three modes of the beam, respectively. A significant increase in the damping ratios is observed, as well as a shift of over 10% in the third natural frequency.

Table 2: Natural frequencies of a controlled beam

	ω_1 [Hz]	ω_2 [Hz]	ω_3 [Hz]
open-loop	32.6	130.1	294.1
closed-loop	32.6	129.6	332.5

An $\mathcal{H}_\infty$ controller was designed and applied to a beam similar to that in Figure 7, but with an overall length of 48 [cm], and an actuator length of 10 [cm]. The external force weighting filter was designed to admit forces at the third open-loop resonant frequency

Table 3: Modal damping ratios of a controlled beam ($\times 10^{-3}$)

	ζ_1	ζ_2	ζ_3
open-loop	0.10	0.41	0.92
closed-loop	10.0	51.0	20.0

of 200 [Hz], and scale them to an amplitude of 1 [N]. The open and closed-loop frequency responses of the beam scaled to 1 [μ] = 10^{-6} meters are presented in [dB]'s in Figure 9. As can be seen good control was achieved for all three fundamental modes of the beam, in accordance with the control design objective. It is interesting to note that for the non-resonant frequencies around 150 [Hz] control 'spill-over' occured, and the control effort led to higher displacements. This undesirable result can be reduced by incorporating the information which was lost due to the discretization of the continuous structure and to the balanced truncation of the states as an unstructured uncertainty in the $\mathcal{H}_\infty$ controller design. This is the subject of further research.

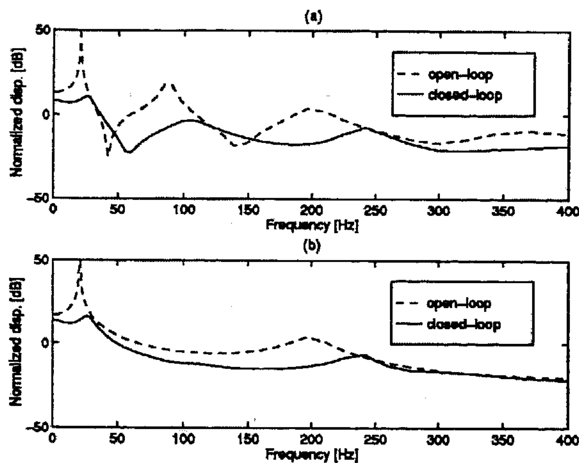

Figure 9: Normalized beam displacement; (a) – left sensor, (b) – midspan sensor

CONCLUDING REMARKS

A general methodology for the design of adaptive structures using the finite element method is presented. Coupled-field piezoelectric elements are shown to be a valuable tool in the initial stages of the design. Replacement of coupled-field elements with equivalent mechanical loads is shown to cause a relatively small loss of accuracy in the model.

The capability of the balanced truncation technique to reduce the order of the model by as much as an order of magnitude without losing significant information is demonstrated. FE sub-structuring in conjunction with balanced truncation are able to reduce large and complex models to orders previously obtainable solely through the modal analysis of idealized structures. This technique enables the use of the full range of FE capabilities in modeling geometrically and materially non-homogeneous structures for the low-order and accurate discretization of continuous structures. The capability of representing complex structures as relatively low-order and balanced systems in state space opens the way for the application of advanced tools for MIMO controller design, as well as for numerical simulations of the closed-loop systems.

Future work should include the design of robust $\mathcal{H}_\infty$ controllers, which take into account uncertainties in the structural dynamic model, as well as boundary conditions and excitation regimes. Proof-of concept experiments should be performed to validate the concepts proposed in this study.

Rolling Bearing Analysis Codes "BRAIN" - The Estimation of Rolling Bearing Performance for an Automotive Application

Hirotoshi Aramaki, Yuji Nakano, and Yoshio Shoda
NSK Ltd.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

A computer program package named "BRAIN" has been developed to simulate the kinematics and the performance of rolling bearings under various running conditions. The calculation time necessary for running BRAIN software on a PC is very short. Various outputs can be obtained using BRAIN such as running torque, roller skew angle, roller slippage, and PV values.

Several experiments have been conducted to confirm the validity of BRAIN. The running torque of a four point contact ball bearing and that of a tapered roller bearing were measured. In addition, the skew of the roller in a needle bearing was measured. These experimental results were compared with the calculation results. The experiments and the calculations showed good agreement.

INTRODUCTION

Typically, a car contains over 100 rolling bearings. The wide range of bearing types includes ball bearings, needle bearings, cylindrical roller bearings, and tapered roller bearings. The quantity and diversity of rolling bearings indicate their vital contribution to the performance of modern automobiles. The requirements on automotive bearings have become more strict every year. Now, user requirements include compactness and low cost in addition to matching, or enhancing, the previous performance level.

As computer technology progresses, designers of rolling bearings rely more and more on computers as a simulation tool to design better bearings to match user requirements within a short time. Rolling bearing static analysis with a computer is very popular. It is essential for the bearing designer to know basic information such as internal load distribution and deflection of the bearing. However, to create high performance bearings, the bearing designer also needs more detailed information such as bearing torque, PV value, and slip rate of rolling elements. In such cases, dynamic analysis of a rolling bearing is required. The dynamic analysis of rolling bearings encompasses friction analysis, so it is much more difficult than the static case. ADORE, which is a commercially available software package, is an example of a well-known dynamic rolling bearing analysis program. Researchers can analyze the performance of roller bearings as well as ball bearings with ADORE[1]. ADORE is a very advanced and sophisticated tool. Since ADORE is a transient analysis program, it takes considerable time to find the steady state of the bearing performance.

We have developed a computer program package named "BRAIN" to simulate the kinematics and the performance of rolling bearings under various running conditions. When running BRAIN on a PC, the calculation time is short, so BRAIN is expected to become a frequently used simulation tool. BRAIN consists of several separate programs that are applicable to angular contact ball bearings (including deep groove ball bearings, thrust ball bearings), four point contact ball bearings, radial cylindrical (needle) roller bearings, thrust cylindrical (needle) roller bearings tapered roller bearings, and self-aligning roller bearings. Various outputs, such as running torque, roller skew angle, roller slippage, and PV values, can be calculated to assist in the design of bearings for advanced applications.

FEATURES OF BRAIN

The name BRAIN was made from the phrase "**BeaRing Analysis In Nsk**." BRAIN is a software package to simulate the performance of rolling bearings. BRAIN consists of six programs as shown in Table 1, namely, BALTAC (Ball bearing), B4PTAC (Four point contact ball bearing), CYLTAC (Cylindrical roller bearing), TNBTAC (Thrust cylindrical roller bearing), TAPTAC (Tapered roller bearing), and SELTAC (Self-aligning roller bearing). Therefore, most types of rolling bearings can be analyzed by BRAIN.

BRAIN has several attractive features. In conventional bearing analysis, an assumption of "pure rolling" is made, i.e. the "Jones control theory"[2] for ball bearings and pure rolling between rollers and inner/outer rings. However, the assumption of "pure rolling" is not rigorous enough especially for high-speed applications. The gyroscopic moment and centrifugal force acting on

rolling elements result in large slip at the contact area.[3),4)] In addition, the skew of the rollers in a roller bearing is usually neglected in conventional analysis although it strongly influences the bearing performance. In BRAIN, a bearing is analyzed on the basis of an equilibrium of forces and moments without resorting to simplifying assumptions of pure rolling, no tilt, and no skew motion of rolling elements.

Several important assumptions are made when using BRAIN.

(1)Inner ring and cage rotational speeds are constant.
(2)The cage center is fixed.(no eccentricity)
(3)The orbital speed of rolling elements and the cage rotational speed is identical.

How BRAIN simulation works might be easily visualized in your mind's eye as follows: Imagine that you are observing the bearing motion by a stroboscope whose frequency is adjusted to Zfc (Z: number of rolling elements, fc : cage rotational frequency). The rolling elements stay at the same positions. The calculation model is similar to that of Harris[5)]. The crowning profile of the roller is considered approximately using a slicing method. More exact analysis, e.g. edge load calculation, requires inputting BRAIN's calculation results, such as contact force, tilt, and skew angle of the roller into software that solves contact problems.

In BRAIN, it is easy to set constraint conditions on the inner ring movement. This function confers an advantage when calculating bearing performance under given misalignments and/or under a position preloading condition.

In many cases, deformed shaft and housing influence the bearing performance. For these cases, BRAIN can import the deformation data relating to the shaft and the housing calculated by FEA. The deformation is considered as a change in the internal clearance of the bearing. Therefore, the internal clearance varies axially and/or circumferentially in BRAIN.

COORDINATE SYSTEMS

The Coordinate frames defined in BRAIN are shown in Fig. 1. Inertial coordinate frame X*Y*Z* is fixed in space. When the outer ring is assumed to be stationary and fixed in a housing, the outer ring coordinate frame XYZ is identical with the inertial coordinate frame X*Y*Z*. External axial load is applied in the X direction. External radial loads are applied in the Y and Z directions. The shaft or housing rotates clockwise around the X axis. Each rolling element has its own local coordinate frame $x_j y_j z_j$, which rotates with the rolling element. All the coordinate systems are right handed ones. Azimuth angle of the jth rolling element is defined by the angle between Z axis and z_j axis. For convenience, radial load is usually applied in the Z direction. Therefore, rolling elements have their maximum contact load at an azimuth angle equal to zero.

FORCES AND MOMENTS ACTING ON ROLLING ELEMENTS

Fig. 2 shows forces and moments acting on rolling elements in a ball bearing. The contact forces between outer/inner ring and rolling elements are Q_1 and Q_2. The centrifugal force and gyroscopic moment are Qi and Mg respectively. Gravity is neglected in the analysis, which is thought to be negligible in automotive applications. Cage contact force Q_{ca}, friction F_{cx} and F_{cz} are considered at the cage pocket area.

Frictional forces work at all contact areas, such as F_{w1} and F_{w2}. For the estimation of frictional force and moment at ring/ball contact area, the elliptical contact area is divided into small slices. The frictional force and moment at the contact area are obtained by a numerical integration of frictional force on each slice. Coefficient of friction is determined by an empirical equation which is a function of the lubricant's viscosity, rolling velocity, slide/roll ratio, and contact pressure. The empirical equation was derived from a friction database based on results from two-disk test machines. Rolling resistance is estimated by Aihara's equation[6)], which use Goksem and Hargreaves' rolling traction force[7),8)]. The basis of the model about BALTAC is described in Aramaki et. al.[9)]. Coulomb friction is assumed for cage/rolling elements in contact with frictional forces F_{CX}, F_{CZ}. Cage land friction F_{CL} is estimated by a simple viscous model.

Fig. 3 shows forces and moments acting on the rolling element in a tapered roller bearing. The half cone angle and half roller cone angle are α and β respectively. The roller is sliced into thin disks. The contact force Q_1 and Q_2 are obtained by numerically integrating the contact force of each thin disk to consider the crowning profile. In tapered roller bearings and self-aligning roller bearings, flange contact force Q_f is also considered. The frictional forces are estimated by numerical integration of the frictional force on each thin disk of the rolling element as well as by the estimation of contact forces.

EQUILIBRIUM OF FORCES AND MOMENTS

BALL BEARINGS - From the balance of forces and moments, one can obtain the following equations for the rolling elements of the ball bearing shown in Fig. 2.

$$0 = -Q_{1,j}\sin\alpha_{1,j} + Q_{2,j}\sin\alpha_{2,j} + F_{w1,j}\cos\alpha_{1,j} - F_{w2,j}\cos\alpha_{2,j} + F_{cx,j} \quad (1)$$

$$0 = F_{y1,j} - F_{y2,j} + F_{d,j} + Q_{ca,j} \quad (2)$$

$$0 = -Q_{1,j}\cos\alpha_{1,j} + Q_{2,j}\cos\alpha_{2,j} + Q_I - F_{w1,j}\sin\alpha_{1,j} + F_{w2,j}\sin\alpha_{2,j} + F_{cz,j} \quad (3)$$

$$I_B(d\omega_{x,j}/dt) = -M_{1x,j} - M_{2x,j} + M_{r1x,j} + M_{r2x,j} - D_a F_{cz,j}/2 \quad (4)$$

$$I_B(d\omega_{y,j}/dt) = -M_{gy,j} + D_a(F_{w1,j} + F_{w2,j})/2 \quad (5)$$

$$I_B(d\omega_z/dt) = M_{gz,j} - M_{1z,j} - M_{2z,j} + M_{r1x,j} + M_{r2x,j} + D_a F_{cx,j}/2 \quad (6)$$

Eq. (1)-(3) are force balances and (4)-(6) are moment balances with respect to x_j, y_j, and z_j directions respectively. Additional contact loads, frictional forces and moments should be considered with four point contact ball bearings. As shown in above equations, the

acceleration term (left hand side) in the force balance equations are neglected. The angular acceleration $I_B(d\omega/dt)$ in (4)-(6) are approximated in the following manner.

$$I_B(d\omega/dt) = I_B(d\omega/d\varphi)(d\varphi/dt)$$

$$= I_B(\omega_j - \omega_{j-1})/(\varphi_j - \varphi_{j-1})\omega_c \quad (7)$$

From the cage assumptions of steady rotation and no eccentricity, the following equation is obtained for the cage moment balance in the rotational direction.

$$0 = -0.5\, D_m\, \Sigma\, Q_{ca} + D_{cr}\, F_{cL} \quad (8)$$

where, D_m : pitch diameter of the bearing
D_{cr} : cage land diameter

The inner ring is assumed to be rotated with a constant speed so that the following five equations describe the five degrees of freedom for the inner ring.

$$F_X = \Sigma\, (Q_{2,j}\sin\alpha_{2,j} - F_{w2}\cos\alpha_{2,j}) \quad (9)$$

$$F_Y = \Sigma\, (Q_{2,j}\cos\alpha_{2,j} - F_{w2}\sin\alpha_{2,j})\sin\varphi_j \quad (10)$$

$$F_Z = \Sigma\, (Q_{2,j}\cos\alpha_{2,j} - F_{w2}\sin\alpha_{2,j})\cos\varphi_j \quad (11)$$

$$M_Y = -\Sigma\, \{ (-0.5\, D_m \sin\alpha_{2,j})Q_{2,j} + (0.5\, D_a - 0.5\, D_m \cos\alpha_{2,j})\, F_{w2,j} \} \cos\varphi_j \quad (12)$$

$$M_Z = \Sigma\, \{ (-0.5\, D_m \sin\alpha_{2,j})\, Q_{2,j} + (0.5\, D_a - 0.5\, d_m \cos\alpha_{2,j})\, F_{w2,j} \} \sin\varphi_j \quad (13)$$

where left hand side F_X, F_Y, F_Z, M_Y, M_Z are external forces and moments acting on the inner ring. In the program, any of the above equations can be omitted to impose a constraint on the inner ring.

Above 6 x (rolling elements) + 6 equations are solved simultaneously using the Newton-Raphson method.

ROLLER BEARINGS - The equilibrium equations are derived for roller bearings. As an example, the following equations are obtained for the tapered roller bearing shown in Fig. 3.

$$0 = -Q_{1x,j} + Q_{2x,j} + Q_{fx,j} + Q_{ix} \quad (14)$$

$$0 = F_{y1,j} + F_{y2,j} + F_{fy,j} + F_{d,j} + Q_{ca,j} \quad (15)$$

$$0 = -Q_{1z,j} + Q_{2z,j} + Q_{fz,j} + Q_{iz} + F_{cz,j} \quad (16)$$

$$I_x(d\omega_{x,j}/dt) = M_{1x,j} + M_{2x,j} + M_{fx,j} + M_{r1x,j} + M_{r2x,j} + M_{rfx,j} + M_{cz,j} \quad (17)$$

$$0 = M_{1y,j} + M_{2y,j} + M_{fy,j} + M_{gy,j} \quad (18)$$

$$0 = M_{1z,j} + M_{2z,j} + M_{fz,j} + M_{gz,j} + M_{cx,j} \quad (19)$$

where M_f : moment due to flange contact
M_c : moment due to cage/roller contact

Excluding the x rotation, the other angular acceleration terms (on left hand side) are ignored.

Eq. (8) is applicable even for the moment balance of a roller bearing. Double row type bearings can be calculated in CYLTAC (cylindrical roller bearings) and SELTAC (self-aligning roller bearings) so that eq. (8) is applied to each cage when two cages are assembled in the bearing. One can also obtain the equilibrium equations for the inner ring in the same way as in eq.(9) - (13).

Some self-aligning roller bearings have floating rings. In this case, force and moment balance equations for the floating ring are necessary in addition to the above equations. Since use of self-aligning bearings in an automobile is very rare, we omit an explanation about the floating ring.

CALCULATION EXAMPLES

As already described, BRAIN can analyze the performance of most rolling bearings. In the present paper, the analyses of a four point contact ball bearing, a radial needle bearing, and a tapered roller bearing are shown.

The use of four point contact ball bearings in an automobile is not popular since they would generate high power loss and severe ring/ball wear due to large spin friction. However, their forward/reverse axial load supporting capability is very attractive in terms of cost and compactness. The estimation of the PV values at ball/ring contact points under radial/axial combined loading condition is a difficult task in a conventional analysis. BRAIN can estimate PV value distribution at each contact area as well as bearing power loss. Therefore, optimization of four point contact ball bearings becomes feasible.

Many needle bearings are used in automotive applications thanks to their compactness. Due to the skew motion of the rollers, however, high power loss is a potential problem. In roller bearings, skewing is defined as an angular rotation of the roller axis in a plane tangent to its orbital direction with respect to the axis of the contacting ring according to Harris[3]. The skew motion of the roller is influenced by many factors, such as lubricant and geometry of the bearing. Although the estimation of the skew of the roller is difficult work, it is very important to analyze the bearing performance including the skew influence.

The final example is a tapered roller bearing. Many tapered roller bearings are used in automobiles. The running torque of tapered roller bearings at relatively low speed can be estimated well by Aihara's equation[6]. However, the drag loss may constitute a relatively large portion of the bearing power loss when the bearing runs at high speed with plenty of feeding oil. A relatively large tapered roller bearing was tested to measure the running torque.

FOUR POINT CONTACT BEARING ANALYSIS - The performance of radial and thrust ball bearings is calculated with the BALTAC program, especially to evaluate the bearing torque (power loss) and PV value at

the ring/ball contact area. For three point and four point contact ball bearings, B4PTAC has been developed for the analysis of gothic-arch shaped ring grooves. B4PTAC is based on BALTAC, and it utilizes many of the same subroutines as BALTAC does.

Fig. 4 shows a schematic view of the experimental apparatus used to measure the running torque. The experiment was conducted to compare the measured bearing torque and the one calculated with B4PTAC. Radial and axial loads were applied to the test bearing through hydrostatic bearings. As the inner ring rotates, the bearing's frictional torque works to turn the bearing housing. The force necessary to restrain the housing was measured and converted to bearing torque. The outer ring temperature was also measured by a thermocouple. The speed range in the experiment was from 1000 rpm to 10000 rpm.

A four point contact ball bearing was used in the experiment. The bore diameter and outside diameter of the bearing are 40mm and 90 mm, respectively. The rest angle of the bearing is 60 deg. 12 balls are inserted in the bearing. The experimental conditions are shown in Table 2. Case A is a pure axial loading condition. Case B is a combined axial and radial loading condition.

The comparison of experiment and calculation results under case A is shown in Fig. 5. Solid line and broken line in the figure show experimental results and calculated ones respectively. Since no radial load is applied, the test bearing works as a conventional angular contact ball bearing. Below about 3000 rpm, the torque increased rather sharply with speed. However, the slope of the torque became smaller as speed increased. Reduction of oil viscosity due to temperature rise seems to play an important role in this phenomenon. The experiment agrees with the calculation excellently. The discrepancy between the experiment and the calculation was below 10%.

The comparison of the experiment and the calculation under case B is shown in Fig. 6. The measured running torque under radial/axial combined load (case B) was about 30% higher than that under pure axial load (case A). Under case B, the agreement between the experiment and the calculation is reasonable. The calculation is seems to always be below the experiment. Although the maximum discrepancy between the experiment and the calculation is about 16%, the tendency of bearing torque to vary with speed is well-simulated by the calculation.

Fig. 7 shows the PV value distribution with the ball azimuth φ under a pure axial loading condition (case A). This PV value is the peak PV value (pressure P$\times$slip velocity V) along the major axis of elliptical contact between the ball and inner/outer ring. Black plots in the figure show axial loading side grooves (outer ring No.2 and inner ring No.1 groove) and white ones show unloading side grooves (outer ring No.1 and inner ring No.2 groove). Under this load condition, a ball always makes only one contact point with the outer and with the inner ring. Therefore, PV values on the unloading side grooves are zero. In such cases, balls can rotate with the minimum spin friction. PV values at inner ring No.1 are about 0.2 [GPa·m/sec].

Fig. 8 shows the PV value distribution under the combined axial and radial loading condition (case B). The PV value has its maximum at a radial loading position (φ = 0). The inner ring has a higher contact pressure and a higher PV value than the outer ring has. The maximum PV value is 1.5 [GPa·m/sec], and it appears at the radial loading position of the inner ring groove No.1. The PV values under case B are much higher than those under case A. In the present calculation, the peak PV value in the ball/ring contact area appears near the edge on the major axis of the contact ellipse due to the spin velocity.

NEEDLE BEARING ANALYSIS - Roller skew angle and axial force generated by roller skewing in a single row needle bearing is analyzed by CYLTAC. Input data for the calculation is shown in Table 3.

A schematic view of the test part is shown in Fig. 9. Needle rollers were inserted without a cage between the housing and the shaft. The shaft was rotated and the housing was stationary. The external radial load and moment were applied to the housing. Two eddy current type gap sensors were aligned axially and mounted in the housing. The housing was fixed by a thin plate and strain gauges were attached to the thin plates.

Roller skew angle was determined by the phase difference in peak signals from the two gap sensors. Axial force was measured by strain gauges on a thin plate. A positive sign for a skew angle means that a roller passed over the sensor 2 before the roller passed over the sensor 1. The directions of shaft rotation and axial force are shown in Fig. 9.

Fig. 10 shows the skew angle of the roller at the maximum loading position (azimuth = 0 deg). Black plots in the figure show the calculated skew angles and white ones show the measured results. The absolute values of measured skew angle are also shown in the figure. In the experiment, the roller skew angle changed from positive to negative suddenly at around 3000 rpm. The absolute values of skew angle were at around 1 deg and almost constant in the speed range of 1000 - 6000 rpm. In the calculation, the roller skew angle is around +1 deg. It is still not clear why the roller changed its sign at 3000 rpm in the experiment. The rollers might have two stable positions (+1 deg and -1 deg) for the roller skew motion.

Fig. 11 shows the axial force generated by the skew motion of the roller. For reference, it also shows the negative of the measured axial forces for the region above 3000 rpm. Accordingly with the change in the sign of the skew angle at 3000 rpm, the axial force also changed its sign in the experiment. The absolute value of the axial force decreased with increasing speed. Though the signs differed in the region above 3000 rpm, the magnitude of the experimental and calculated values showed good agreement.

TAPERED ROLLER BEARING ANALYSIS - The performance of tapered roller bearings such as running torque, roller revolution, cage rotation, roller skew angle, is analyzed by TAPTAC. Input data of the calculation is

shown in Table 4. The test bearing is HR32217 which has a bore diameter of 85 mm.

The experimental apparatus was similar to that shown in Fig. 4. However, the shaft was arranged horizontally instead of vertically as shown in Fig. 4. Jet lubrication system was adopted in the experiment and a mineral oil having a viscosity of 32 mm^2/s at 40°C was used. Three jet nozzles were arranged to feed the oil to the bearing.

Fig. 12 shows the relationship between bearing torque and speed. Plots show the measured torque while the broken line shows the calculated torque. The measured torque agrees with the calculated one when the oil feeding rate was 1 l/min. On the other hand, the calculated torque shows higher values than the measured one, especially in the mid-speed range when the oil feeding rate was 2 l/min. This difference is attributed to drag loss, since good agreement existed when fed with a small amount of oil. Although the maximum discrepancy is 20% at most, more research effort is necessary to estimate the drag loss better.

CONCLUSION

A new rolling bearing analysis program package named BRAIN has been developed. BRAIN software gives results in several minutes when run on a PC. BRAIN can calculate the kinematics and the performance of most rolling bearings. The calculation results are useful, especially for advanced applications involving rolling bearings.

The experiment with the four point contact ball bearings was conducted to compare results with those from BRAIN. The running torque of the four point contact bearing was well-simulated by BRAIN. The PV distribution of the four point contact ball bearing was also calculated. The PV value of four point contact ball bearings is an essential design parameter in any attempts to reduce the power loss and to prevent severe wear.

A needle bearing experiment was also conducted. The skew angle of the rollers and resultant axial force were measured and compared with those from BRAIN. The measurements agreed with the calculations although their signs were opposite of each other in the high speed region.

The running torque of a tapered roller bearing was measured and compared with the calculation from BRAIN. The tendency of the measured torque was well-simulated by BRAIN. The agreements between the experimental and calculated results were good.

Development of Dynamic Simulation Models of Seated Reaching Motions While Driving

Xudong Zhang and Don B. Chaffin
University of Michigan

Deborah Thompson
Chrysler Corporation

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

A research effort was initiated to establish an empirical data base and to develop predictive models of normal human in-vehicle seated reaching motions while driving. A driving simulator was built, in which a variety of targets were positioned at typical locations a driver would possibly reach. Reaching motions towards these targets were performed by demographically representative subjects and measured by a state-of-the-art motion analysis system. This paper describes the experiment conducted to collect the movement data, and the new techniques that are being developed to process, analyze, and model the data. Some initial findings regarding the role of torso assistive motion, the effect of speed used in completing a motion on multi-segment dynamic postures, and illustrative results from kinematic modeling are presented.

INTRODUCTION

The proliferation of computer technology has been renovating conventional ergonomics. The design as well as the analysis of human-machine systems such as a driver-vehicle system is becoming more and more computerized. As this trend continues, the development of human models that realistically predict how people behave and interact with the system is of great importance. Not only can such models facilitate quantitative, easy-to-conduct ergonomic analysis, but also can economize the design by providing recommendations and changes early in the process prior to costly prototyping.

Most of the existing human models that can be used to facilitate vehicle design and ergonomic assessment are static biomechanical models [1,2,3,4]. Although there are a limited number of computer-aided design programs that feature dynamic human models (e.g., JACK), these models usually are not based on empirical studies of preferred human movements. Rather, they use overly simplified heuristics or rough estimates of human kinematics, and therefore the realism of rendered human dynamic motions remains untested and questionable. There is a pressing need for dynamic human models that are empirically validated for a typical range of driving tasks and for people of varied anthropometry, gender, and age.

Recognizing this need as well as the emerging new techniques to measure, analyze, and model complex 3D human movements, the Center for Ergonomics at the University of Michigan and Chrysler Corporation have initiated a collaborative research project. The first phase of this project has three primary goals: 1) to establish an empirical database of in-vehicle human reaching movements (concurrent with driving); 2) to derive models that accurately predict dynamic, multi-segment postural profiles during such movements; 3) to develop a computer-aided design (CAD) software tool which generates graphical animation of normal human movements predicted by the database and the models. The specific purpose of this paper is to describe the experiment conducted to acquire three-dimensional seated reaching movement data and the techniques to analyze and model the resulting large scale, complex data. Some preliminary findings and results achieved are also presented as illustrations.

EXPERIMENTAL PROCEDURES

SUBJECTS - Thirty-eight subjects including 20 males and 18 females, demographically representative in terms of anthropometry and age, served as subjects and were paid for their participation. Table 1 provides some descriptive statistics for the age and gross anthropometry of these subjects.

REACHING-WHILE-DRIVING TASKS - A driving simulator has been developed at the Center for Ergonomics of the University of Michigan. It consists of a mock-up vehicle and a graphically rendered driving scene on a big screen monitor integrated with the primary controls (e.g., steering wheel, acceleration pedal, etc.) of the vehicle. As illustrated in Figure 1, forty-one targets grouped into six areas that emulate the typical location zones that a driver would normally reach to, are presented in the simulated vehicle. These six areas include left side corner (door or mirror control), headliner, shift console, instrument panel (radio &

climate control), glove box, and passenger side door. The number of targets within these areas was 3, 5, 5, 18, 8, and 2, respectively. Note that the instrument panel and glove box areas can be moved in and out, which doubles the number of targets in these two areas and also somehow emulates two different size vehicles. The three targets placed at the left side corner are used to evaluate the left-right motion symmetry.

Table 1.
Descriptive Statistics of Age and Gross Anthropometry Information of the 38 Subjects

Attribute	Mean	Std. Dev.	Minimum	Maximum
Age	35.3	15.4	19	72
Stature (cm)	171.3	11.1	152.8	201.2
Weight (lb)	155.6	35.8	100	293

While the subjects were performing driving tasks, they were intermittently signaled to reach towards the 41 targets in a discrete, natural, preferred manner. Each target was reached twice, and the order of 82 reaching movements was generally randomized (reaches to the in and out positions of the instrument panel and glove box area targets, and to the three left side targets, were blocked but randomized within the blocks). Instructions and a training session were provided to the subjects prior to the reaching task performance that was actually measured. The seat position was adjusted as individually preferred at the beginning of the experiment but remained fixed thereafter.

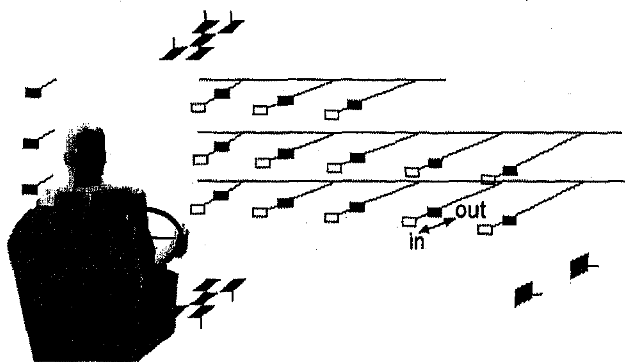

Figure 1. A simulated vehicle where 41 targets are positioned in six areas: left side corner, headliner, center console, instrument panel, glove box, and passenger side door. The instrument panel and glove box area targets can be moved in and out to create twice as many targets.

DATA ACQUISITION - Eleven spherical reflective markers were placed on palpable body landmarks or on rigid fixtures attached to the body identifying the right hand, right wrist, right elbow, right & left shoulder, head, suprasternale, right & left anterior-superior iliac spine (ASIS). The three markers on the right hand and one on the right elbow were moved onto the left hand and elbow during left side reaching movements. As illustrated in Figure 2, these markers formed a virtual stick-figure representation of the biomechanical system of our particular concern. This representation is also often referred to as a linkage representation, with the assumption of each segment being a rigid link. The kinematics of this linkage describe the dynamic postures of the torso, right upper extremity, neck and head. An opto-electronic motion analysis system (MacReflex™, Qualisys Inc.) with four cameras was employed to measure the movements of the markers at a sampling frame rate of 25 Hz. The system has the capability of tracking the captured motions as a succession of 2D images (four images corresponding to four cameras for each instant time frame) and then delivering the 3D marker Cartesian coordinates of in a time series.

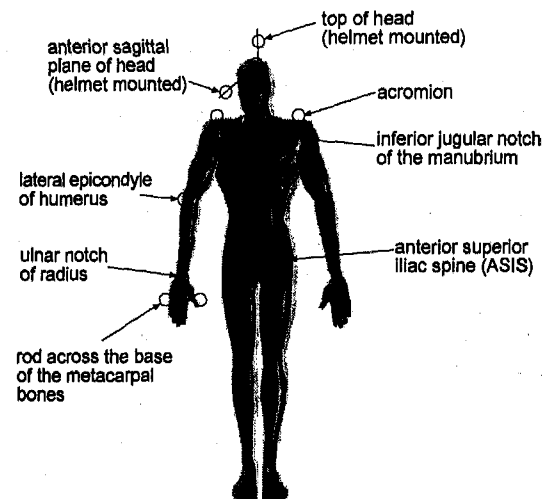

Figure 2. The placement of 11 reflective markers which describe the kinematics of the torso and right upper extremity. The three markers on the right hand and one on the right elbow were moved onto the left hand and elbow during left side reaching movements.

ANALYSIS & MODELING

JOINT ANGLE DERIVATION - In order to enhance the realism of our linkage representation and to better describe the kinematics using more truthful angles, the coordinates of surface markers were transformed into those of internal joint centers for the shoulder, elbow, and wrist joints. There was no existing kinematic algorithm readily applicable to carry out this transformation for our specific marker placement situation, since most algorithms require at least three markers on each body segment. A new, experimentally confirmed, heuristic method was developed to accomplish the transformation [5,6]. Based on the enhanced linkage, a comprehensive set of joint angles was defined [7] and computed. These joint angles include absolute angles needed for completely determining a posture (i.e., linkage configuration) and some relative angles (e.g., elbow included angle) that are more revealing and easier to visualize.

STATISTICAL MODELING - It is intended to present our empirical data base in the form of a robust population statistical model which predicts movement profiles for in-vehicle reaching motions. This model uses the derived angular profiles as dependent variables, and the target location and subject individual attributes as independent variables. This major statistical modeling effort takes place at the Statistics Department of The University of Michigan. A new modeling approach based on regression analysis for functional responses has been established [8].

In addition to the principal statistical effort of generating a robust population model, a multitude of statistical analyses have been conducted or are being explored, using subsets of the collected data, to address specific issues. Such issues include the effects of target location on the amount as well as the direction of torso assistive motion, the effect of the speed used in completing a reaching movement on dynamic postures, the effects of individual anthropometry on the preferred seat position reflected by the ASIS location, etc. The results from these analyses can either aid in developing the general statistical dynamic posture prediction model or be used singly to provide useful design information.

KINEMATIC MODELING - In parallel with the statistical modeling effort, kinematic modeling is also being undertaken. The linkage representation described earlier is simplified as a four-segment chain with seven degrees of freedom to kinematically represent the upper torso and right upper extremity. Figure 3 portrays this simplified linkage which consists of the torso, right clavicle, right upper arm, and right forearm (including the hand which is treated as a rigid extension of the forearm). The degrees of freedom possessed by this linkage account for torso flexion/extension, torso medial/lateral lending, torso twisting (modeled as clavicle rotation), shoulder flexion/extension, shoulder ad/abduction, humeral rotation, and elbow flexion/extension.

What posture prediction poses is a classic problem of solving kinematic redundancy in biomechanics. That is, given an instantaneous hand location, how the configuration of the linkage is determined from an infinite number of possibilities to position the body segments? Optimization has been a viable tool for solving this redundancy problem, based on the theory that an inherent optimal strategy is followed by people in posture control. Previous three-dimensional models concerning seated reaching postures were static, relying on tedious moment-to-moment optimization procedures [3,9,10], and therefore have limited practicality. We propose a unique velocity-domain approach for solving the kinematic redundancy problem in a dynamic fashion. We view it as a problem of determining how changes in hand coordinates are allocated among changes in degrees of freedom, and theorize that people employ an optimal allocation strategy to minimize the total weighted energy-type effort in dynamic posture control. Weighting parameters assigned to individual body segments quantify the "cost" of their participation in a movement. More detailed descriptions of this approach can be found in Zhang and Chaffin [11].

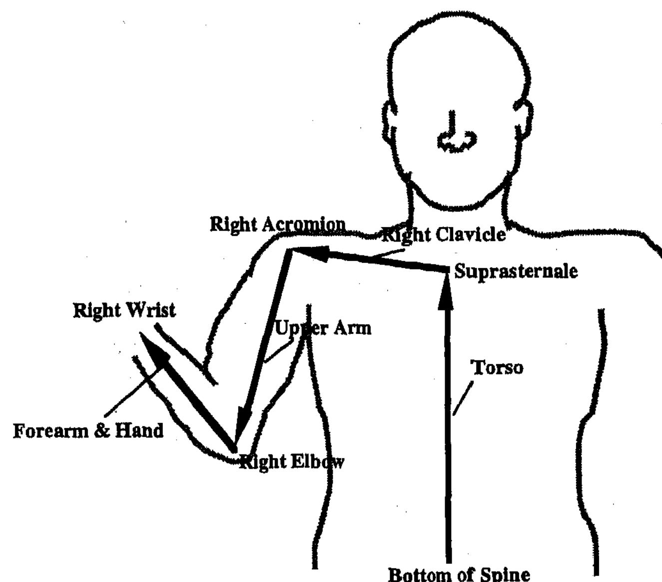

Figure 3. A four-segment seven-degree-of-freedom linkage to model the upper torso and right upper extremity.

RESULTS

STATISTICAL ANALYSES - The primary statistical analysis that promises to deliver a robust statistical model predicting the behavior of in-vehicle reaching movements is ongoing. A number of "satellite" analyses however have been concluded. One analysis which examined the movement speed effect on postural profiles revealed an insensitivity of instantaneous postures to speed variation—a difference in the speed mode used to complete a movement merely had a scaling effect on the angle displacement as well as velocity profiles. This analysis therefore suggested excluding the speed as a modeling element. Another analysis showed that the torso motions towards the targets located in the instrument panel and glove box areas have interesting and predictable characteristics. The torso was found to be a very adept prime mover in reaching targets located within or beyond the arm length. The amount and direction of torso motion can be well predicted ($R^2 = 0.85$-0.95) by linear regression models using independent variables derived from target location and distance with respect to a driver. This latter analysis helped convince ourselves that there is some inherent strategic planning involved in modeling of human movements.

OPTIMIZATION-BASED INVERSE KINEMATIC MODEL - The proposed model is being subjected to empirical tests using a subset of acquired movement data. Preliminary results indicated an averaged (across different movements and subjects) mean error (across the entire movement and seven joint angles) of 3 degrees in the predicted angular profiles with respect to the measured one. Such a level of accuracy compares favorably with what was achieved by previous posture prediction models most of which were two-dimensional and/or static. Figure 4 is an illustration of

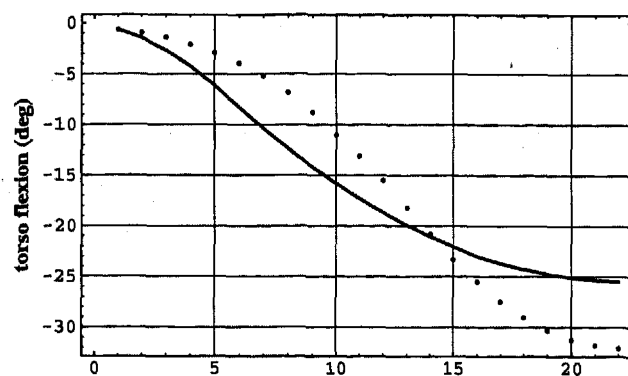
predicted angular profiles versus the measured ones for a reaching movement towards a target in the glove box area. The mean error of prediction (across the entire motion and 7 joint angles) was 4.5 degrees for that particular trial.

It was also found that the weighting parameters (which quantify the allocation strategy among the body segments) demonstrated some difference between, but also congruence within, types of reaching movements driven by different in-vehicle target locations. Future efforts will continue in validating the model using more experimental data. Particularly, the emphasis will be placed on synthesizing the model parameters from one set of subjects and applying them to another set of subjects. Some statistical means will also be needed to summarize these parameters and present them for population prediction purposes.

CONCLUSION

Researchers and practitioners in the field of ergonomics are cognizant of the trend toward computerized ergonomic analyses to aid the design of increasingly complex systems. However, the lack of a realistic, three-dimensional, dynamic model of human movements has been the roadblock to the quest for accurate and comprehensive computer-aided ergonomics. Our research effort has made an initial but important step toward the development of such models. To our knowledge, it is the first major effort of studying and modeling three-dimensional, multi-segment human reaching movements under a realistic context. Based on the encouraging results we have harvested so far, we are fully confident of accomplishing the stated goals. We are also prepared for expanding the current effort to a variety of system configurations and human physical tasks other than driving.

Our effort is unique in that we are able to enjoy the advantage of having two concurrent modeling approaches. Considerable benefit has been and will continue to be gained from the cross-fertilization between statistical and kinematic modeling approaches.



Beyond the practical motivation of developing an advanced dynamic simulation tool, strategic issues related to human motion control also underscore the theoretical significance of studying and modeling human reaching movements in a systematic fashion. It is believed that the findings gained from this effort will contribute to advancing knowledge in that respect as well.

Development of Human Back Contours for Automobile Seat Design

Barry L. Frost III, Robert P. Hubbard, and Robert L. Boughner
Michigan State University

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Driver and passenger comfort, as related to automotive seats, is a growing issue in the automotive industry. As this trend continues, automotive seat designers and developers are generating a greater need for more anthropometrically accurate tools to aid them in their work.

One tool being developed is the JOHN software program that utilizes three-dimensional solid objects to represent humans in seated postures. Contours have been developed to represent the outside skin surfaces of three different body types in a variety of postures in the sagittal plane. These body types include: the small female, the average male, and the large male.

INTRODUCTION

Comfort in automotive seats is an issue that has increased in interest over the past decade. Seats are being contoured to promote spinal curvature and designed with variable contours to promote movement and variation of spinal curvature and posture. Historically, seat designers have created seats mainly with templates on paper. The use of templates has become increasingly difficult in the design of highly contoured seats. Testing the seat design for comfort could not be done until a physical prototype was built. With the advent of computers and three-dimensional solid modeling programs, seat designers developed the ability to generate surface contours. If human back contours can be represented with computers, seats that fit people's contours can be designed. While not sufficient for comfort, the ability to fit seats to human contours is one of the necessary steps for creating comfortable seats. The use of computers in seat design also reduces the need for costly physical prototypes.

The following paper discusses several additions that have been made by the Michigan State University Biomechanical Design Laboratory to the JOHN software program, developed using the I-DEAS solid modeling software from Structural Dynamics Research Corporation. The first addition was the improvement of the existing JOHN contours. The software program was then rewritten to allow contour generation for any amount of movement of the lumbar spine in the sagittal plane. New contours for the large male and small female were also added to the program. The JOHN program was originally introduced at the Society of Automotive Engineers International Congress in 1992 by Hubbard, et al., as paper no. 930110, titled "New Biomechanical Models for Automobile Seat Design" [1]. This paper will begin with a historical overview of the JOHN model examining four previous key developments. Each of the three new additions will then be discussed, followed by a conclusion.

BACKGROUND

In the early 1980's, the University of Michigan Transportation Research Institute (UMTRI) conducted an anthropometric study for crash dummy development by determining how the occupant is positioned within the automobile [2]. In their study, UMTRI placed people in a simplified model of the driver's side of an automobile and used a combination of seat surface castings and photographs of anthropometric landmarks on the subjects to determine exterior skin contour points. Anthropometric data were collected for a wide variety of individuals and they were classified and averaged into three categories: the mid-sized male [3], the small female, and the large male [4]. An example of the contour data collected for the average adult male with external and internal landmarks is shown in Figure 1.

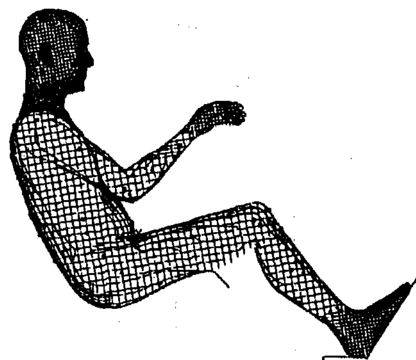

Figure 1. UMTRI Average Male Contour

In the late 1980's, Michigan State University (MSU) began developing computer models of the

human musculo-skeletal system for seat design [1]. The first work at MSU was done by Haas [5], who developed a two-dimensional computer model, called JOHN, to determine the relative position of the head, thorax, and pelvis of an average human male, as shown in Figure 2.

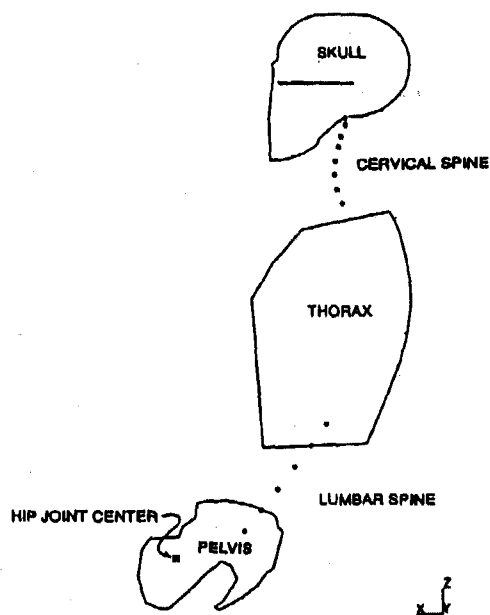

Figure 2. Two-Dimensional JOHN Computer Model

The JOHN software program utilizes solid objects to represent humans in seated postures. The head, thorax, and pelvis segments in the Haas model were connected by a series of points depicting joint centers in the cervical, thoracic, and lumbar spinal regions.

During this time at MSU, two anthropometric variables were defined for the JOHN model. Torso Recline Angle (TRA) is defined as the angle, measured from vertical, of the line that passes from the T_{12}/L_1 spinal joint center to the L_5/S_1 spinal joint center, as seen in Figure 3. The second is an internal anthropometric variable known as Total Lumbar Curvature (TLC). A back with a flat lumbar section where all the spinal joint centers are collinear is defined as TLC=0°, Figure 4. Given a reference line on the pelvis or ribcage that is parallel to the TLC=0° line, TLC can then be determined for any amount of lumbar curvature by measuring the angle between the reference line and a line passing between the T_{12}/L_1 and L_5/S_1 spinal joint centers, Figure 5. TLC is defined as positive when the back of the lumbar spine is concave.

The next study at MSU, by Boughner [6], took the two-dimensional program of the adult male developed by Haas and created a three-dimensional solid model program, Figure 6. Boughner created models of the entire major skeletal structure using data

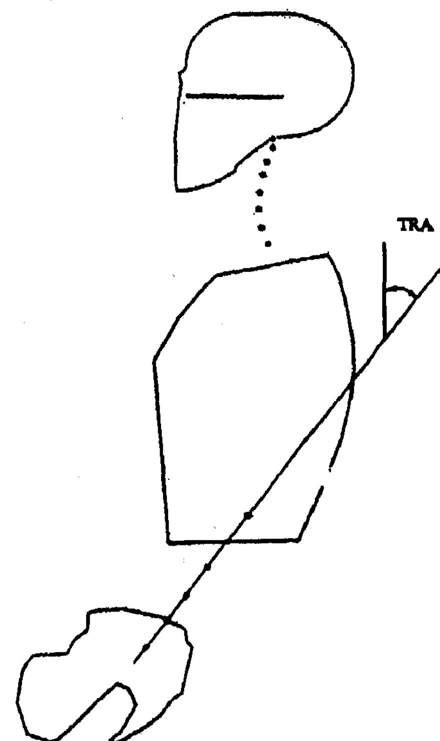

Figure 3. Torso Recline Angle (TRA)

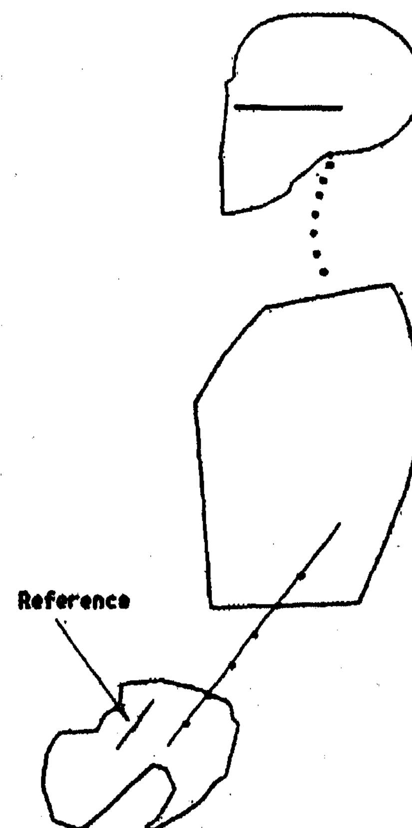

Figure 4. Total Lumbar Curvature = 0°

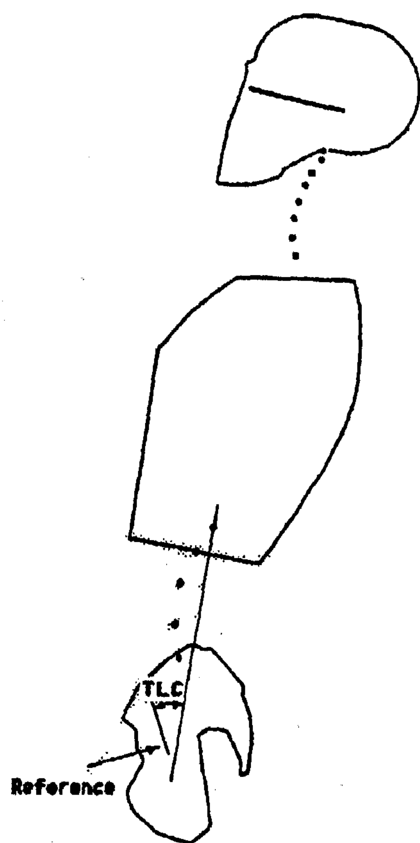

Figure 5. Total Lumbar Curvature > 0°

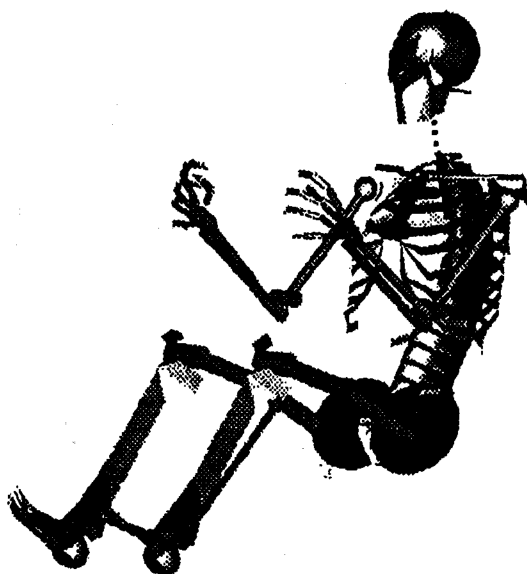

Figure 6. Three-Dimensional JOHN Computer Model

from several anatomy texts [6,7,8] and data from the UMTRI study [3]. Boughner further refined his program by adding the ability to model leg muscle geometry and calculate hamstring length for the JOHN model.

In another investigation, Bush [9] developed models of the *erector spinae* muscles, the muscle groups that lay directly to either side of the spinal column and external skin contours for the back of the JOHN model, Figure 7. Tissue thickness of the model was determined by examining cross-sections of cadavers presented by Koritké and Sick [10]. Bush developed skin contours for the JOHN model at discrete values of Total Lumbar Curvature (TLC), specifically at values of -10°, 0°, 10°, 20°, 30°, and 40°. Because three-dimensional renderings of the UMTRI body contours were not available at that time, Bush was limited to examining these two contours at specific points only and was not able to perform an in-depth comparison between his contours and the UMTRI contours.

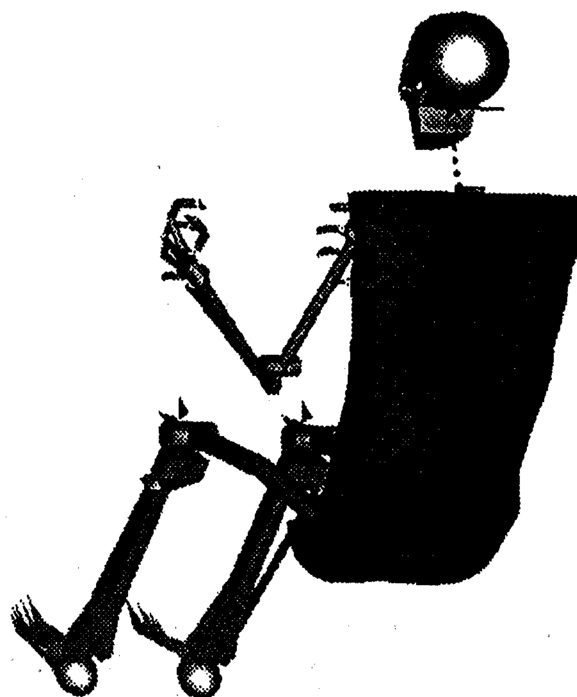

Figure 7. JOHN Model with Bush Contour [9]

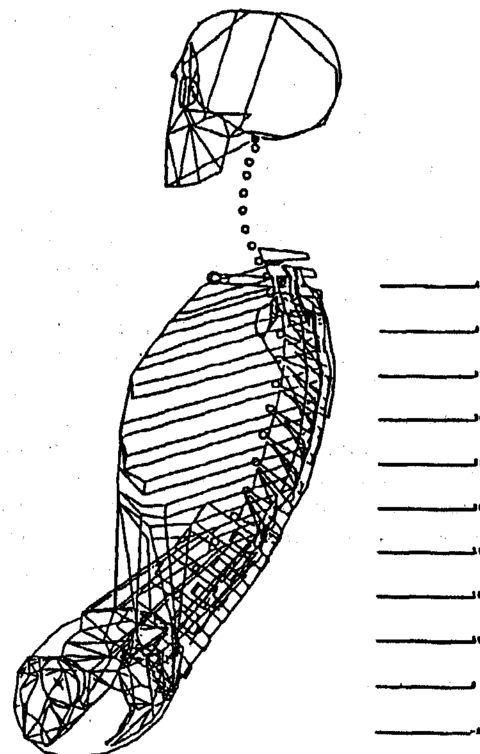

Figure 8. JOHN Model with Bush Cross-Sections [9]

METHODS

REDEFINITION OF THE JOHN CONTOUR

In his research, Bush performed a comparison between his contours and the contours developed by UMTRI [3]. Even though the body surface landmark data from the UMTRI study had been available for some time, without computer models Bush was limited to analyzing his data in comparison to UMTRI's at a few surface landmarks. More recently, complete three-dimensional UMTRI contours became available as computer files. With the new contour files, the complete UMTRI contour data could be analyzed on the computer at every point.

To analyze the differences between the contour created by Bush and the UMTRI contour, both contours were placed over the JOHN musculo-skeletal system. The UMTRI contour represents an average adult male in a single posture with a flat lower back, or straight lumbar spine (TLC = 0°). Therefore, the UMTRI contour was compared with Bush's contour for a TLC = 0°.

Cross-sections of the contours in the back region were created through each of the vertebrae down the spinal column, seen in Figure 9. Each cross-sectional plane was defined by the mid-plane between the top and bottom of each vertebrae. In the lower buttock region, the cross-sectional planes were defined as the y-z plane, also known as the vertical transverse plane, where y represents the width dimension and z is the vertical height dimension. The y-z planes were created at distances from the H-point in a range from 50 mm to -70 mm, at 20 mm increments from front to rear. In the upper buttock region the cross-sectional planes were defined by rotating the vertical transverse plane 45° about the y axis. Three sections were made at distances, measured perpendicular to the plane from the H-point, of 50, 70 and 90 mm in the rearward direction.

Once the new vertebral cross-sections were created, the Bush contour line was compared to the UMTRI contour line at each cross-sectional level. In the upper body, sections of the back varied no more than 14 millimeters in the posterior direction and the differences between the contours in the lateral direction varied between 3 to 39 millimeters. In the lower body, or buttock region, the Bush contour and the UMTRI contour had differences in the inferior direction ranging between 17 and 26 millimeters and lateral differences varying between 14 to 47 millimeters.

New contour lines were then drawn at each vertebral level. While the UMTRI contour [3] was used as a guide to the overall size of the new contour, an attempt was made to keep the muscle and bone definition shown in Bush's contour [9]. In sections where there was a large difference between the positions of the Bush and UMTRI lines, the new contour was positioned closer to the UMTRI contour while attempting to maintain the basic shape of the Bush contour.

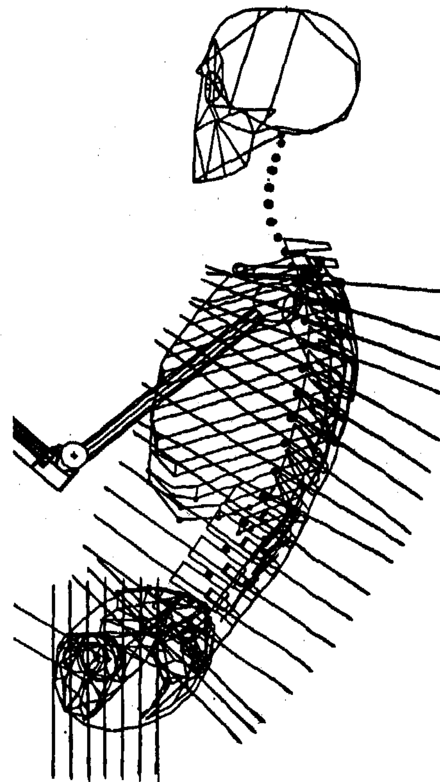

Figure 9. JOHN Model with Cross-Section Locations

The approach for representing body contours had been to try to model JOHN as if the model had no deformation of the skin surface, or zero forces acting upon the body. The goal of undeformable contours was difficult to obtain because every model examined in the development of JOHN was in a deflected, seated posture. Therefore, several approximations were used to move closer to the goal. Allowances were made due to UMTRI's method of data collection including using casting tape, which spanned across concave contours of the back and buttocks region. Allowances were also made for the averaging technique used by UMTRI to obtain the final contour. The averaging technique used by UMTRI caused several concave regions to become less severe in their concavity.

Once the new contours were defined, point coordinates along each contour line were calculated according to the reference axes of the JOHN system. Each cross-sectional line was defined by the same number of points to create fully defined vertical lines down the length of the model. The coordinates were then entered into the JOHN model. Splines were calculated for each cross-section and down each vertical line to create a wireframe mesh, Figure 10.

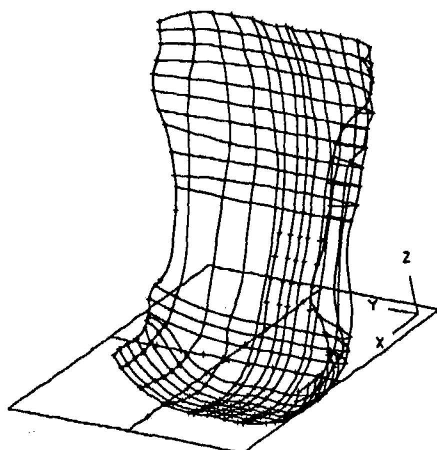

Figure 10. JOHN Contour Wireframe Mesh

A solid object skin surface was developed from the wireframe mesh. Due to the constraints of our computing system, I-DEAS would only allow approximately 20 splines to be chosen at one time in the generation of skin contours. Not all of the splines could be chosen to create the solid. Therefore, all of the vertical splines were chosen and cross-sectional splines were only chosen at each of the following levels:

1. Third thoracic vertebrae level (T_3),
2. Eleventh thoracic vertebrae level (T_{11}),
3. Third contour line below the fifth lumbar vertebrae level (UB_3), and
4. Seventh or lowest contour line in the lower buttocks region (LB_7).

The four cross-sectional splines were chosen as they are nearly equidistant along the length of the contour. The final new skin contour can be seen in Figure 11.

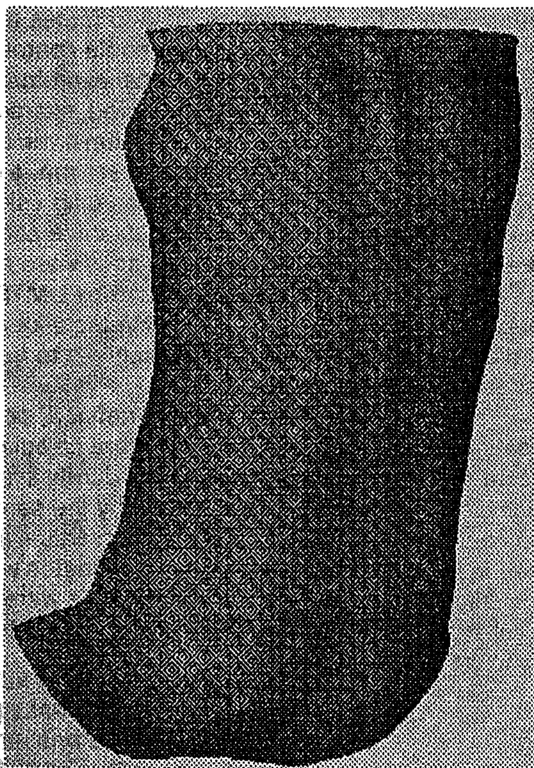

Figure 11. The New JOHN Contour

Even though more information on human contours are being developed by current research at MSU, the new contour described above is the best contour possible with the currently available data for TLC = 0°. Once the contour data comes available from MSU and other sources, the JOHN contours can be further validated and refined. The importance of having highly representative contours can not be overstated. By using better contours, seat designers can design seats to have a better fit.

CREATION OF "VARIABLE" CONTOURS

The second objective was to design and implement a method to create contours at any value of TLC and TRA. In the original development of contours for the JOHN average adult male by Bush [9], contours were created for six different values of TLC. While keeping the amount of TRA at a constant 35°, the JOHN model was placed at angles of TLC equal to -10°, 10°, 20°, 30°, and 40°. At each TLC value, Bush created horizontal cross-sections as he had done for the 0° TLC model. Once again, contour lines had been drawn over the modeled muscles and bones with an offset thickness.

A limitation of the Bush contours was that seat designers only had the ability to evaluate seats with those six contours. If a designer wanted to design a seat for a TLC value other than one of the 10° increments, they would not be able to set the musculo-skeletal model at that TLC value, but would rather have to add an overlying contour at a 10° increment nearest the TLC value.

By examination of the ribcage and its skin surface, it was assumed that points on the skin surface over the thoracic and pelvic regions tend to remain in place relative to the rib cage and pelvis, respectively, over a wide range of motions in the sagittal plane. For this reason, points were attached to the rib cage, pelvis, spine, and muscles of the JOHN musculo-skeletal model. These skin points would then move with those objects as JOHN's posture changed to different values of TLC. Once the designer has set the musculo-skeletal system in a preferred posture, points can then be splined through and the contours for that exact selected posture would be created in the same manner as the 0° TLC contour. This process allows for both a systematic and repeatable method for contour generation.

A new articulation program was developed based upon Boughner's program [6], in which the musculo-skeletal objects and skin surface points articulate about the lumbar spinal joint centers. Once this motion is completed, the points are splined and a solid contour is generated from the splines. The program then rotates the musculo-skeletal system, with the new contour, to the specified TRA and aligns the *ischial tuberosities* to their original position. Leg and arm motion is then manipulated at the request of the user.

By allowing the contours to articulate with the musculo-skeletal system, contours can be made for any degree of TLC. The seat designer no longer has to

design a seat for occupants only at TLC values of -10, 0, 10, 20, 30, and 40 degrees.

SMALL FEMALE AND LARGE MALE CONTOURS

Even though JOHN is a useful representation of the average U.S. man, designers have the need to determine if seats will also accommodate people who are tall or short in stature, or large or small in corpulence. Due to that need, two more models were developed by MSU in addition to the JOHN model. In order to model tall, heavy men, the JERRY model was developed to represent the 95th percentile male in stature and weight. To represent small women, a 5th percentile (stature and weight) female model was developed called JANE. These models were based on studies by UMTRI [4] that established skeletal landmark locations and body contours for tall, heavy men and short, light women.

The large male and small female contours were developed by scaling from the average male contour. By using the average male model as the basis, the small female contour and the large male contour would then be related in a known way, creating a basis for future models different from the 95th male, 50th male and 5th female sizes.

Scaling factors were developed by examining the differences between the dimensions for the UMTRI average male and the dimensions for the UMTRI small female and large male. By examining the distances between different skeletal landmarks and comparing the related distances between the three models, scaling factors were established. The torsos of the UMTRI contours were separated into three segments: thoracic, lumbar and pelvic with different scaling factors chosen for each segment. This was done because of differences in the relative proportions of these three body segments between the male and female.

Scaling factors for the thoracic region were determined by examining the distances between the following points defined by UMTRI [2], seen in Figure 12:

1. *Mesosternale* to the T_4 *spinous process*
2. Lowest (inferior) point on the right 10^{th} Rib to the lowest (inferior) point on the left 10^{th} Rib
3. C_7 *spinous process* to the T_{12} *spinous process*

These distances were chosen because they lie mainly in the direction of each of the coordinate directions. The scaling factors between the points were calculated as shown below in Table 1. The scaling factors in each of the coordinate directions were calculated by dividing the distances for the small female and the large male by the related distance of the average male.

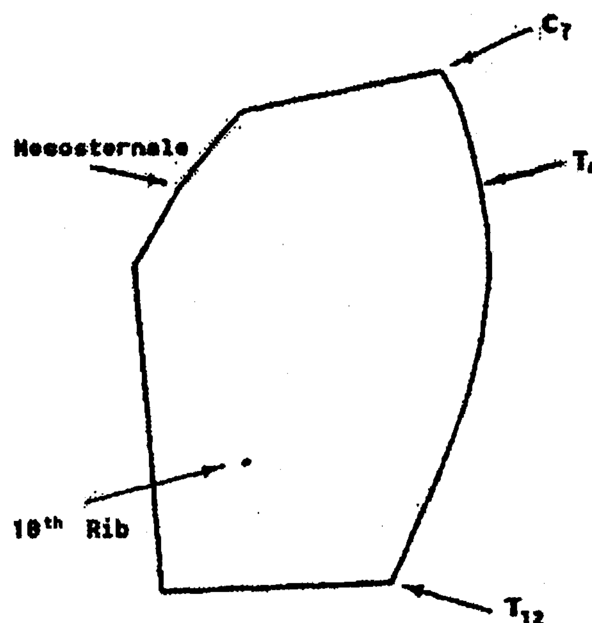

Figure 12. Thoracic Scaling Points

Table 1. Thoracic Scaling Factors

	Mesostem. - T_4 sp. pro.	Right 10^{th} rib - left 10^{th} rib	C_7 sp. pro. - T_{12} sp. pro.
JOHN Distance (mm)	195.1	312	343.6
JANE Scaling Factor	0.77	0.83	0.95
JERRY Scaling Factor	1.1	1.24	1.1

Scaling factors for the pelvic region were determined by examining the distances between the following points, seen in Figure 13:

1. L_5 *spinous process* to the center of the line between the right and left Anterior Superior Iliac Spine (ASIS)
2. Right ASIS to the left ASIS
3. *Iliocristale* to the Inferior Tuberosity projection on the mid-sagittal plane

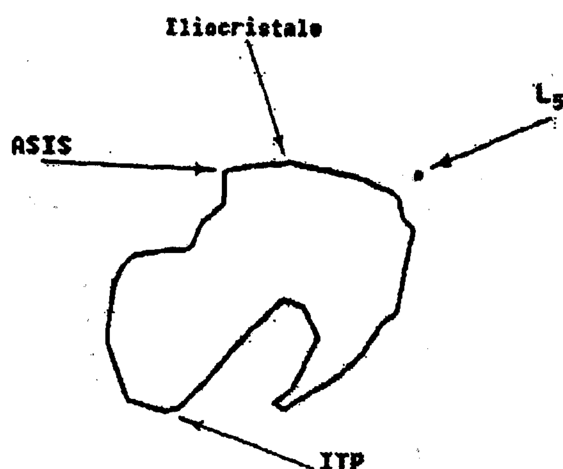

Figure 13. Pelvic Scaling Points

Again these dimensions were chosen due to their similarities in direction with the coordinate axes. Table 2 shows the scaling factors in the pelvic region.

Table 2. Pelvic Scaling Factors

	L_5 sp. pro. - ASIS	Right ASIS - left ASIS	Iliocrist.- Inf. Tub. pro.
JOHN Distance (mm)	164.6	222	231.7
JANE Scaling Factor	0.89	0.93	0.89
JERRY Scaling Factor	1.15	1.09	1.15

Once the scaling factors had been established for both the thoracic and the pelvic regions, a systematic approach was developed to place the scaled regions in the proper orientation. It was apparent that there were postural differences between the UMTRI contours of the small female, the average male, and the large male. These differences in posture were determined by scaling the torso segments of JOHN. The scaled torso segments were then fit to the UMTRI surface landmarks of the large male and small female. The UMTRI contours showed that large men tend to slouch more than average-sized men with a -3° TLC difference between the two. The small female contour showed a 15° more erect posture (+15° TLC) relative to the average male. In order for the scaled JOHN contours to be in the orientation of the UMTRI contours, the JOHN contour was first articulated and then scaled to match the posture of the UMTRI contours.

When an object or point is to be scaled in I-DEAS, two parameters are required: the scaling factor and the point from which the object or point will be scaled from. When an object or point is scaled from any single point, the scaling procedure will cause all other points to move. Because all of the points in the JOHN model were scaled from the origin, located at the H-point, each of the scaled regions required a translation to move them back into the correct position.

In order to realign the newly scaled pelvic regions, the x value of the L_5 *spinous process* point and the z value of the Inferior Tuberosity projection point were each compared to their related values in each of the three models. These values were used because it was assumed that the height of the seat surface and the depth of the seat back were well defined due to the methods used in the UMTRI study [2]. The skin points were translated to align the L_5 *spinous process* and the Inferior Tuberosity projection.

To position the newly scaled thoracic regions, it was assumed that because the C_7 *spinous process* is a easily palpated point, the location was accurately measured by UMTRI. This point was then compared to the newly scaled C_7 spinal point to determine translation values.

Scaling factors for the lumbar region were determined after the both the thoracic and pelvic regions were scaled and positioned. By examining the distances between the newly positioned points of the thoracic and pelvic regions, scaling factors for the lumbar regions were established. Because each of the models had a TLC=0° posture, the points on the lumbar spinal processes are positioned in a straight line in the sagittal plane. This linearity, therefore, causes the scaling factor for the x (anterior) direction to be the same as the scaling factor for the z (superior) direction. To determine this scaling factor, the distance was calculated from the newly placed T_{12} *spinous process* point to the newly placed point defining the midpoint of the top upper buttock (UB) contour line. Table 3 shows the calculated distances and the resulting scaling factors. It should be noted that these scaling factors are smaller than those for the pelvic and the thoracic regions for both the large male and the small female. This may be explained by Boughner's three-dimensional model [6], which was based upon the two-dimensional model developed by Haas [5]. Even though Haas lowered the position of the pelvis relative to the thorax from the UMTRI position for the average male, creating a longer lumbar spine in the JOHN model, the positions of the large male and small female pelvic regions were never fully examined. It is likely that the pelvises in both the UMTRI small woman and large man were also positioned too high, as was discovered for the UMTRI average man.

Table 3. Lumbar Distances and Scaling Factors

	JOHN (mm)	JANE (mm)	JANE Scaling Factor	JERRY (mm)	JERRY Scaling Factor
T_{12} sp. pro. - UB midpnt.	206.4	162.3	0.78	212.2	1.02

Information about the y (lateral) direction in the lumbar region was not available from the UMTRI data

because all of the points in that region lie on the mid-sagittal plane (y = 0). In the JOHN model, the points defining the skin contour in the lumbar region covers only a narrow area down the center of the spine and over the *erector spinae* muscles directly to each side of the vertebral column. Therefore, it was assumed that using the y scaling factor calculated for the thoracic region, Table 1, would suffice over the narrow width of the lumbar region for both the small female and the large male.

The placement of the lumbar region was determined by the final placement of both the pelvic and thoracic regions. The points associated with the lumber region were rotated and translated into position by examining the position of the point associated with the T_{12} *spinous process* and the midpoint of the top upper buttock contour. The angle of the lumbar region was determined by calculating the angle between a line drawn from the T_{12} point to the pelvic spinal point and a line in the -x (posterior) direction. Once the lumbar region was rotated to the calculated angle, the region was translated into position such that the point associated with the T_{12} spinous process was placed in its original position. Table 4 summarizes the calculated angle of the lumbar region and the amount of translation to move the region into position for both the small female and the large male.

Table 4 Lumbar Translation Values

	JANE	JERRY
x (anterior) translation (mm)	-22.5	-31.155
z (superior) translation (mm)	16.6	5.924

Oblique views of the JANE and JERRY contours at a value of 0° TLC are shown in Figure 14. In comparing each of the new contours to the contours created by UMTRI for the small female and the large male, the respective contours match to within several millimeters of one another. Figure 15 is a front and side view of JANE's contour overlaid onto the UMTRI small female contour. The front and side view overlay of JERRY's contour with the UMTRI large male is seen in Figure 16.

Each of the new contours of JANE and JERRY are representative of the size and shape of the small female and the large male and each maintain muscle and bone definition throughout the contour. The JANE and JERRY contours can also be articulated into any degree of TLC and TRA, as their contours are based upon surface points as in the JOHN contour. By scaling the contours of JANE and JERRY from the JOHN contour, each contour is now related to the other. The seat designer now has the ability to model seats for not just the average male, but can design seats that fit a larger array of occupant sizes.

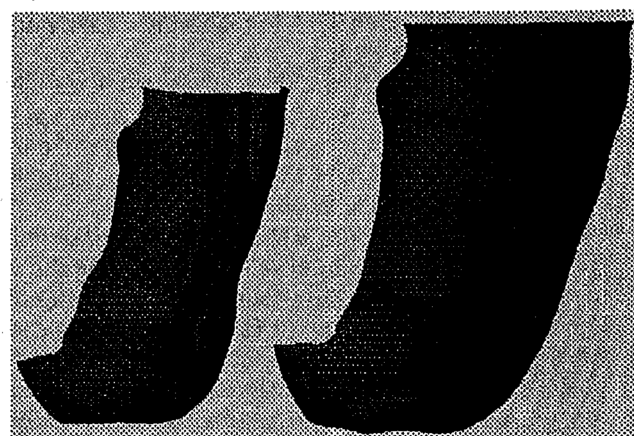

Figure 14. JANE and JERRY Contours

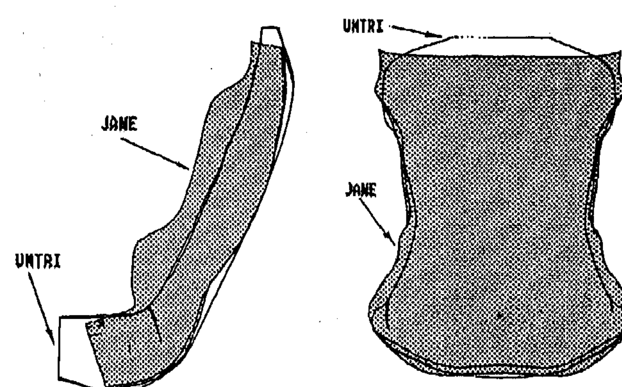

Figure 15. Comparison of JANE and UMTRI Contours

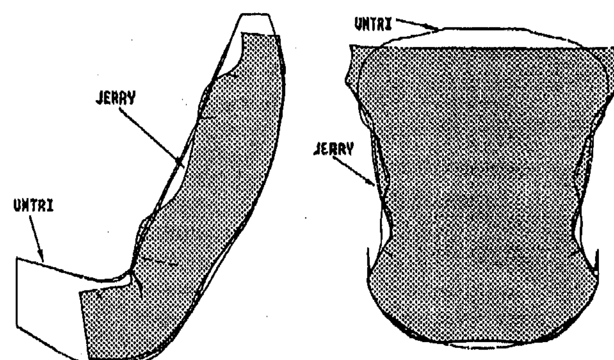

Figure 16. Comparison of JERRY and UMTRI Contours

CONCLUSION

The external contour of the JOHN model was reconfigured to be a more anatomically representative model of an undeflected skin surface. The new contour was developed using the contour created by Bush [9] and from studies done by UMTRI [2,3]. The new JOHN contour, which is partially based on the UMTRI average male contour, has a more representative size but also retains the muscle and bone definition noted in Bush's model.

A contour articulation program for each of the adult skeletal models was created. The external contours of the small female, the average male, and the large male can now be articulated in the sagittal plane to

any value of TLC and TRA to follow the underlying musculo-skeletal systems.

External contours for both the small female and the large male were developed from the JOHN average male model. Both of the JANE and the JERRY contours are scaled from the JOHN contour, thus making all of the contours related to each other.

With a more representative size and definition for the model, the designer will be able to use the model to create seats that fit the occupant better. Being able to use contours at any value of TLC and TRA, the designer will be able to fit occupants in seats in a larger variety of postures. By allowing the designers to model not only the average male but also the small female and the large male, he or she can design a seat that will fit a larger segment of the population. Fit, while it is by no means the sole component, is one of the most important elements to designing comfortable seats. If seat design tools, like the JOHN family of models, can better represent how a large variety of people fit in seats in different positions, seats designed with those tools should be more comfortable.

Kinetic Computer Modeling of Human Posture in Automotive Seats

ABSTRACT

To assist automotive seat development and evaluation, a technique for predicting the posture of seated occupants has been developed. The method involved modeling the torso geometry and articulation of a mid-size male, based on information presented in SAE paper number 930110 [1]. This mid-size male model, known as 2-D JOHN, was developed in a commercial kinetic modeling software and used in a comparative seat evaluation study between a current production automotive seat and a prototype articulating seat. The 2-D JOHN model was supported a greater range of postures, defined as Total Lumbar Curvature (TLC) and Torso Recline Angle (TRA), in the prototype seat than the automotive seat.

INTRODUCTION

An important design goal of the automotive industry for the past 40 years has been to accurately locate the position of seated occupants within the interior space of the automobile. Knowing occupant positioning is very important for factors such a visibility, safety restraint positioning, and comfort. The position of the occupant in the seat and interior has a strong influence on comfort, because the occupant position will affect posture and seat pressure.

Since the early 1960's, the main tools used in the design and development of automotive seating have been the 2-D drafting template (Figure 1) and 3-D testing manikin (Figure 2) specified in SAE standard J826 [2]. Though originally designed only for locating the occupant within the automotive interior, the SAE J826 tools have been used extensively to design seat shapes and thereby affect the posture and comfort of seated occupants. However, the SAE tools do have a major drawback in that they have a combined thigh-pelvis segment and torso segment that together only articulate about the H-point (the hypothetical center of motion of the hip joint), so that unlike true human motion, the SAE tools do not have the ability to represent a change in lumbar curvature. In addition, the posture that the torso segment represents is a slumped posture, with a flat back in the lumbar region.

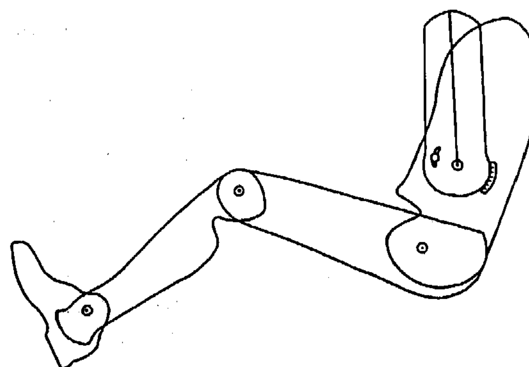

Figure 1 - SAE 2-D Drafting Template

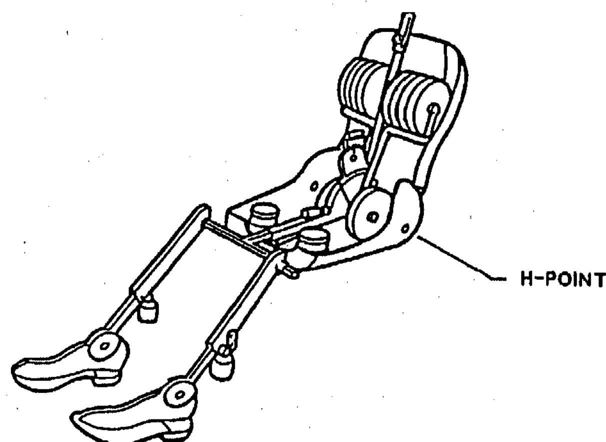

Figure 2 - SAE 3-D Testing Manikin

Due to these limitations, the J826 3-D manikin is unable to fit well in many automotive seats with large amounts of lumbar prominence. If the 3-D testing manikin is placed into a seat with a large amount of lumbar prominence, the manikin is unable to conform to

the shape of the seat back and the torso segment will either pivot about the lumbar area as it is forced back into the seat, which causes the thigh-pelvis segment to shift forward in the seat, or the torso segment will not be able to recline into the seat at all due to the large amount of lumbar prominence pressing on the segment.

In recent years, biomechanical research at Michigan State University (MSU) has been directed toward the development of human body models for automotive seat design. The main thrust of the work at MSU has been in improving the representation of human torso shape and posture by introducing lumbar curvature as a movement factor. To accomplish this, the human body models developed at MSU have been designed to represent more body segments than the SAE models. The models were designed to have separate thorax, lumbar, pelvis and thigh segments.

The human body model of the average size male (approximately 5'9", 165 lbs.) which was developed at MSU was named JOHN, to recognize the support of Johnson Controls, Inc. Details regarding the development of JOHN are described in SAE paper number 930110 [1], but descriptions of the positioning parameters are detailed here. The position of JOHN is described through the use of three variables, Total Lumbar Curvature (TLC), Torso Recline Angle (TRA), and Hip Joint Center (HJC). To represent the articulation of the human torso from a slumped to an erect posture, a one-to-one relationship of motion between the pelvis and thorax was selected [3]. For example, a 5° rotation of the pelvis corresponds to a 5° counter rotation of the thorax. This relationship of thorax to pelvis rotation was defined as TLC. The zero reference for TLC (0°) is a straight lumbar spine, with the angular orientation of the pelvis and thorax based on the seated occupant posture defined in a study by the University of Michigan Transportation Research Institute (UMTRI) [4, 5]. Figure 3 shows the pelvis and thorax articulation as the JOHN model moves from 0° TLC to 40° TLC. TRA is the measure of overall torso recline and is defined as the angle between vertical and a line passing through the top and bottom lumbar joint centers. These joint centers are the twelfth thoracic/first lumbar (T12/L1) and the fifth lumbar/first sacral (L5/S1), respectively. Figure 3 shows the 2-D JOHN model with a TRA of 30°. The HJC is the representation of the center of rotation between the femoral head and the acetabular socket of the pelvis.

The previous work at MSU concentrated on modeling the geometry and motion, or kinematics, of the human body in seated postures. For this study, a computer model was developed that was kinetic, predicting both the motion and forces acting on the body segments, while continuing to represent the posture of the JOHN model.

The 2-D JOHN kinetic computer model was developed with the aid of Working Model™, a commercial software product. This program is used for design of mechanical systems. To simulate mechanisms, it is possible to constrain the model bodies with elements such as pin and rigid joints, gears, and springs. Gravity and other forces can be applied to bodies in the software, and the program will automatically detect and represent collisions between bodies.

The development of this model represents a step forward in understanding and modeling the force-posture relationship of seated humans in automotive seats. By understanding this relationship, the iterative process of re-designing prototypes to support particular occupant postures can be shortened through use of the 2-D JOHN model. Predicting human posture in the design stage will allow seat designers to compare and refine seat designs on the computer before making prototypes, saving both time and money.

Specifically, the objectives of this study were to 1. develop the 2-D JOHN kinetic computer model and 2. undertake a comparative study between a current production seat and an articulating prototype seat using the 2-D JOHN model in order to study the effect of different seat designs on the final posture of the model.

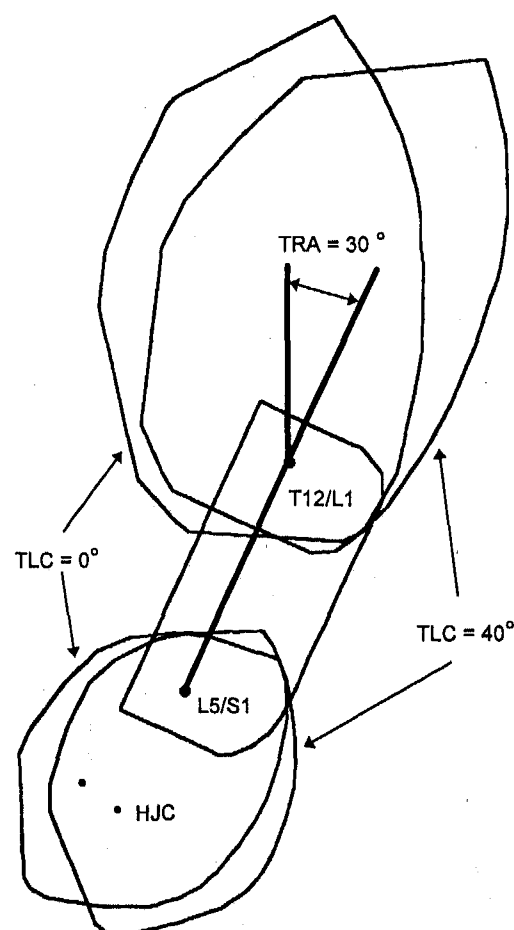

Figure 3 - 2-D JOHN model at a constant 30° TRA showing 0° TLC and 40° TLC

METHODS

2-D JOHN KINETIC MODEL CONSTRUCTION - The first step in the construction of the 2-D JOHN kinetic computer model was to develop the torso segments. Numerous contour points were selected from pre-existing 2-D CAD drawings of the pelvis, lumbar and thoracic body segments that were developed for the JOHN model, and these points were entered into the Working Model™ software as the vertices of polygons. The body segment contours represented the skeletal geometry of the three segments surrounded by soft tissue. The contours were adapted by Hubbard, et. al. [1] and Bush [6], based on data obtained from UMTRI [4, 5], and a corrected pelvis location that had been used in the development of the JOHN model in which the lumbar spine was lengthened by 30 mm. This anthropometric data was also used to locate the joint centers on the torso body segments. In Working Model™, points were placed on the body segments at the HJC, L5/S1, and T12/L1 joint centers (Figure 4).

After the torso had been completed, the legs for the 2-D JOHN model were constructed. The average male legs from the SAE J826 tools were imported into Working Model from a CAD computer file. Unlike the typical practice of using the SAE 95th percentile leg lengths with the 50th percentile body, the average male legs were used for this study. A consistent anthropometry was preferred because the study was concerned with seat issues, and not package issues. Because the 2-D JOHN model included a pelvis segment, the SAE thigh-pelvis segment was reshaped to represent only a thigh. Once the thigh had been reshaped, the joint centers were located on the segments in Working Model™.

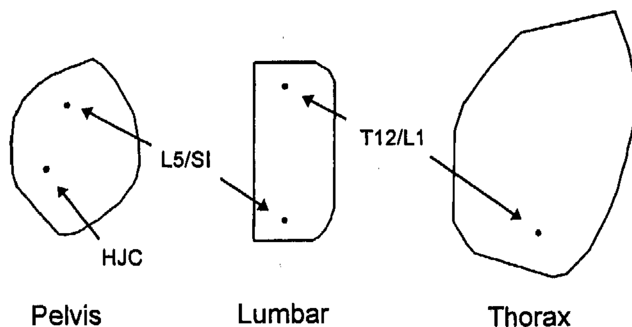

Figure 4 - 2-D JOHN kinetic model torso segments

With all the body segments sized appropriately and the joint center locations specified, the 2-D JOHN model was assembled with the motion constraints. Gear circles were created and rigidly pinned to the pelvis and thorax body segments. The lumbar segment was joined to the gear circles, creating the T12/L1 and L5/S1 joints. The pelvis, thigh, shank and foot segment were joined together, creating the HJC, knee joint and ankle joint. Finally a gear linkage was placed between the two gear circles, creating the 1:1 counter-rotation mechanism that controlled the torso articulation.

After initial trial simulations had been run with the 2-D JOHN model, it became apparent that another constraint was needed to keep the model from slumping so far that it would achieve a posture beyond the range of normal human movement. As a solution to this problem, a rope was added between the lower rear of the thorax and upper rear of the pelvis, that stopped the 2-D JOHN model from achieving a posture below -10° TLC. Figure 5 shows the constructed 2-D JOHN model.

BODY SEGMENT CENTERS OF MASS - When the 2-D JOHN model had been completed, the next step was to assign the center's of mass (COM's) for each body segment. For ease in modeling, a sagittal, symmetrical posture was assumed. As a result, the masses of the 2-D JOHN model thigh, shank and foot segments are the combined mass of the respective right and left body segments. In addition, because this study was focused on the effects of seat geometry, and not interior packaging, it was decided to eliminate the steering wheel in the model. This negated any possible effect of the wheel on the posture of the model due to the moment placed about the lower back when the arms are held out to grasp the wheel. An equivalent COM was calculated for the thorax, combining the mass of the head, neck, thorax both arms, with the arms oriented so that they were straight down by the sides of the body.

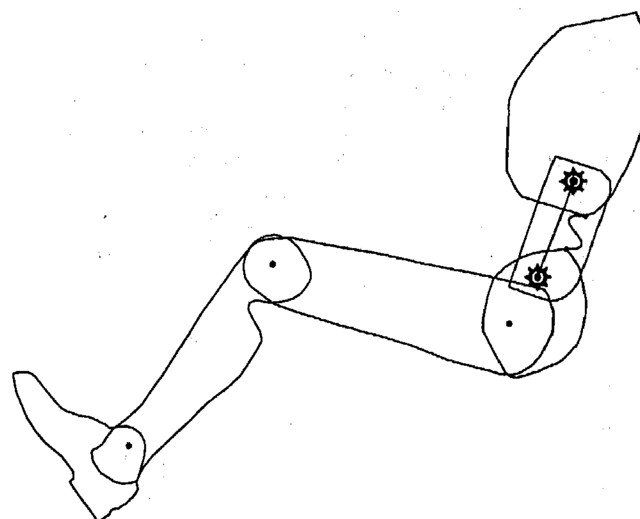

Figure 5 - 2-D JOHN model showing gear and rope constraints

The COM for the foot, shank, thigh, pelvis and lumbar segments were located utilizing average size seated male data developed in the UMTRI study [4, 5], and the COM of the body segments in Working Model™, were adjusted to correspond with the UMTRI data.

The equivalent COM for the thorax was calculated utilizing data of the average size male from the UMTRI seated occupant study [4, 5]. The head, neck, and thorax were kept in the same orientation as described in the UMTRI study. The upper and lower arm body segments, and the respective COM's, were re-oriented so that they hung straight down (vertical) the

sides of the body from the shoulder joint (glenohumeral joint). After the thorax equivalent COM location was calculated, the COM of the thorax segment in Working Model™ was repositioned to the calculated location (Figure 6).

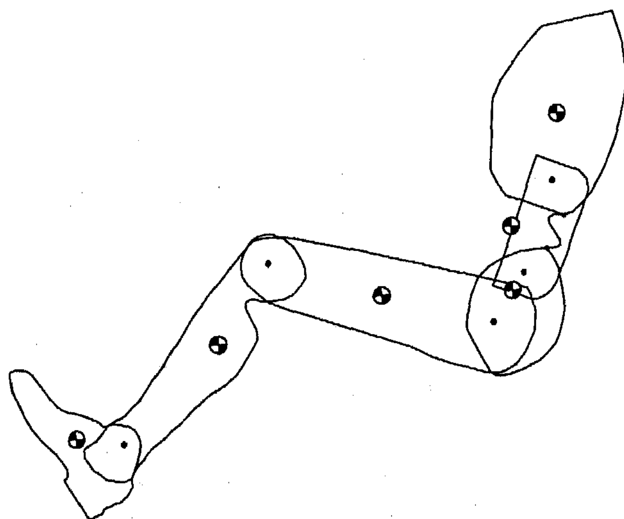

Figure 6 - 2-D JOHN showing location of COM's

CONSTRUCTION OF SEAT MODELS - When the 2-D JOHN model had been completed, it was used in a study to compare two different seat designs. The purpose of this study was to determine which seat geometry could support a greater range of postures, which are TLC values, at different levels of torso recline (TRA). The two seats that were compared were a prototype articulating seat, called the Biomechanically Articulating Chair (BAC) [7,8], and a current production automotive seat with an adjustable lumbar support, from a mid-size sedan automobile.

BAC model development - The BAC was designed to support the body in a wide range of postures by matching the motions of the chair to the motions of the body, defined through the JOHN model. There are 3 pieces to the BAC seat model; a pelvis support that cradles the back and bottom of the pelvis and rotates under the ischial tuberosities, a thorax support that pivots in the middle to upper back and allows rearward rotation of the top of the shoulders, and a recline bar that connects the pivots of the pelvis and thoracic supports. The full-size prototype of the BAC includes two independent thigh supports which were not included in the BAC seat model for modeling purposes. Like the 2-D JOHN model, the thorax and pelvis supports of the BAC move together in a one-to one relationship where a rotation of the pelvis support results in an equivalent counter-rotation of the thorax support. For this reason the position of the BAC supports is described in terms of the TLC and TRA promoted by the seat. The coupled rotation of the pelvis and thorax supports results in a change of TLC, and a seated person's TRA can be changed by adjusting the angle of the recline bar.

To develop the BAC in the Working Model™ simulation, dimensions of the thorax support, pelvis support and recline bar angle were measured from a full size prototype of the BAC. In addition, the angular relationship between the thorax and pelvis support were measured using a full size 2-D template of the JOHN model [6]. These dimensions and angles were used to construct and orient the rigid seat support surfaces in the simulation. The seat was then assembled with pin and rigid joints (Figure 7).

Mid-size sedan seat model development - To develop the mid-size sedan seat model (Figure 8), a design drawing for the seat was obtained from the seat manufacturer. The first step in developing the mid-sized sedan seat model in Working Model™ was to construct the visual references. To accomplish this, points from the seat frame and undeflected foam contours were measured from the design drawing and used to construct polygon bodies, with the H-pt of the design drawing as the origin of the coordinate system. After the thin, undeflected contours were created they were anchored to the background of the model. The seat frame was anchored to the background with a pin joint located at the recliner position.

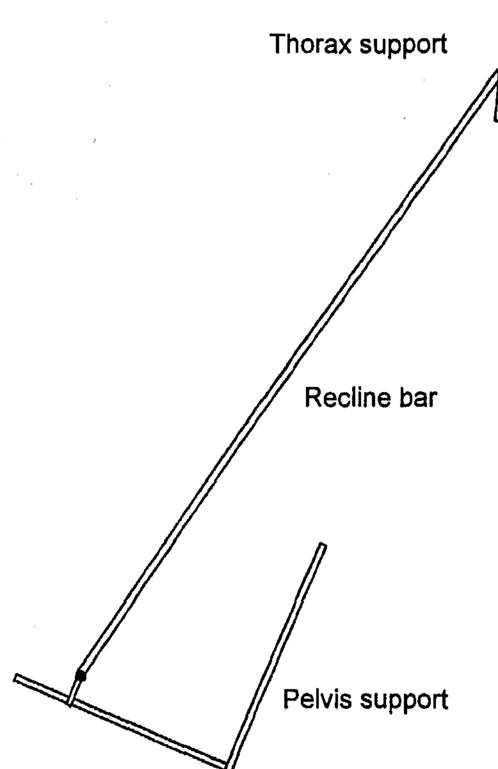

Figure 7 - Picture of BAC seat model

The second step involved developing the deflected seat contours for the seat cushion and seat back. The contour shape used for the deflected seat cushion was a reference line from the design drawing that represented the interface between the deflected seat cushion and a fully loaded SAE 3-D testing manikin. Seventeen points along this reference line were

measured from the design drawing and used to create a thin polygon to represent the deflected seat cushion contour. Then, seven small, thin rectangles were created and oriented on top of the deflected contour, following it as smoothly as possible. These seven polygons were anchored to the background and were the rigid seat cushion surfaces that the 2-D JOHN model contacted. The piecewise contour was used instead of the one-piece contour in order to improve the speed of the simulations, which ran slowly with the one-piece contour.

The seat back contour represented deflection of the known foam thickness in four regions. These regions were the top of the frame (upper thorax support), mid-back wire tie down, lumbar support and rear pelvis wire tie-down. To develop the contour, the distance between the undeflected contour and the back of the foam was measured from the seat drawing in these regions. The maximum deflection into the seat at these four regions was estimated as 65% of the foam thickness. The deflections at the four regions were calculated and then four rectangle bodies were created and positioned appropriately in Working Model™ to represent the deflected seat back surface at each of the regions.

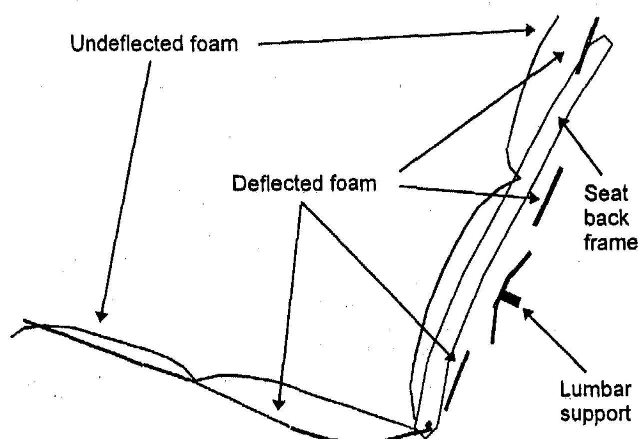

Figure 8 - Picture of the mid-size sedan seat model

The final step in the development of the BAC and mid-size sedan seat models was to specify the material properties for all contact surfaces. The two material variables were coefficient of friction and coefficient of restitution. There is little data on the coefficient of friction (μ) between a clothed human and an automotive seat, and so to determine the coefficient of friction to be used, a series of simulations were run using the 2-D JOHN model and the mid-size sedan seat model. From the results of these simulations, a μ of 0.7 was chosen as the smallest value where no slip between the 2-D JOHN model and the seat was observed.

Due to the nature of the modeling software the collisions between the 2-D JOHN model and the seat model bodies were simulated as rigid collisions. In order to counteract the elastic rebound between the rigid seat surface and 2-D JOHN model bodies and to more closely simulate a real person sitting into an automotive seat, the coefficient of restitution was set at 0.02.

SEAT EVALUATION PROTOCOL - With the 2-D JOHN model and seat models completed, study conditions and a simulation protocol were developed. To study the ability of the seat models to support different postures, the effects of two different seat factors on the posture of the 2-D JOHN model were simulated. The seat factors chosen were:

1. amount of lumbar curvature promoted, defined for the JOHN model as TLC.
2. angle of the torso support relative to vertical, defined through the JOHN model as TRA.

The two variables of the mid-size sedan seat that produced such posture changes were the seat back recline angle, and amount of lumbar prominence. The seat frame recline angle was defined as the angle between the a line parallel to the lumbar region of the seat frame and vertical, and the amount of lumbar prominence was defined as the distance the lumbar support was forward of a fully retracted position, along a line perpendicular to the seat frame. The corresponding variables for the BAC were the recline bar angle, and the angular relationship between the thorax and pelvis supports. The recline bar angle was defined as the angle of the recline bar with respect to vertical, and the relative angular position of the thorax support to the pelvis support was defined as the TLC measured with the JOHN 2-D articulating template.

In order to study whether the mid-size sedan and BAC could support a wide range of postures, different values of the mid-sized sedan and BAC seat variables were chosen and placed on different axes of a matrix, forming a set of study conditions. Mid-sized sedan seat frame angles and BAC recline bar angles were chosen to support upright, reclined and intermediate angles of torso recline. Values of lumbar support prominence for the mid-sized sedan model and angular orientation of the pelvis support to the thorax support for the BAC were chosen that would support slumped, erect and intermediate postures. The two variables affecting torso recline and lumbar curvature for each seat were placed on the axes of their respective matrix and when the possibilities were combined, the 3x3 grid resulted in nine seating conditions for each seat.

The mid-sized sedan seat design drawing was used to determine the starting values for the matrix. The design position of the lumbar paddle was defined as 0 mm of prominence, which was the fully retracted position. The design angle of the seat frame in the lumbar region was 28°, which corresponded to an SAE 3-D testing manikin torso angle of 24°. This angle was used as an intermediate value of seat frame angle. Upright and reclined values of the seat frame angle were selected as 23° and 33° respectively. Intermediate and

erect levels of lumbar prominence were defined as 12.5 mm and 25 mm.

To support an upright through reclined torso postures in the BAC seat model, values of the recline bar angle were selected that would promote a 23°, 28°, and 33° TRA in the 2-D JOHN model. As discussed earlier, the mid-sized sedan seat variable, amount of lumbar prominence, corresponded to the BAC variable of angular relationship between the pelvis and thorax supports, which was the TLC promoted by the seat. To model from a slumped to an erect posture, values of this angular relationship were selected that would promote TLC's of 0°, 20° and 40°. Recall that a TLC of 0° is defined for the 2-D JOHN model as a straight lumbar spine, corresponding to a slumped posture.

When the matrix of study conditions had been completed, a simulation protocol was developed and specified as follows:
1. the 2-D JOHN model was oriented in a 40° TLC posture
2. the TRA of the JOHN model was adjusted to match the predicted torso angle promoted by the seat for that particular seat set-up
3. because the 2-D JOHN model pelvis rolled rearward on the ischial tuberosities as the pelvis collided with the seat surface, the 2-D JOHN model was positioned with the HJC located 33 mm forward and 6 mm above the design H-pt location for the mid-sized sedan seat, and above the ischial tuberosity pivot for the BAC
4. the simulation was started.

Due to the effects of gravity and the mass of the body segments, the model collided with the seat surfaces, and its final posture and position was determined by the location of the seat supports and the mechanism controlling the movement of the 2-D JOHN model. When the model did not have a change in TLC and TRA for 20 consecutive time-steps, the simulation was manually stopped and the TLC and TRA values were recorded. The simulation was reset and the seat variables were until all nine simulations for each seat model had been completed.

After the 18 simulations described above had been completed and the data analyzed, another four simulations were performed using the mid-size sedan seat model. These simulations were run to study the effect of the upper thorax support location on the final posture of the model. The seat configuration used for these simulations was the one that produced the greatest amount of lumbar curvature in the mid-size sedan seat model. The effect on the 2-D JOHN model posture due to the proximity of the upper thorax support was studied by moving the upper thorax support rearward, perpendicular to the seat frame, in 10 mm intervals. The upper thorax support was moved back until the 2-D JOHN model was no longer in contact with the upper thorax support after becoming stable.

RESULTS

The results for the mid-size sedan simulations and the BAC simulations are shown in Table 1 and Table 2 respectively [9].

Figure 9 displays the results for the mid-size sedan simulation at 28° frame angle, with maximum lumbar prominence. Figure 10 shows the simulation results from the BAC seat model set up to promote a 28° TRA and 20° TLC.

Table 1 - Mid-sized sedan simulation results

Lumbar prom. / Seat frame ang.	0 mm	12.5 mm	25 mm
23°	TLC = -10° TRA = 25°	TLC = -10° TRA = 24°	TLC = -10° TRA = 21°
28°	TLC = -2° TRA = 30°	TLC = -8° TRA = 29°	TLC = 3° TRA = 29°
33°	TLC = -1° TRA = 35°	TLC = 5° TRA = 38°	TLC = 14° TRA = 38°

Table 2 - BAC simulation results

TLC / TRA	0°	20°	40°
23°	TLC = -1° TRA = 22°	TLC = 20° TRA = 23°	TLC = 40° TRA = 23°
28°	TLC = -2° TRA = 27°	TLC = 21° TRA = 28°	TLC = 40° TRA = 28°
33°	TLC = -2° TRA = 32°	TLC = 21° TRA = 33°	TLC = 39° TRA = 33°

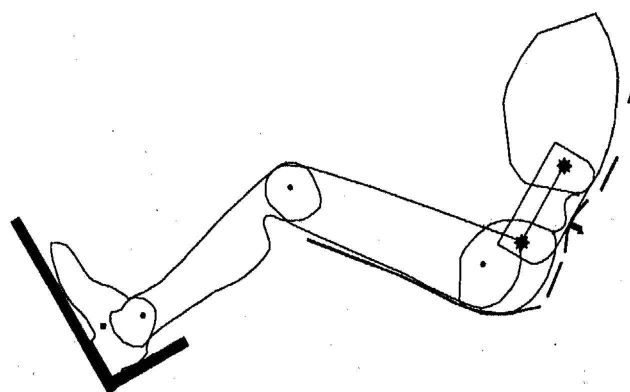

Figure 9 - Mid-size sedan simulation results for 28° frame angle, maximum lumbar prominence

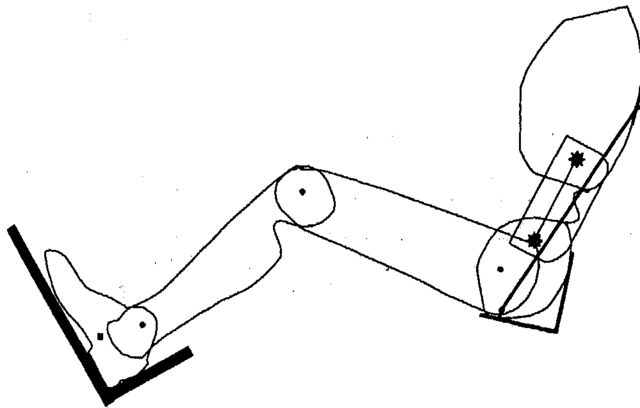

Figure 10 - BAC simulation results for 28° TRA promoted, 20° TLC promoted

Figure 11 summarizes the results from the mid-sized sedan and BAC seat simulations in graphical form. The graph plots the change in TLC versus the change in TRA for a constant seat recline angle. Therefore each line on the graph has three points, one point for each level of lumbar curvature simulated at each seat recline angle. The numbers 1,2, and 3 next to points on the plotted lines represent the amounts of lumbar curvature promoted by the seat for a particular seat recline angle. A slumped posture is represented by the number 1, an intermediate posture by number 2 and an erect posture by number 3.

As can be seen from Figure 11, the three lines representing the BAC simulations are all horizontal, and long. This shows two things, first, that TLC change was independent of TRA change, meaning that the BAC was able to support a range of TLC values while holding the TRA of the JOHN model constant. This was possible for every level of seat recline angle tested, 23°, 28°, and 33°. The second point is that the BAC was able to support a very wide range of TLC values, from 0° to 40°, at each level of seat recline. This is the ideal situation for a seat, supporting a wide range of lumbar curvature at any level of torso recline angle.

The results from the mid-size sedan simulations show a different story. Looking first at the results from the 23° seat frame angle, it can be seen that the line is vertical, opposite that of the BAC results, and is constant at -10° TLC. This demonstrates that at an upright seat frame angle, the mid-sized sedan seat was unable to promote any amount of lumbar curvature, and that as the lumbar prominence increased, the only result was that the TRA of the 2-D JOHN model decreased. At 28° seat frame angle, the line shows that the TLC of the JOHN model changed from -2° to -8° back to 3° TLC as the lumbar prominence increased, but the TRA of the 2-D JOHN model remained relatively constant. So at design position, the TLC of the JOHN model can be changed with increased lumbar prominence, but the change is erratic, and the posture that the 2-D JOHN model maintains is still very slumped, around 0° TLC. At 33° seat frame angle, a very reclined seat set-up, the results show that the mid-size sedan seat is able to promote a medium amount of lumber curvature, showing a total change of 15°, while keeping the TRA of the 2-D JOHN model fairly constant. However, this may not be a chosen driving posture, due the recline angle of the seat.

The results from the supplemental study to evaluate the effect of the upper thorax support on the final posture of the 2-D JOHN model are added to the graph of Figure 11 and are shown in Figure 12. The graph shows that moving the upper thorax support rearward 30 mm allows the TLC of the 2-D JOHN model to increase an additional 11°. Allowing the upper thorax support to move allows the number of TLC values possible in the particular seat set-up to almost double, with a minimal change in the TRA of the 2-D JOHN model. This shows that if the final posture of the model is supported, or restricted, by the upper thorax support then allowing the upper thorax support to move rearward can have a dramatic effect on the final posture of the 2-D JOHN model.

DISCUSSION

The main observation from the simulations was the effect of the pelvis support on the final posture of the 2-D JOHN model. In all nine BAC simulations the pelvis comes to an immediate stop when it contacts the pelvis support. The TRA and thorax position continue to adjust slightly, but TLC change stops soon after the pelvis stops. The different amounts of TLC possible in the BAC are directly dependent on the starting distance between the rear of the 2-D JOHN model pelvis segment, in an erect 40° TLC posture, and the pelvis support. When this distance is very small, as in the case of all three simulations to support 40° TLC, the pelvis support constrains any rotation of the pelvis, thereby keeping the TLC at 40°. When the distance is the largest, as with the cases for 0° TLC, the pelvis will rotate rearward, resulting in a decease in TLC, until it comes into contact with the pelvis support. At that time the rotation of the pelvis stops, and the TLC does not change any further. The closer the pelvis support is to the rear of the 2-D JOHN model pelvis when the model contacts the seat surface and begins to slump, the greater the final TLC of the model.

In both the BAC and mid-sized sedan seat, the location of the upper thorax support is the second most important factor in determining the final posture of the 2-D JOHN model. If the upper thorax support is too far forward, relative to the pelvis support, then the 2-D JOHN model will come into contact with the upper thorax support before the pelvis support and the 2-D JOHN model will be unable to obtain an erect posture. The contact with the upper thorax support stops all rearward torso translation of the model, the change in TRA, therefore, any motion that occurs must be a rotation of the thorax and pelvis, or TLC change. This results in a more slumped posture. One of the reasons that the 2-D JOHN model could not obtain a large value of TLC in the

mid-sized sedan seat was due to the contact interference with the upper thorax support. In contrast, the upper part of the 2-D JOHN model thorax was free of obstruction in the upper thorax region.

From the simulation results, it was observed that the human torso can be thought of as two structures and a linkage, the structures being the thorax and pelvis, and the linkage the lumbar segment. Controlling the posture of the torso by influencing the position of the structures, like the BAC does, is much more effective than trying to control the posture of the torso by pushing on the lumbar region, like in the automotive seat. It seems clear from the simulation results that, in order to control the posture of the seated occupants, it is necessary to replace the current method of a single lumbar support with a more influential support system. The new system would involve a rear pelvis support, lower thorax support and an ability to let the upper part of the shoulders to move rearward. If a seat model can support a simplified mechanistic model of the human body, with no muscle forces, in an erect posture, then it can surely support a relaxed human body in a real seat.

CONCLUSIONS

This paper described the development of a kinetic computer model of the human body. This model is called JOHN and was based on the model described in SAE paper 930110 "New Biomechanical Models for Automotive Seat Design". The model was used in a study to compare between two seat designs, one of which was a prototype articulating seat, and the other was a current production automotive seat. The construction of the 2-D JOHN model and seat models were described, and the seat testing protocol was detailed. The results from the simulations were discussed, showing that the prototype seat was able to support a wider range of postures than the automotive seat. Finally, a new method of supporting the human body in seated postures was described.

The ability to represent and simulate the interaction between a seat model and the 2-D JOHN kinetic human body model is a step forward in understanding the relationship between the posture of seated humans and the forces acting between the occupant and the automotive seats. Automotive designers now have a tool that can allow them to see the postural effect on the 2-D JOHN model by modeling different seat contours and posture controlling mechanisms. This effect can be related to the posture, and ultimately comfort, of a seated person. Through the use of the 2-D JOHN kinetic model, seat designers can modify seat contours on the computer, thereby saving time and money by reducing the amount of prototyping needed.

Measuring and Modeling of Human Soft Tissue and Seat Interaction

ABSTRACT

Deformations of soft tissues and seat cushion foam are significant factors in determining the interface contours between the seat and the back of the thigh. This paper describes the measurement of forces, deformations, and contours of people's thighs and seat cushion materials. The goal of this work is to represent the human interactions with seats. A two-dimensional, plane strain finite element method was used to develop a contact model between the cross section of the human mid-thigh and flat surfaces, which can be a flat, rigid surface or a flat, foam cushion of various thicknesses and densities. Results of human and seat interactions for various subjects were measured, modeled, and compared. The present work showed a good agreement between experiments and models for various subjects and foam densities. The important results showed that the stiffness of the foam does not depend on the foam thickness.

INTRODUCTION

Even though the behavior of living tissues is known to be non-linear and viscoelastic (1), the assumption of linearly elastic soft tissues is commonly used in finite element models (2,3,5). The contact mechanics can be categorized as a highly non-linear problem because geometry, boundary conditions and material properties are non-linear, therefore, by using linear material behavior in the finite element model the computation time can be reduced.

Applying non-linear properties of human soft tissues in finite element model becomes of growing interest as more powerful computer hardware and software become available. Vannah, et al. (7) used Jamus-Green-Simpson strain energy function to represent bulk muscular tissue between tibial plateau and ankle in their model. The geometry of the model was using CT scans with horizontal cuts at 20 mm intervals. A quasi-static test was conducted on bulk muscular tissue. The test was performed on the calf (posterior muscle belly) of the lower leg. A high distortion indentor test was chosen to deform the tissue. They assumed the tibia and fibula were rigid in comparison with the muscular tissue, and they represented the bones by nodal constraints in their model. A mold-making silicone rubber (HSII®, Dow-Corning Corp., Midland, MI) whose properties are similar to muscular tissue was tested uni-axially to obtain the Jamus-Green-Simpson coefficients for modeling. The results of finite element models and experiments due to 8 and 19 mm indentation were compared. They showed good agreement between models and experiments in load-deformation results.

Deng (6) studied the load-deformation responses of the hamstring regions of human thigh in seated postures. A seating fixture with load cells and electronic gauges was built to support people in variety of seated postures. A flat, rigid plate was pushed into the back of people's thighs. The tests were performed for different knee angles at 90, 120, 150, and 165 degree. Deng found that the thigh tissue became stiffer as the knee angle increasing. A 2D finite element model of hamstring muscle in contact with a rigid surface was developed. Ten males and females human subjects with various thigh sizes were selected and ten corresponding models were created. All the models used the assumption of a single property for the hamstring muscle and the only differences were the hamstring muscle dimensions of the subjects. The diameters of hamstring muscles of the mid-thigh were chosen based on the mid-thigh diameter of the subjects. The polynomial form of strain energy potential was chosen for hamstring muscle modeling. The load-deformation results of the experiments were compared with the models. Besides a good agreement between experiments and models, the results also showed the stiffness of muscle increases as the knee angle increases.

In this paper, the non-linear properties of soft tissues have been included in the model, however, the viscoelastic behavior of the tissues was considered not important for a subject who sits for a long period of time. Moreover, there is no benefit by adding the viscoelastic behavior in the model if the tissue-seat interaction is expected not occur in the short period of time, and it will increase the computation time. The objective of this study was to measure and model the interaction of human soft tissues of the posterior side of the right thigh with various foam densities.

METHODS

The soft tissue and foam were modeled as elastomer materials such that the systems of deformable bodies undergo large deformations; Ogden strain energy functions (8,9) were used to formulate these material properties. For practical purposes, the soft tissues and foam were each represented in the model with single, uniform materials with a rigid femur. To obtain the material parameters of the foam in the model, stress-strain curves were measured by uniaxial compression testing. Poisson's ratio effect is very small and it can be neglected. The Ogden formulation for foam will be used to fit these experimental data. Unlike the foam, the soft tissue's properties cannot be obtained with the testing machine. To get the soft tissue properties, the load-deformation curve of the simulation model (thigh in contact with rigid, flat surface) was compared with experiment until the good fit be obtained. Then the chosen soft tissue properties were verified for subjects with different sizes. These soft-tissue properties were also used for thigh-foam modeling.

EXPERIMENTAL - To measure the load-deformation characteristics of the posterior side of human thighs, a chair was designed to support a person in a variety of seated postures that affect the length and tensions in the hamstring muscles on the back of the thigh (6). This chair provided a backrest, a pelvis support, and a movable footrest. The footrest was designed such a way that the knee angle can be changed from 90 to 180 degrees. The knee angle was defined as the angle between two vectors: one from the femur greater trochanter to the lateral condyle of femur at the knee, and another from the lateral condyle of the femur to the lateral malleolus at the ankle. The backrest had a pivot that allowed rotation about lateral axes to comfortably accommodate the subjects. The chair dimensions were adjustable to correspond to each individual's body size. The backrest was adjustable both vertically and horizontally and supported the subject's torso. A flat plate supported the back of the pelvis, and two flat plates supported the right and left buttocks. A load cell was put under each plate to measure the force under the buttocks.

Seven human subjects were tested for the thigh and seat cushion interactions in seated postures. The heights of the subjects ranged from 65 to 76 inches, the weights ranged from 110 to 280 lbs., ages ranged from 18 to 36 years, and the thigh circumferences ranged from 447 to 695 mm. The physical characteristics of the seven subjects were summarized in Table 1.

Table 1
Subject Physical Data

Subject Number	Gender	Age (years)	Height (in)	Weight (lb.)	Mid-Thigh Circumference (mm)
1	Male	18	76	175	520
2	Female	23	67	135	531
3	Male	19	72	155	510
4	Male	21	71	135	462
5	Male	36	70	205	608
6	Male	26	76	280	695
7	Female	29	65	110	447

Based on UM-TRI (10) study, the subjects were divided into three categories according to the circumference of their mid-thigh such as small female (5th percentile), mid-sized male(50th percentile), and large-male (95th percentile) in erect seated postures. The measurements summarized in Table 2

Table 2
Thigh Circumference for Small Female (5th Percentile), Average-Male (50th Percentile), And Large-Male (95th Percentile)

Subjects	Minimum (mm)	Mean (mm)	Maximum (mm)
small female	370	427	472
average-male	442	504	550
large-male	485	559	635

Figure 1a shows a subject sitting on the testing chair. The subject's right thigh was aligned in such a way that it was level on the surface of a piece of foam (267 x 216 x 100 mm^3) and the mid-thigh was placed in the middle of that foam. The contour measurement system was located underneath the foam and above a load cell. The load cell was used to measure the reaction force under the thigh. The foam, contour measurement system, and load cell were moved up by a hydraulic jack with a six ton capacity and 254 mm stroke such that the back of a right thigh deformed due to the stationary the femur. A digital caliper was fixed from the jack to the contour measurement system and was used to measure the vertical displacement of the system. The thigh lateral deformation was recorded by placing another digital caliper across the middle section of the thigh and adjusted throughout the subject.

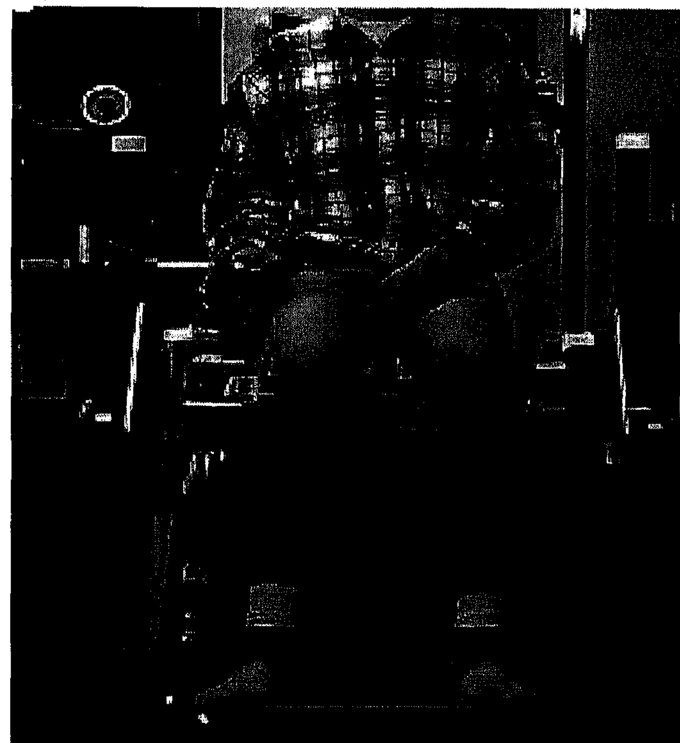

Figure 1a. A subject sitting on a testing chair.

Figure 1b. shows the right thigh of a subject in contact with a piece of flat foam. Under the foam, there was a contour measuring system.

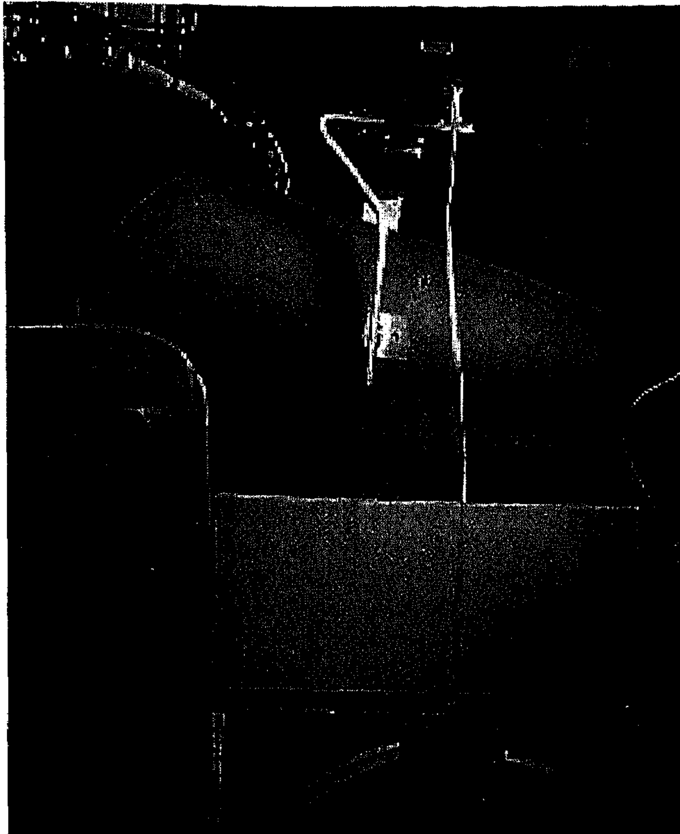

Figure 1b. The right thigh of a subject on a flat foam.

The Contour Measurement System - The contour measurement system uses wires through the seat cushion foam samples. This was used to measure deflections of people's soft tissues with seat cushion foams of different stiffness and thickness. When the foam was deformed, the wires were displaced an equal amount. The video camera captured an image for each wire displacement. These displacement images were digitized using a computer connected to the camera. While raising the contour measuring system into the back of the thigh, measurements of load, contour, and deformation of the foam and thigh were collected.

Thigh-Foam Interaction Tests - The chair was adjusted according to the subject's body size. The subject sat in the seating fixture, feet placed firmly on the footrest plate, head and body in a relaxed posture. All subjects wore shorts during testing, so that clothing was not a variable. The contour measurement system was displaced in a quasi-static manner up into the back of the subject's thigh. Contact was identified when the measurement force exceeded 0.22 N. The digital caliper attached to contour measurement system recorded the total vertical deformation of the thigh and foam for a given position. The foam was raised into the thigh in displacement steps of 5 millimeters. Each displacement step was held for 20 to 30 seconds before the resulting force was recorded. A rest time of 20 to 30 seconds was chosen in order to allow for stress relaxation. After this time, the forces were stable. The contour measurement system was displaced until the reaction force lifted the leg so that the foot was lifted from its rest. The total deformation (δ_{Total}) in the vertical direction was measured by the displacement of the contour measurement system and the foam deformation (δ_{Foam}) was recorded by the displacement of the wires. A video camera captured the wire displacement image for each reaction force and was digitized by the computer. The foam deformation can be obtained by the following formulation:

$$\delta_{Foam} = \delta_a - \delta_b$$

where:

δ_b: The end position of wires before the foam deformation.

δ_a: The end position of wires after the foam deformation.

The vertical deformation of the mid-thigh at the contact area with the foam was calculated by subtracting the foam deformation from the total deformation. This can be formulated as follows:

$$\delta_{Thigh} = \delta_{Total} - \delta_{Foam}$$

This computation was based on two assumptions: (1) the femur did not move during the test (Figure 2); (2) the frictional force between the foam and thigh prevented the thigh's tissue from sliding at the contact surface.

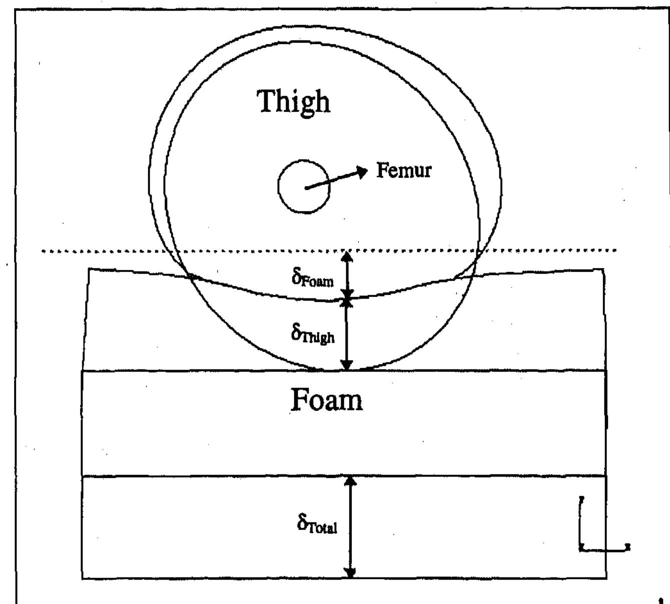

Figure 2. Definitions of total, thigh and foam vertical deformations.

The deformed contour of the foam, which is in contact with the thigh, can be obtained through the wire displacements. Figure 3 shows the measured contour of a piece of foam that was deformed by contact with thigh.

Two foam densities, 51 kg/m^3 (very stiff), and 41 kg/m^3 (softer) with two different thicknesses (100 mm, 25 mm) were used in this experiment.

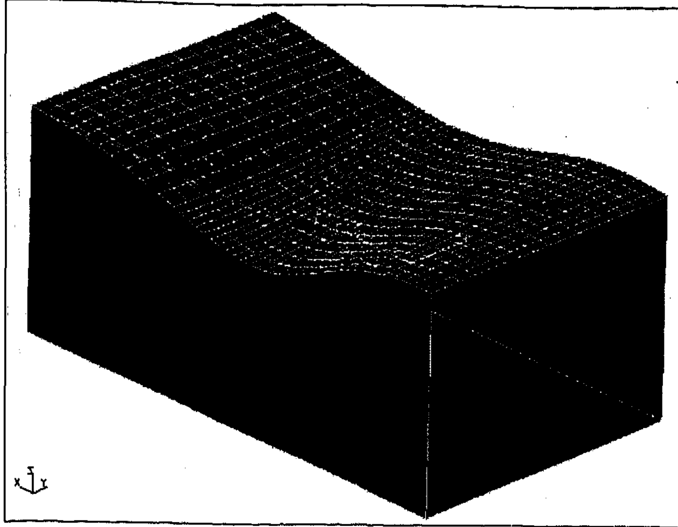

Figure 3. The contour of foam deformation due to a contact with the right human thigh.

FINITE ELEMENT MODEL- A two-dimensional, plane strain finite element model was used to represent the interaction of the mid-thigh and a seat cushion foam. A cross section of the mid-thigh which was used in model was based on sitting position of a subject with 100 degrees knee angle. For simplicity, a single uniform material property was used to represent the composite of the tissue (fat, muscle, skin, etc.) in the model. Large deformations occurred in the tissue when the back of the thigh was in contact with a flat, rigid surface or a piece of foam. Even though the stiffness of the hamstring muscle may be different from one person to another, the models employed the same properties for all subjects. This is very important for practical purposes because the model can be scaled easily to simulate the thigh geometry of each subject without considering different tissue properties for various subjects.

Two commercial finite element software packages, ABAQUS and MARC, were used for modeling. It was very important to run the model with more than one software for verification because there is no analytical solution of these models. The soft-tissue has a low stiffness which increases with deformation and the foam has an initial stiffness which decreases. These differences in material properties of soft tissues and foam make the problem more difficult to solve due to the convergence problem if a large deformation occurs in the model. Small volume change is assumed in the soft tissue with Poisson's ratio close to 0.5. On the other hand, the uniaxial compression test of the seat cushion foam showed that the lateral displacement was very small even though with compression up to 80%. It means the zero Poisson's ratio effect is a practical assumption. To model the soft tissues, the hyperelastic material with Ogden form was chosen rather than polynomial form of the strain energy potential. This strain energy form contains a bulk modulus term which controls the compressibility of the hyperelastic material. Even though there is a slight difference in formulating a generalized Ogden strain energy potential in ABAQUS and MARC, we can still find a similarity between them. The following expressions of the Ogden potential strain energy for ABAQUS and MARC are:

- ABAQUS

$$U=\sum_{n=1}^{N}\frac{2\tilde{\mu}_n}{\tilde{\alpha}_n^2}(\bar{\lambda}_1^{\tilde{\alpha}_n}+\bar{\lambda}_2^{\tilde{\alpha}_n}+\bar{\lambda}_3^{\tilde{\alpha}_n}-3)+\sum_{n=1}^{N}\frac{1}{D_n}(J_{el}-1)^{2n}$$

- MARC

$$U=\sum_{n=1}^{N}\frac{\mu_n}{\alpha_n}J^{-\frac{\alpha_n}{3}}(\lambda_1^{\alpha_n}+\lambda_2^{\alpha_n}+\lambda_3^{\alpha_n}-3)+4.5K(J^{\frac{1}{3}}-1)^2$$

where $\bar{\lambda}_i=J^{-\frac{1}{3}}\lambda_i$ is a principal stretch ratio, and the elastic volume ratio J_{el} is a ratio between the total volume ratio J and the thermal volume ratio J_{th}. The J_{th} is a function of the linear thermal expansion ε_{th} such that $J_{th}=(1+\varepsilon_{th})^3$. Material parameters are $N,\mu_n,\alpha_n,\tilde{\mu}_n,\tilde{\alpha}_n,D_n$, and K.

A simple two dimensional plane strain models of a flat rigid surface in contact with the back of a thigh was used to defined how many terms were needed for Ogden model to represent the behavior of human soft tissues. The results of using seven healthy human subjects with various thigh sizes showed that only one term is sufficient for representing a thigh tissue. Typical material parameters in the plane strain model are as follows:

$N=1$, $\mu_1=1900\ N/m^2$, $\alpha_1=1.75$, $K=15{,}875\ N/m^2$,
$\tilde{\mu}_1=1662.5\ N/m^2$, $\tilde{\alpha}_1=1.75$, $D_1=1.4\times10^{-5}\ m^2/N$, $\varepsilon_{th}=0.0$.

Several flat cushion foams, with dimensions 400 x 400 x 100 mm^3 were tested to obtain their properties by applying standard uniaxial compression test using Instron machine. Unlike the hyperelastic materials which are slightly compressible, the hyperfoam materials are highly compressible. Both commercial finite element software packages, ABAQUS and MARC, provide a similar strain energy potential for foam modeling. The generalized Hill strain energy potential for foam modeling was used in ABAQUS and it can be written as:

$$U=\sum_{n=1}^{N}\frac{2\tilde{\mu}_n}{\tilde{\alpha}_n^2}[(\bar{\lambda}_1^{\tilde{\alpha}_n}+\bar{\lambda}_2^{\tilde{\alpha}_n}+\bar{\lambda}_3^{\tilde{\alpha}_n}-3)+\frac{1}{\tilde{\beta}_n}(J_{el}^{-\tilde{\alpha}_n\tilde{\beta}_n}-1)]$$

The generalized compressible Ogden model was used in the MARC program and the strain energy is defined as:

$$U=\sum_{n=1}^{N}\frac{\mu_n}{\alpha_n}(\lambda_1^{\alpha_n}+\lambda_2^{\alpha_n}+\lambda_3^{\alpha_n}-3)+\sum_{n=1}^{N}\frac{\mu_n}{\beta_n}(1-J^{\beta_n})$$

Here, J_{el} is elastic volume strain like a hyperelastic material. The only difference is the β_n and $\tilde{\beta}_n$ terms in foam modeling and D_n and K terms in tissue modeling. The β_n can be related to Poisson's ratio effect v_n such that

$$\beta_n=\frac{v_n}{1-2v_n}\quad\text{or}\quad v_o=\sum_{n=1}^{N}\frac{-\beta_n}{\alpha_n-2\beta_n}$$

where ν_0 is the initial Poisson's ratio.

Neglecting the Poisson's ratio effect means the β_n and $\tilde{\beta}_n$ terms become zero. The parameters of the hyperfoam model were obtained by using non-linear curve fitting method. The stress-strain curve of uniaxial compression test was fitted using the hyperfoam models. In order to fit the stress-strain curve from uniaxial data, two terms were needed. The parameters of a selected foam which has specific weight 41 kg/m^3 are:

- ABAQUS

  $\tilde{\mu}_1 = 18345.226$ N/m^2, $\tilde{\alpha}_1 = 17.41$,
  $\tilde{\mu}_2 = 210.46$ N/m^2, and $\tilde{\alpha}_2 = -1.984$.

- MARC

  $\mu_1 = 2107.39$ N/m^2, $\alpha_1 = 17.41$,
  $\mu_2 = -212.2$ N/m^2, and $\alpha_2 = -1.984$.

Figure 4 shows an undeformed mesh of 2D model with a piece of flat foam. The tissue model consisted of 900 four-noded quadrilateral elements which accommodate the compressibility behavior and the foam consisted of 102 four-noded quadrilateral elements. This size of mesh is good for deformation up to 50 mm and finer mesh was required in the contact region to prevent element distortions.

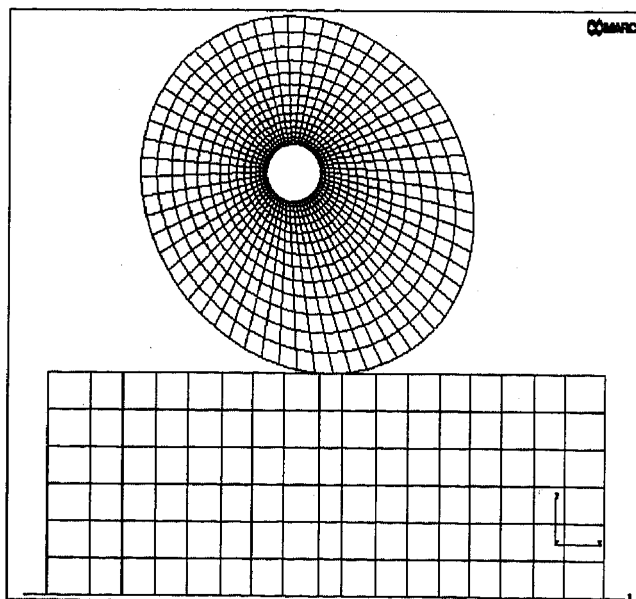

Figure 4. The finite element mesh of mid-thigh-foam cross section.

RESULTS AND DISCUSSION

The thigh-foam interaction responses of seven subjects were analyzed and the results of these subjects showed a similar behavior. For the convenience of this paper, an average male subject was chosen for comparing an experiment and a model. Therefore, all the results reflected to the average male.

Load-deformation responses of the foam and the thigh in seated postures were analyzed to study the mechanical behavior of soft tissue deformation interaction with different foam stiffness and thickness. Two trials of loading and unloading the thigh (Figure 5a) and the foam (Figure 5b) with a rigid plate were conducted to check the test repeatability. The graphs from these tests exhibited hysteresis behavior, and the different between the results of the two test trials was very small, so the tests were repeatable.

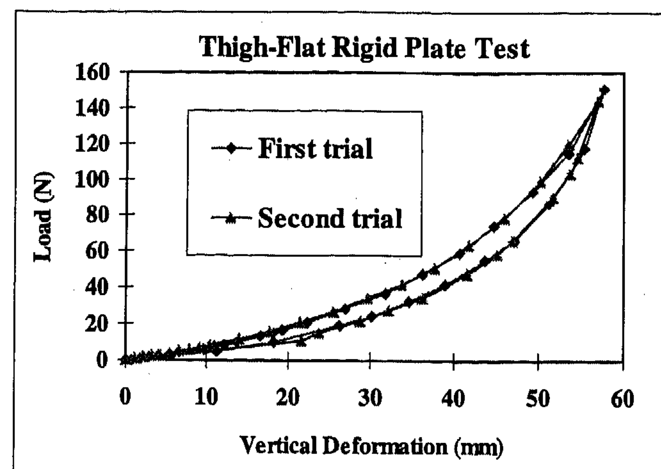

Figure 5a. Two deformation trials of thigh with a flat, rigid surface.

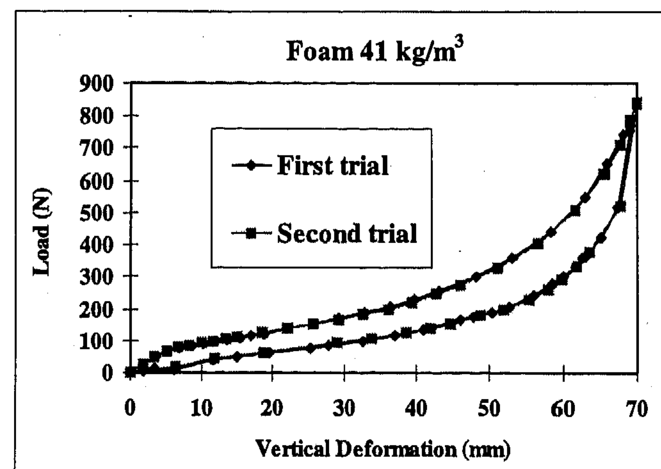

Figure 5b. Two deformation trials of foam with a flat, rigid surface.

The deformations of the two wires in the center of the foam sample were used to study the thigh-foam interaction. These two wires represent the first contact point between the foam and the thigh. A typical nonlinear load-deformation relationship of the thigh and foam for one of the two selected wires was shown in Figure 6. There were three curves which represented the thigh, foam, and total deformation versus load. One interesting thing can be seen in this figure that the stiffness of the thigh tissues is initially much smaller than the foam stiffness. After the initial loading, the stiffness of the

thigh increases and becomes greater than the stiffness of the foam.

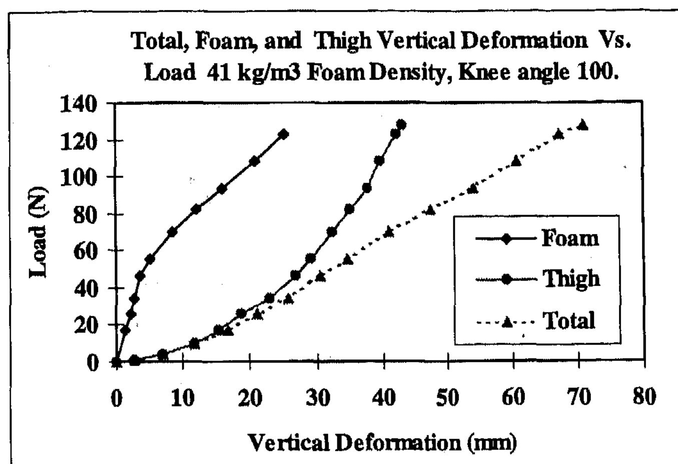

Figure 6. A load-deformation curves (total, thigh, and foam) with 100 degrees knee angle, and 41 kg/m^3 foam density, and 100 mm foam thickness.

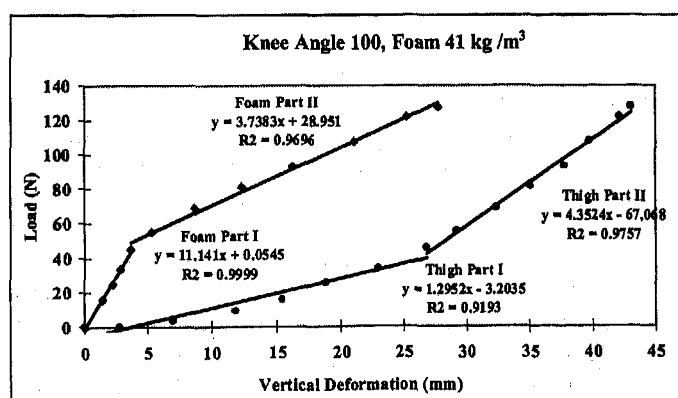
To simplify the thigh-foam interaction response, the non-linear load-deformation curve of the thigh and foam was split into two linear parts. The first part was from 0 to 7% of a subject weight, the second part ranged from 7 to 16% of a subject weight. The second part of this curve represented the working region of the thigh stiffness when the thigh interacts with seat cushion in seated posture. This working region was defined based on the contact pressure of the thigh-foam interaction from the results of pressure mat for various people in the seated posture. The straight line for each part represented the experimental data, and a best-fit line was obtained for each part. The lines were highly correlated to the data with correlation coefficients at least 0.92. The slopes of the best-fit line of the thigh deformation in the first and second parts in Figure 7 were 1.3 and 4.4 N/mm, respectively. The stiffness of the second part was higher than the first part, meaning that the thigh became stiffer as the displacement and contact region increased. The stiffness of the foam in the second part was smaller than the first part. The slopes of the best-fit line of the foam deformation in the first and second parts were 11.1 and 3.7 N/mm, respectively.



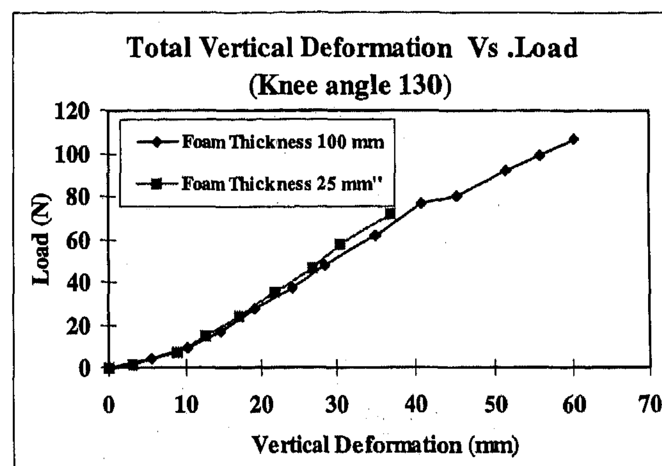


Figure 7. Linearization of thigh and foam deformation curves.

Two foam thicknesses (25 and 100 mm) and two densities (41 and 51 kg/m^3) were selected for the thigh-foam tests. Two different knee angle positions of the subjects were examined. The results of the test showed that the foam thickness did not affect the thigh vertical deformations. (Figure 8). The thigh deformations due to the different foam densities were very close for the same load (Figure 9). Larger knee angle resulted in stiffer thigh response. This change in the thigh stiffness occurred because the tension in the hamstring muscles increased as the knee angles increased. Figure 10 shows the change in the thigh stiffness when the knee angle changed.

Figures 8. Thigh vertical deformation versus load for two types of foam thicknesses.

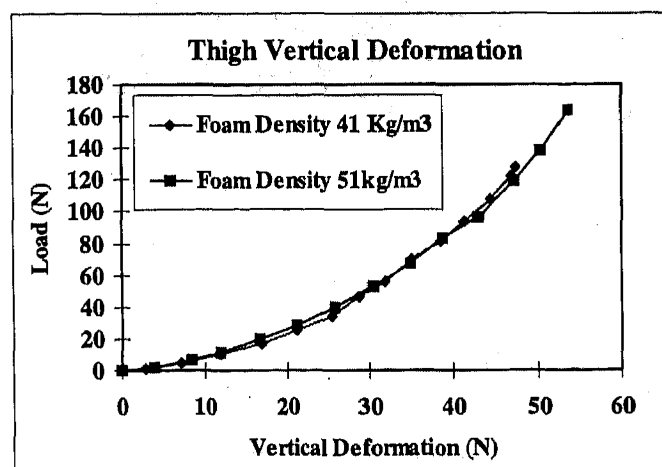

Figure 9. Thigh vertical deformation versus load for two types of foam densities.

The experimental results of load-deformation curves of ten healthy human subjects were used to predict the material properties of the thigh tissues (6). Although it has been reported in the literature that the human tissues are viscoelastic and non-linear, linear elastic material is still in common use. We assumed that soft tissues behave like a rubber material, with the Ogden strain energy potential, which can experience large deformations. Results of ten subjects show that a single

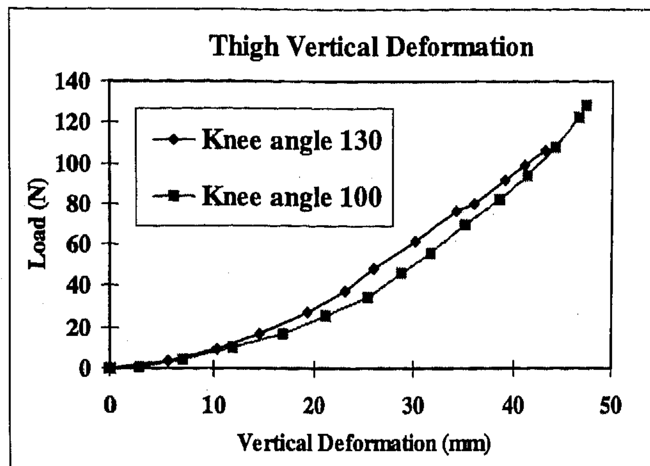

Figure 10. Thigh vertical deformation versus load for two different knee angle positions.

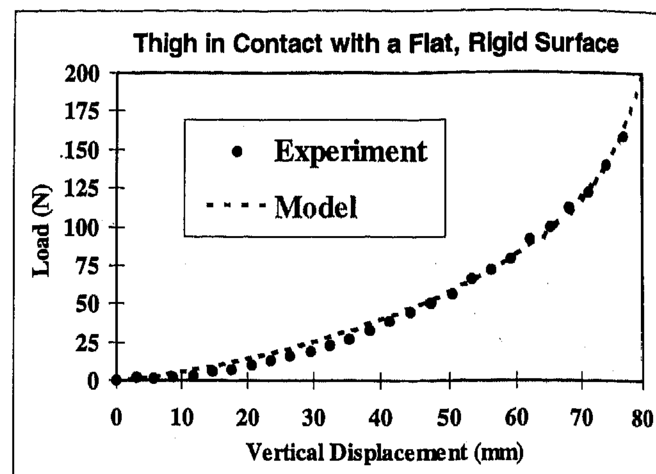

Figure 12. Total deformation of the soft tissues versus load due to a flat, rigid surface.

term of Ogden model is sufficient for representing human thigh tissues. Figure 11 shows a deformation of the thigh tissues due to the displacement of a flat rigid surface.

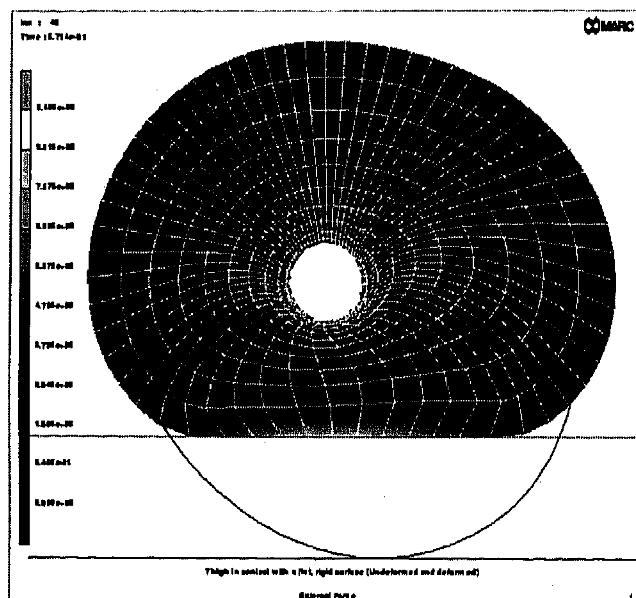

Figure 11. External force distribution of the deformed soft tissues due to a flat, rigid surface

The load-deformation were used as a basis to compare the results of the models and experiments. A load-deformation curve of a thigh deformation due to a flat rigid plate of a model and an experiment for a selected subject is shown in Figure 12. There was a close agreement between a model and an experiment.

The equivalent von Mises stress distribution due to the deformation of the two dimensional model of the mid-thigh in contact with a piece of foam (41 kg/m^3) was shown in Figure 13.

Total deformation of the thigh and a flat rigid surface is actually a deformation of the thigh itself because a flat rigid surface cannot deform. However, the total deformation of a thigh-foam model is a deformation of the thigh and the foam.

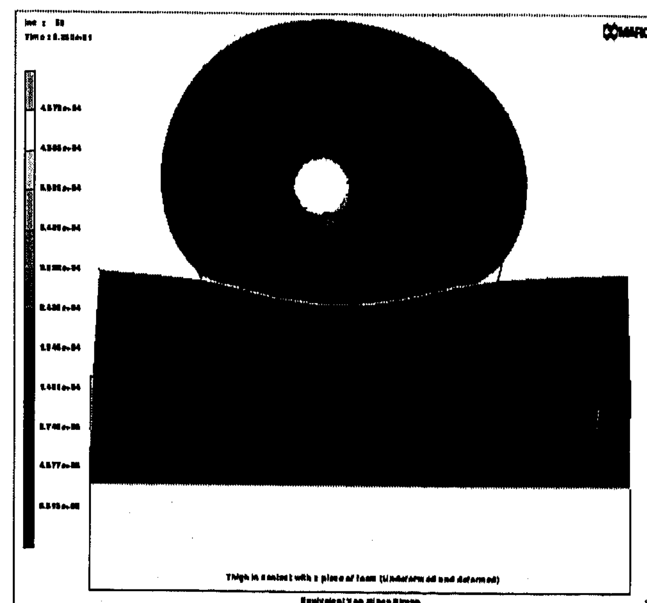

Figure 13. The von Mises stress distribution of the thigh and foam after 50 mm total deformation.

To compare a model and an experiment, a total deformation (thigh and foam deformations) was used. Knowing that the foam thicknesses did not affect the thigh and foam deformations, the 100 mm foam thickness was selected for comparing experiments and models. The results of two different foam densities (41 and 51 kg/m^3) of experiments and models were shown in Figure 14. The results of load-deformation responses of experiments and models for two different foam thicknesses showed good agreements.

The deformations of a flat foam due to the contact with the right thigh were measured through the displacement of the wires. The element sizes of the foam model were chosen in such a way that three element sizes is equal to the distance of the two wires. There were twenty-four wires in the foam, but deformations of two wires in the center of the foam sample were chosen for comparing experiments and models. A contact

reaction and vertical deformation of the wires were generated in the experiments and models. Figure 15 shows the results of models and experiments for one of the selected wires. There were close agreements between experiments and models for two types of foam densities.

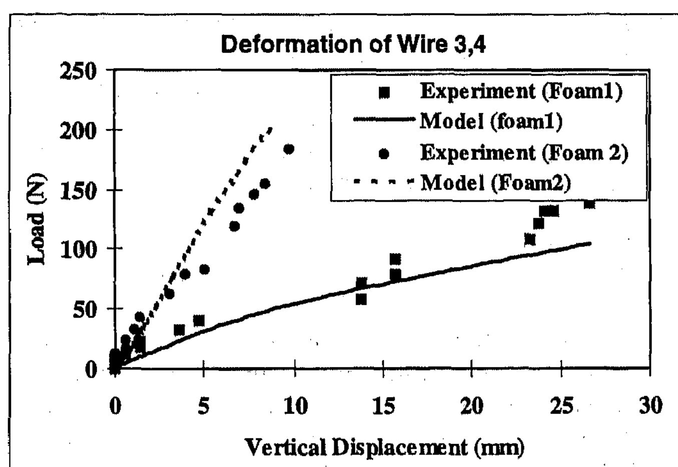

Figure 15. Deformation of one of selected two wires due to two different foam densities, 41 and 51 kg/m^3.

CONCLUSIONS

The cushion materials in a seat and the soft tissues of the human thigh deform when a person sits. These tissue and seat deformations result in the deformed contours between the person and seat. In this study, deformations and contours of human thighs and seat cushion foams were measured and modeled. The measurements were accomplished by transferring the deformed shape of the cushion surface to a video image using wires through the cushion. The contact between the thigh and foam was modeled with finite element methods using large deformation formulations for thigh tissues and foam properties. The results given in the paper are for a single subject, but they are typical of the results for all subjects. As the thigh and foam are loaded, the deformations of the thigh are relatively large and the initial stiffness is low. The initial deformations in the foam are smaller with stiffness that is greater than the thigh. As loading increases, the stiffness of the thigh increases and the stiffness of the foam decreases. The results from measurements and modeling agreed well. This study provides a basis for development of computer models of the entire thigh and buttocks that are in contact with a seat pan cushion. With such a model, seat and tissue deformations could be simulated to predict occupant position. With tissue and seat deformations, contact pressures could be predicted. These results would be useful for correlation to seating pressure patterns that are perceived to be comfortable.

Redefining Seat Comfort

Wenqi Shen and Alicia M. Vértiz
Delphi Interior and Lighting Systems

ABSTRACT

This paper proposes a new concept towards the understanding of seating comfort. Physical comfort is defined as the physiological and psychological state perceived during the autonomic process of relieving physical discomfort and achieving corporeal homeostasis. In addition to static and dynamic comfort in an automotive seat, the occupant will also experience transient comfort. This is the comfort perceived during posture change or fidgeting on the seat. It may depend most on the material properties if posture requirements are satisfied. Lumbar support is exemplified to illustrate this concept. New seat comfort evaluation tools should be developed to account for the transient properties of the seat supporting system.

INTRODUCTION

Under the restrictions of vehicle packaging, the automotive seat is evaluated through sensory measurements such as seat-occupant interface pressure, comfort and seat feature ratings etc., and through human posture measurements such as lumbar curvature, pelvic rotation, joint angles etc. It is also evaluated through physical measurements of seat systems and/or components such as pressure distribution pattern, force-deflection test, vibration transmissibility etc. Some techniques are only appropriate for research purposes due to either the sophisticated instrumentation or the invasiveness of implementation.

The capability of seating comfort assessment is gained through continuous fundamental and applied research. Basically, two categories of knowledge have been accumulated. One is human sensory aspect in seated posture and it includes psychometric measures of seated comfort/discomfort and psychophysical measures of stimulus induced discomfort. A battery of subjective measurement techniques are available (Corlett, 1989) such as checklists, rating scales, and cross-modality matching. A number of rating scales were evaluated in terms of their validity and reliability for seated comfort assessment (Shen and Parsons, 1997). Research on stimulus-perception relationships such as vibration discomfort (Griffin, 1986) and pressure discomfort (Shen, 1994; Shen, Parsons and Vértiz, 1995; Shen and Vértiz, 1996) provides fundamental knowledge for the understanding of seated comfort and for establishment of industrial testing criteria. The other category of knowledge is the assessment methods and techniques of seated comfort and discomfort. Extensive reviews can be found in Corlett (1989) and Lueder (1983).

For practical evaluation of seat products, more attention has been paid to seat system/component tests than sensory and posture measurements, because posture is more individual and undetermined whereas seat features are more to the interest of product engineers. Indeed, from an engineer's point of view, the physical performance and comfort properties of a seat system is the major concern and they can only be improved through work on seat features and components. Findings from fundamental studies may not directly help engineers solve problems in seat comfort due to at least three reasons as summarized below.

1. Factors such as interface pressure and vibration which above certain thresholds could cause distinctive sensory discomfort, may no longer be significant for automotive seating. Discomfort prediction through psychophysical relationships may become improbable at very low stimulus levels e.g. around discomfort thresholds in automotive seating, owing to the improvement of product quality. With better vehicle dynamic performance and road conditions, the vibration levels that a seated occupant is subject to can be substantially lower than those for a vehicle on the road twenty years ago. Similarly, seat surface contour is becoming more harmonious to promote appropriate sitting posture and conformity with human body shape. This leads to fewer hard spots or regional protrusions which are frequent sources of excessive local pressure. When seats of different design meet basic requirements for comfort and are free of significant sources of discomfort, the sensitivity of comparative evaluation is much reduced.

2. When discomfort due to excessive physical stimuli become minimal, it can be difficult to predict which seat is more comfortable. The most severe component principle (Shen and Vértiz, 1995) states that when there are two or more sources or components of discomfort, overall seated discomfort is determined by the component inducing the highest discomfort. When all discomfort components become less severe, it may be obscure as to which is the true

source or component. Some apparently non-important features may start playing a major role. Moreover, there are other contributors to comfort than the absence of discomfort. As is well known, pressure distribution on seat-occupant interface relates both to occupant seated posture and to seat properties or features, and pressure measurement is one of the readily used tools for seat evaluation. Most of the car seats can provide acceptable support without producing pressure far higher than discomfort threshold. Yet two seats which produce similar pressure distribution may yield quite different comfort ratings even under static conditions. Some intrinsic properties in cushioning materials are essential to comfort perception but yet need profound exploration, apart from better understanding of the meanings of seat comfort.

3. Assessment techniques do not produce immediate solutions to improving seat comfort. Objective techniques, measure sources or covariants of discomfort, and subjective techniques measure levels of discomfort resulting from inappropriate design. In using these techniques, we can only interpret as to what features and properties, and to what direction, we should tackle to possibly improve seats. Take seat cushion material as an example. While we understand that cushion support is provided by the assembly of suspension, padding, trim cover, etc., the properties of padding materials are of great importance due to its unique supporting features. A number of properties of foam material contribute to cushioning comfort as well as to durability, such as density, indentation force/load deflection (IFD or ILD), support factor, resilience, compression set, and dynamic fatigue over time. We do not know for sure what are the relationships between each parameter and seated comfort, although indicative guidelines are available. There are other issues in seating comfort on which controversial opinions exist. Ideally, human factors research on seating comfort should be combined with physical testing in order to identify the problem and produce feasible solutions.

With this paper, we attempt to functionally and operationally redefine seating comfort for better understanding of seating comfort in today's vehicles. A three stage comfort model is proposed to explain subjective judgment of seat comfort as well occupant's sitting behavior in riding. Finally, the properties of lumbar support is discussed as an application of the new comfort concept. We hope this work could inspire further thinking and discussion for better design of automotive seating systems.

PHYSICAL COMFORT: A PROCESS OF RELIEVING DISCOMFORT

Human comfort is not a concept that is precisely defined due to its different attributes in various domains, although it could be considered as "a generic term for a pleasant state of psychological, physiological, and physical harmony between a human being and the environment" (Slater, 1985). We have psychological aspect of comfort of personal well-being and satisfaction, physiological aspect of comfort of being in good health and free of illness, and physical aspect of comfort without negative disturbance from external environments. There are perhaps not many words that are used so often in so many aspects of our daily life as *comfort*. This fact along shows how wide a notion it conveys and how difficult to define it. In the assessment of seats, the lack of agreed definition of seated comfort often causes confusion in both the methods of evaluation and the techniques used for it.

Let's first look at some previous definitions of comfort or seat comfort in literature.

Comfort is some state of well-being or being at ease (Oborne and Clarke, 1973). Similar definitions: Griffin (1995) states that comfort implies a conscious well-being, and Reynolds (1993) describes comfort as an occupant's empirical perception of being at ease. Product and environment design could improve physical aspects to promote to an extent psychological and physiological comfort. Such a definition is very general. We may find a number of words to associate with this broad notion of comfort but none exclusively express it. Obviously, this definition does not denote any means of measuring and/or promoting comfort.

Comfort is the absence of discomfort (Branton, 1969, Corlett, 1973, Hertzberg, 1958). To argue for this definition against positive state of comfort, Branton (1969) stated that he fount it "most difficult to envisage deriving extreme feelings of well-being merely from sitting however good the chair may be. In our view, therefore, the possible continuum extends only from indifference to extreme discomfort." From an operational point of view, Hertzberg (1958) stated that "although we tend to speak of comfort and discomfort as if they were two states of consciousness, for testing purposes it is more realistic to consider that there is only one, discomfort, and that 'comfort' is only the absence of discomfort". According to this definition, one cannot provide comfort in a seat design, one can only eliminate sources of discomfort. Take car seats as an example, as was stated by Verbrugge (1990), "Although automotive engineers and advertisers may hope that a car seat can promote a sense of delight or pleasure, and may want to have research that helps them to enhance this, it is an impossible goal scientifically. A goal of 'indifference' is far more sensible and feasible". This type of definition of "indifference" insinuates that comfort is not measurable or comparable because it is regarded as the starting point of a continuous discomfort scale. We know from experience and from testing that this is not true. One can easily compare comfort sitting in two seats by stating "I feel more comfortable in this seat than being in that one" or "this seat is more comfortable than that one". Of course we agree he/she experiences different levels of comfort. The problem now is: as both seats are not uncomfortable, what is the basis for him/her to compare comfort?

Physical comfort should naturally be related to discomfort, but it is more than absence of discomfort. We propose a definition of physical comfort as follows:-

Physical comfort: the physiological and psychological state perceived during the autonomic process of relieving physical discomfort and achieving bodily homeostasis.

This definition needs some detailed explanation. Comfort and discomfort are not two states which are distinctively separated at two opposite directions. They are not necessarily in the same continuum. But rather, one can instantly suppress the other. As by definition, comfort exists when physical discomfort id reducing. If the removal of severe discomfort is by a leap, comfort can instantly prevail. As an example, think what you may feel when the annoying sound of a power drill suddenly stops.

Comfort is dynamic as is experienced during a process, rather than static. This is a key point to understand comfort. Discomfort can be static and exist for as long as the bodily balance is not assumed, but comfort exists only when some positive change is being made. When no discomfort is present, comfort does not necessarily exist, and it is only "indifference" (Branton, 1969). It denotes a relatively stable state of no awareness of a bad feeling and does not necessarily entail a positive affectation. Therefore, "absence of discomfort" does not define comfort. Comfort only occurs when the environment around you makes or is made a positive change. When you take a shower after an intensive treadmill exercise, the sticky sweat and fatigue is being washed out and you feel a sensation of comfort. Yet soon you will be indifferent and the level of comfort does not sustain even if the thermal condition in the room remains neutral.

This is to say feelings of comfort may gradually saturate or even disappear some time after discomfort is eliminated and homeostasis is reached. Fisher and Connolly (1970) defined physical comfort as a state in which man's physiological needs have been satisfied and homeostasis exists between the internal and external environmental forces. According to the Webster's Dictionary (1984), homeostasis is a state of equilibrium between different but interrelated functions or elements, as in an organism or group. In physiology it concerns the self-regulation of body functions. According to this concept, when there is no discomfort, a man should be always "comfortable". This may not be the case in reality. We know that human beings are stimulus seekers and that human sensory functions work as cycles of excitation and adaptation. When the body is in ease and in homeostasis for a period of time, external excitations are gone and, as excitation induces sensation, the sensation of comfort is also gone. Reporting comfort is an evaluative experience and involves a lot of attention to judge and report the intensity level. When nothing in the environment is being changed, there is no fresh stimulus.

This phenomenon has its psychophysical interpretation. No matter what factors induce stimulus to seated person, the perception of comfort / discomfort always follows similar characteristics to other human sensory modalities. According to the adaptation level theory (Coren *et al.*, 1979), a stimulus is not simply weak or intense, it is weak or intense when judged against the subjective adaptation level, which is established by pooling the effects of three classes of stimuli: focal, background, and residual. If the subject's attention is directed to the background, the identity of the background is shifted to focal stimulus. This context change can affect our perceived intensity. Residual stimuli, the stimuli that occurred in the past and are no longer physically present in the judgment situation, can also affect the perception of sensory magnitude. In the case of seat comfort perception, the focal stimuli are from those seat features that significantly attract the occupants attention for being pleasant or unpleasant. The background stimulus is the general seated environment including seated posture and contact pressure. The identity of focal and background stimuli is not fixed and, as soon as some background features become prominent, the background and the focal shift positions. For example, some background factors, such as sustained medium pressure under the thigh or persistent low back muscle exertion, may become focal stimuli and cause discomfort in a long period of sitting.

When some seat features have already induced discomfort, the elimination process of discomfort will be the focal stimulus to elicit perception of comfort. Towards the diminishing of discomfort, focal stimulus gradually descends to background, and the perception of comfort also falls into a state of unawareness. Comfort as "indifference" expresses only the state of mind when the process has settled. Corlett (1973) once remarked that comfort "can be seen as arising from the summation of all the bodily sensations, each having a random distribution of levels. In any given situation, if the balance is such as not to draw attention to any one sensation, a person can be said to be comfortable". What he denotes may still be the state of having no discomfort, but not the comfort as a capability or a potential of removing discomfort.

To summarize, perceived comfort relates both to the level of discomfort and to the elimination process of discomfort. This approach can be described with hypothetical time courses of changing discomfort and comfort, as shown in Figure 1. At Phase I when discomfort is severe, comfort is at the lowest. At Phase II, discomfort level is being reduced, and comfort increases due to the less severe level and to the reduction rate of discomfort. Phase III is when discomfort is removed but perception of comfort adapts, possibly to an "indifference" saturation level. At Phase IV, some insignificant feature may become the focal stimulus and discomfort creeps up to attract occupation attention, so that perceived comfort drops. Phase V represents another cycle of discomfort removal.

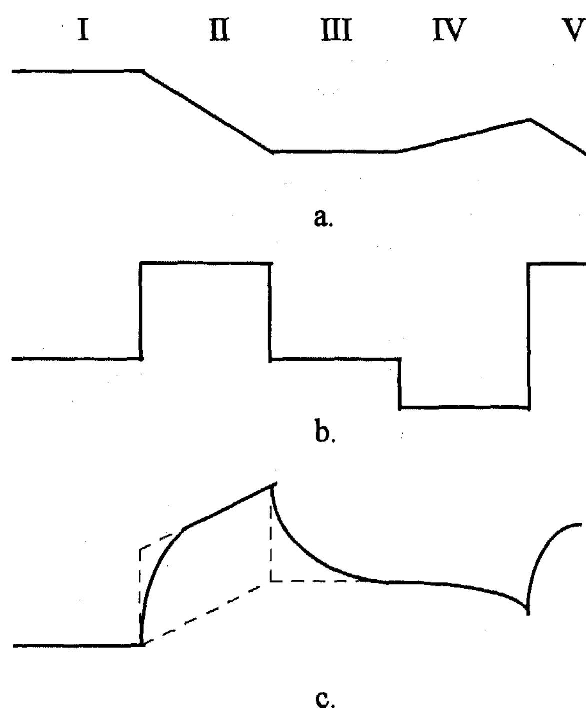

Figure 1. Time courses of comfort. (a) time course of discomfort, which serves as the stimulus to elicit comfort; (b) rate of reduction of discomfort; (c) time course of comfort, as a delayed response function of both discomfort level and the rate of its decrease.

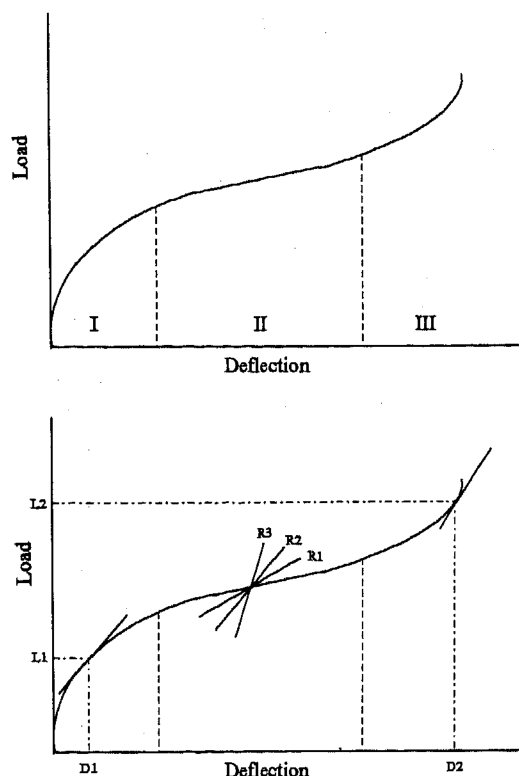
THREE MODES OF SITTING COMFORT VS. CUSHION PROPERTIES

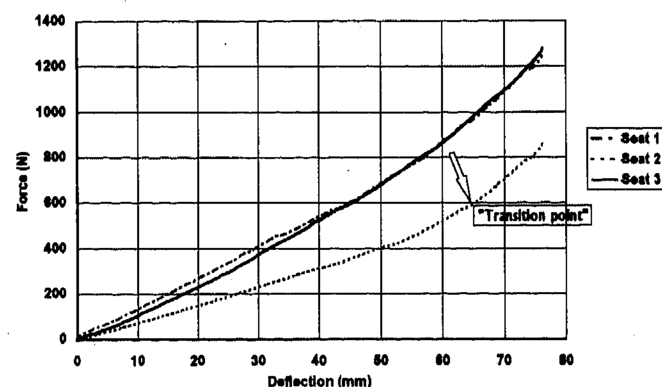
The concept of temporal comfort has its important implication to the design of seats, vehicle interiors and other consumer products. Experience tells us that just as any other tasks, sitting is a naturally fatiguing process. No matter how good a seat or a vehicle is, it cannot maintain an occupant free of discomfort for hours of sitting. And this is a biological mechanism to protect the human tissues from compression damage. If a product is to excel, it has to provide effective ways to minimize the accumulation of discomfort and help remove it. Careful consideration should be given to provide features for soothing and relieving discomfort. With such an active approach towards comfort, we can suppress some of the factors that cause occupant discomfort.

The temporal comfort model also broadens the scope for seat evaluation techniques. In retrospect, current evaluation tools for seat comfort are actually for discomfort assessment. Generally, those tools include interface pressure distribution, postural indicators of muscle activity and spinal shrinkage, and thermal properties for static evaluation, as well as vibration for dynamic evaluation. When anything drifts away from relevant criteria, the occupant may experience discomfort. However, absence of discomfort at a particular rating moment does not guarantee sitting comfort. According to Figure 1, we have to evaluate a seat in terms of its capability of relieving or eliminating discomfort, in addition to testing the absence of discomfort. Cavender (1993) stated that "the very best time to look at properties such as load bearing, resiliency, load ratio, etc. is during the period of loading or the time that work is actually being done to flex the cushioning material". We feel that there are some seat features which may promote comfort and, for lack of proper terminology, we call them transient features. If a seat provides proper postural support and occupant protection, the judgment of comfort is often made at the moments when the occupant is being seated and/or when he/she is seeking change of posture by fidgeting or re-positioning. He/she may sit on the seat, bouncing around and compressing and twisting the body on the seat, a ubiquitous practice when someone is asked to give a quick rating on seat comfort. Unfortunately, no valid tools or techniques are available to measure this kind of phenomenon except some observational or behavioral methods for sitting behavior and postural change (Corlett, 1989). These behavioral techniques have not been proved as practical. Objective tests either on human physiological responses or material properties can be more appropriate to describe such transient stage of comfort.

To better understand the transient features, we can classify the process of ride comfort into three modes: initial comfort, transient comfort, and dynamic comfort. The following explanation will be made in respect to Figure 2, a hypothetical load-deflection curve of a seat cushion assembly.

INITIAL COMFORT. The seat should provide a gradual, gentle, cozy support to the "landing" or indenting of occupant's body upon seat cushion (Pham *et al.*, 1987, and Stone, 1965). The initial softness and sensation of being gently but progressively cushioned is very important to occupant's perceived comfort. To properly support riding postures, the cushion should further produce increasing resilience to the body load indenting the seat, a feature well held in polyurethane foam. This property in foam padding may be expressed by SAG-factor (65% IFD/25% IFD, ASTM Standard D 3574 - 91), and the initial local modulus of the load-deflection curve. In terms of this principle, the local modulus at (D1, L1) of Phase I, Figure 2, should not exceed that of Phase II which is the normal supporting phase. The local modulus is the gradient of the curve at a given deflection under load. Stone's work (1965) concluded that the two seats with low initial local modulus were apparently more comfortable and preferred than the two seats with the highest initial local modulus. ASTM Standard D 3574 - 91 even includes a Modulus Irregularity Factor (MIF), derived from load-deflection curve, and indicates that high, positive MIF value may result in some discomfort in seat applications. As an example, the situation depicted in Figure 2 obviously fails this requirement. Of course, the presumption is there are no significant problems with other seat features such as contouring. On seat-occupant interface, body pressure distribution may examine the supporting quality by identifying hard points and inappropriate posture.





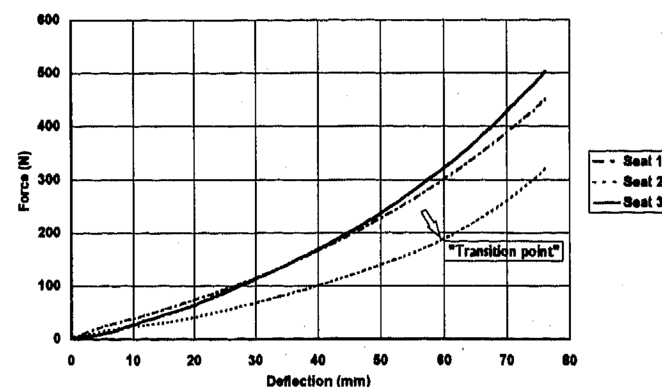


Figure 2. Seat force-deflection curves. Left: three stages of deflection. Right: local modulus at (D1, L1) and (D2, L2), and dynamic modulus at vibration rates $R1<R2<R3$.

TRANSIENT COMFORT. As mentioned earlier, transient comfort is perceived as the subject adjusts posture or fidgets around on the seat. Riding tasks often require frequent change of posture, so do the muscle groups when some relaxation is in need. A comfortable seat should not constitute any local impact or interfere with such changes, but provide gentle damping effect on the transient loading. This again relates to the local modulus on the basis of settlement deflection, the deflection at static body load. The hardness measured as Indentation Force Deflection (IFD) value at 40% or 50% is the mean modulus for up to 40 or 50% of total deflection. Therefore all IFD stands for is the accumulated "dynamic/ local" IFDs. After the occupant sits down and the cushion settles, neither the initial local modulus nor IFD at 40% affects perception, but the local modulus at the settled deflection starts to influence the perception of cushion comfort. The amount of settlement deflection depends mainly on occupant's body weight as well as IFD value. The majority of automotive seats operate at a settlement deflection of 15 - 50% (Cunningham *et al.*, 1994), at the second stage on the load-deflection curve. However, a large and heavy occupant may indent the seat more than 50% close to the Phase III when the cushion hardens up or "bottom-out". A small occupant may indent less than 15%, and in the case shown in Figure 2, the seat would also feel harder. To evaluate seat performance for supporting a range of occupants of different body weight, we may need more comprehensive indices than a single IFD value. Although SAG factor can generally indicate the effectiveness of support, the local modulus for supporting 5% female and 95% male weight should be derived on load-deflection curve to ensure the settlement deflection points lie well in Phase II.

Figure 3 describes results of a force-deflection test on three automotive seats, using (a) a buttock-form indentor and (b) a three-inch-diameter flat indentor, simulating the vicinity of the right ischial tuberosity. Seats 1 & 3 have no apparent differences between stages and were subjectively perceived as being slightly too hard. Seat 2 has low modulus before 65 mm deflection, the "transition point", and then the modulus increases to a level similar to that of the other two seats. This feature provides excellent initial and transient comfort if the cushion deflection is less than 65 mm under the occupant's body weight. Yet the support is effective without bottoming-out as the modulus increases after 65 mm deflection. Figure 3b indicates that, in order to ensure initial and transient comfort, the weight taken by each ischial tuberosity should be less than 200 Newton. Since the ischial tuberosities take the majority of body weight in sitting, this load limit to the region is important to avoid the numbing feeling of the buttocks.

(a) Using buttock-form plate indentor

(b) Using a three-inch-diameter indentor at buttock-pocket

Figure 3. Force-deflection test for three seats.

DYNAMIC COMFORT. Seating comfort under vibration conditions can be considered as the transient comfort when the imposed loading upon static settlement deflection is either cyclic or random. The local modulus or rather, dynamic modulus, depends partially upon the vibration rate, or frequency. The higher the frequency, the higher the dynamic modulus (Figure 2). However, transmissibility measurements of real vehicle seats show high levels of vibration isolation above 20 Hz. Actual vibration sensitive frequency is between 0 and 6 Hz. For this frequency range, reducing seat dynamic modulus is very important for achieving vibration comfort. However, measurement of such modulus may have technical difficulties.

Physical properties of seat supporting system is not as simple as a single IFD value. The three modes of seat comfort suggest for other more potent indices. It is likely these indices would be most related to cushioning material tests. This is an exciting area for comfort enhancement but more knowledge is needed on test methodologies.

MYTH OF LUMBAR SUPPORT

Lumbar support is another seat feature that is of vital importance in seating comfort. A proper amount of lumbar lordosis is fundamental for maintaining the torso upright or reclined and the eyes at the right vision level. Without lumbar support, back muscles have to work to keep the potentially forward-rotating rib cage upright and overcome the weight. If the lumbar support is appropriate, the lumbar spine will shape into natural lordosis, which helps the pelvis rotate forward. Moreover, a secured lumbar support carries a large amount of torso load from above the rib cage, and the lumbar support actually serves as a second pivot point, on which the rib cage is caught safely and the abdomen of the occupant opens up. This action in turn enables the occupant's shoulder to be supported on the upper back and each region on the back can obtain adequate support. A lumbar support also provides stability of the pelvis.

Proper lumbar support can reduce lumbar spine loads as measured by intradiscal pressure. Based on a series of physiological studies, Andersson *et al.* (1979) advocated that lumbar prominence should be 50 mm. However, this amount of lumbar prominence has not been validated as generally achievable and preferable. Porter and Norris (1987) used a wooden test seat to gauge the preferred lumbar prominence and found that 20 mm prominence was preferred to 40 and 50 mm with both reclined and vertical back angles. Incidentally, Dowell (1995) measured 773 seated persons at a vertical back angle and obtained the apex depth of the lumbar curve. Mean lumbar depth was 25 mm for male and 22 mm for female. We also found with our routine seat tests that large amount of lumbar prominence is not actually favored as many people would think. A 20 mm prominence is about the right amount. It seems that the purpose of lumbar support is more for catching the rib cage and maintaining a relatively stable back posture and pelvis than being for a lordosis itself. After all, the lumbar lordosis in a seated posture will be reduced as compared to a standing position by as much as 38° on average(Andersson *et al.*, 1979), due to the tendency of backward rotation of pelvis under hamstring muscle tension.

Preference of less lumbar prominence is related to how the lumbar support is engineered. We often see people test seat back comfort through moving around and swinging the upper trunk fore-aft. If the seat back supports the human back properly along the spine and is still compliable, it may feel comfortable. During actual vehicle riding, it is only too often for the occupant to move slightly adjusting posture and relieving muscle activities. If the lumbar prominence is achieved through a rigid mechanism or hard padding protrusion, the lumbar would stick forward on the occupant's back and cause pressure discomfort. Occupant's back is literally pushed forward so that other back regions cannot maintain close contact with the seat. We experienced many situations when subjects liked the lumbar prominence but the mechanism to achieve it was objectionable.

Therefore a delicate balance should be reached between the prominence and compliance, among other relations in the total seat system. Greater prominence may be preferable if it is achieved through soft padding and flexible lumbar mechanism and suspension. A number of lumbar adjustment systems are commercially available. Unfortunately, when prominence is increased, compliance tends to reduce. A close examination of seat-back load-deflection property should be carried out. This property may change dramatically by using different lumbar adjustment mechanisms. To date, most effort in lumbar support has been on the amount of prominence, and the regional force-deflection property has hardly been investigated.

CONCLUSIONS

Acknowledging that seat comfort is a temporal process rather than a static condition, the authors of this paper proposed a new definition of seat comfort. The approach treats comfort as the reliving process of discomfort instead of being simply the absence of discomfort. The philosophy also leads to a three-modes seat comfort model including initial, transient, and dynamic comfort. Some cushion material properties are analyzed and the lumbar support is illustrated to exemplify the concept. The following aspects can be summarized as conclusions:-

1. As to an automotive seat, comfort is not a static property but a potential of relieving the occupants of any posture and contact associated discomfort. A seat free of discomfort stressors is not necessarily a comfortable one but it must have comfort enhancers.

2. As to an occupant, comfort is not a sustaining feeling accompanying a fixed seated posture, but it is a sensation perceived when discomfort is relieved during transient periods of sitting, e.g. landing on the seat, posture change, and fidgeting.

3. To be comfortable, a seat should provide be capable of providing initial and transient comfort. It should comfortably accommodate posture change and the changed posture. Lumbar support should especially be compliable for adaptation to different lumbar prominence preferences.

4. New seat comfort evaluation tools should be developed to account for the transient properties of the supporting system.

ACKNOWLEDGMENTS

Thanks are due to Raghu Gurram and John Bruce for conducting the force-deflection test.

Limitations in Predicting Human Vibration Response Characteristics From Manikins and Rigid Body Masses

Suzanne D. Smith
Department of the Air Force

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

The objective of this study was to use the driving-point impedance and transmissibility techniques to evaluate and compare the resonance behavior of two male humans, the Hybrid III aerospace manikin, and a rigid body mass using a rigid seat and a selected helicopter seat cushion. All occupants represented the 95th percentile or higher of the male population for weight. The results showed that the resonance frequencies associated with the peak impedance, chest, and head transmissibilities were significantly higher in the manikin regardless of the seating configuration or input acceleration level. While the magnitude of the peak impedance was higher in the manikin, differences in the chest and head transmissibilities depended on both the seating configuration and acceleration level. Neither the manikin nor the rigid body were effective in predicting the primary human resonance effects occurring in the sensitive region of 4 to 8 Hz. However, some similarity did exist when comparing the manikin response to human spine transmissibility data. A discussion of an alternative method for predicting human body resonances using mathematical models is included in this paper.

INTRODUCTION

The operation of both civilian and military ground vehicles, including automobiles, tanks, and trucks, can expose the occupants to whole-body vibration which has been shown to affect comfort, performance, and health. Griffin [1] applied the ISO 2631 [2] to seat transmissibility data collected on cars, buses, and trucks operated over several terrain surfaces. For all vehicles, the vertical seat vibration was found to be more severe than vibration measured in the other translational axes. The weighted accelerations were found to be about twice as severe on the poorer surfaces. For the cars, the values reached the reduced comfort boundary [2] within 30 minutes of operation over the poorer surface. The exposure limit, which should not be exceeded according to the ISO 2631 [2], occurred within as little as 4 to 8 hours. Griffin [1] observed that higher weighted acceleration levels and shorter acceptable exposure durations occurred with the operation of buses and trucks. In the military, health hazard assessments of new Army ground vehicles have shown that the exposure limit can be reached within as little as one hour [3]. Pilots of both Army and Air Force Black Hawk helicopters have reported symptoms of low back pain and general discomfort after about four hours of flight [4].

The improvement of comfort, performance, and safety in ground vehicles challenges the commercial and military communities with designing vehicle suspensions and seating systems which minimize vibration effects. Both experimental testing and mathematical modeling provide the methods for evaluating suspension and seating system design concepts for reducing human body vibration, however, both methods must be capable of properly predicting human body resonance effects. For example, vibration testing and analysis methods have used manikins and rigid body masses to evaluate seat and cushion concepts for human use, particularly when human testing was not feasible. Gurram et al. (1995) compared the vibration response of a human and a plastic water-filled dummy of similar weight while sitting in a seat/cushion system. Transmissibility was measured between the output acceleration at the subject/cushion interface and the input acceleration at the shaker table. The seat itself was shown to have a transmissibility near unity. The primary resonance of the human occurred at 4.25 Hz with a secondary peak observed between about 7 and 8 Hz. The single resonance peak observed for the dummy occurred at 7.5 Hz. The magnitude of the response was found to be quite higher in the dummy. Using both the driving-point impedance and transmissibility techniques, Smith (1994, 1996) tested military aircraft cushions using humans weighing between 50 and 105 kgs, and using rigid masses weighing between 39 and 68 kgs. While the primary resonance peak for all of the human subjects occurred between 4 and 7 Hz, the single peak observed for the rigid mass tests occurred between 8 and 15 Hz. The limitations of the manikin and rigid body mass in simulating human body resonances should be well understood before using

these methods to optimize seating systems for human use. The objective of this study was to evaluate and compare the vibration response characteristics of the human, manikin, and rigid body mass of similar weight using a rigid seat and a selected helicopter seat cushion. The driving-point impedance and transmissibility techniques were used to generate frequency response profiles for the whole-body and for specific anatomical structures or regions. The resonance behaviors observed in these profiles were evaluated and compared between the humans, manikin, and rigid body mass. Also included in this paper is a discussion of the mathematical modeling method for predicting human body resonance behaviors and seat cushion effects.

METHODS AND MATERIALS

Four 'occupants' of approximately the same weight were used in the study. Two of the occupants were human males weighing approximately 104 kgs. The third occupant was a Hybrid III aerospace anthropomorphic manikin obtained from First Technology Safety Systems, Inc. and weighing approximately 99 kgs. The fourth occupant was a rigid body mass comprised of bags of metal shot weighing approximately 101 kgs. All occupants represented the 95th percentile or higher of the male population for weight.

An electrodynamic vibration platform (Unholtz-Dickie) was used to provide the vertical vibration exposures. The system was designed to operate in the frequency range of DC to 5000 Hz with a force limit of 6672 N peak and a payload of 113 kgs. A rigid aluminum test seat was mounted on top of the platform and included a seatback, lapbelt, and double shoulder harness. The angle between the seatback and seatpan was 90 degrees. The test seat has been shown to respond as a rigid system for the subject weight and frequency range under investigation. No additional padding was provided for the seated subjects. The humans were loosely restrained, similarly to what would be expected during the operation of civilian ground vehicles. The human subjects used in this study were experienced in vibration testing and fully understood the importance of maintaining the upright posture during data collection. The presence of the seatback aided in this process. It was necessary to restrain the manikin more tightly to maintain the upright posture. Due to the seat payload limitations, both the human and manikin legs were allowed to hang freely. The subjects hands were folded and placed in their lap during testing. The transmitted force of the combined seat and occupant was measured by three load cells (Strainsert FL1U-256 KT) located between the seat and vibration platform. Two accelerometers (Kulite GYD-4-280-20 and Kistler 815A5) were attached to the seat for measuring the input acceleration magnitude and phase, respectively. Vertical accelerations were measured using miniature accelerometers (Entran EGA-125-10D) attached with double-sided carpet tape to specific anatomical regions on the occupant. For the human, accelerometers were attached on the chest (at the level of the manubrium) and on a bitebar (head) molded with dental acrylic. For the manikin, an accelerometer was similarly attached at the chest (on the surface). Manikin head acceleration was measured using an accelerometer mounted within the head. The location was slightly anterior to and above the attachment site for the head and neck. For the rigid body mass, an accelerometer was attached on top of the mass.

In order to evaluate the effects of a cushion on the vibration response of the occupants, tests were also conducted using a seatpan cushion obtained from a Black Hawk helicopter and placed between the rigid seating surface and the occupant. The cushion was fabricated of three layers of foam with different densities. The bottom layer was made of high density plastic foam and varied in thickness from about 1 cm at the back to 6 cm at the front, providing a contour or "bucket" seating surface. Air vents ran from the front to the back along the inside surface. The top layer consisted of polyurethane foam about 2.5 cm in thickness. Sandwiched between these two materials was a layer of polyurethane foam of greater density than the top layer and approximately 1.5 cm in thickness. The cushion was covered with black lambswool and weighed 910.5 gm. For the cushion tests, a ride quality meter, consisting of three orthogonal accelerometers imbedded within a rubber disk, was placed between the occupant and cushion for calculating the interface transmissibility. Only the vertical acceleration was used for the evaluation and comparison.

The three input vibration profiles at the seat included discrete sinusoidal frequencies and two sum-of-sines profiles generated by combining the discrete sinusoidal frequencies. The frequency components used for all three input profiles ranged from 3 to 21 Hz in 1 Hz increments. Two seat acceleration levels were used; 0.59 m/s^2 rms and 2.35 m/s^2 rms (0.06 g_{rms} and 0.24 g_{rms}). While the frequency content and rms acceleration levels were identical for the two profiles, the crest factor (CF= 2.9 and 4.2) was varied by altering the phase relations between frequency components. The crest factor, defined as the ratio of the peak acceleration to the rms level, is an indicator of the impulsiveness of the motion. Figure 1 illustrates the two sum-of-sines profiles (P1 and P2) at 0.59 m/s^2 rms. A computer program was used to generate the vibration profiles at the seat and for simultaneously collecting all transducer data. Data were collected for two seconds at a sampling rate of 1024 Hz. A Fast Fourier Transform algorithm was used to determine the transducer magnitude and phase difference between the sum of the three load cell forces and the input velocity calculated from the input acceleration at the seat. The impedance frequency response profiles were calculated as the magnitude ratio and phase difference between the transmitted force and input velocity at each discrete frequency component between 3 and 21 Hz. The impedance of the rigid seat (collected separately) was subtracted from the calculated impedance to obtain the impedance frequency response profile of the occupant. The magnitudes of the vertical transmissibility frequency response profiles were calculated as the ratios between the accelerations measured at the chest, head, ride quality meter, and rigid body mass, and the input acceleration at the rigid seat at each discrete frequency component between 3 and 21

SUM-OF-SINES VIBRATION SIGNALS

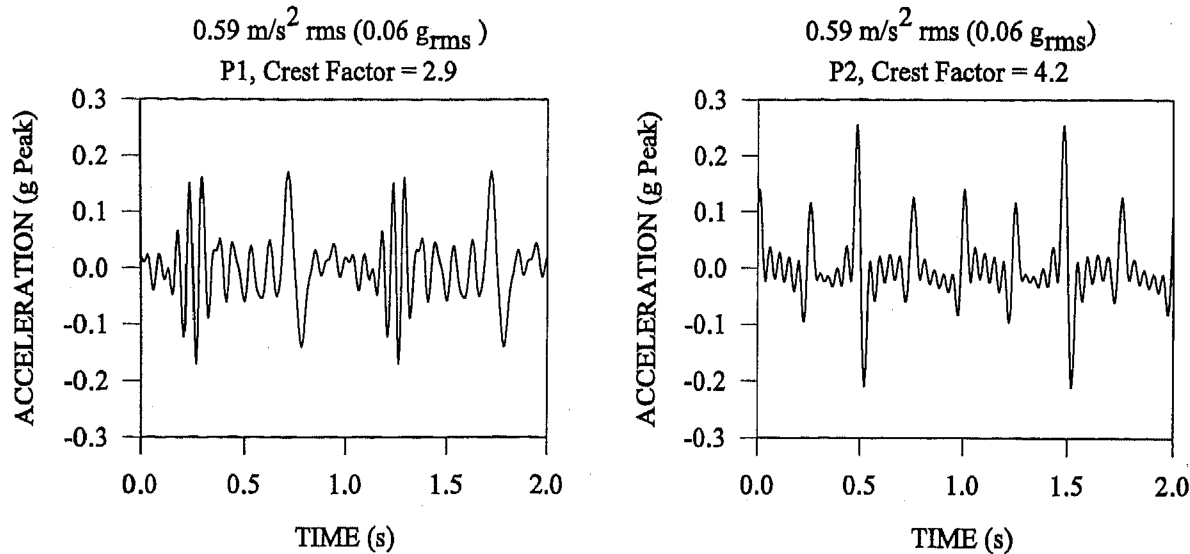

Figure 1 Sum-of-sines vibration profiles.

Hz. The impedance magnitude and phase, and the transmissibility magnitude frequency response profiles were generated at each of the two acceleration levels. The three magnitude frequency response profiles (sinusoidal and sum-of-sines) were used to compare and evaluate the frequency location and magnitude of the peak or resonance responses. The means and standard deviations were calculated for the resonance frequencies and peak magnitudes extracted from these data and represented the subject response variability occurring for different types of vibration exposures. In addition, the mean impedance and transmissibility magnitude frequency responses were calculated from the three profiles.

RESULTS

RIGID SEAT EFFECTS - Figure 2 illustrates the mean impedance magnitude and phase frequency response profiles for the occupants using the rigid seat at the lower acceleration level (0.59 m/s² rms). Figure 3 shows the means ± one standard deviation for the primary impedance resonance frequencies and peak magnitudes occurring at the two acceleration levels for the humans and manikin using the rigid seat (labeled R in the figure) and seat cushion (labeled C in the figure). The seat cushion effects are discussed later in the paper. The impedance response of the rigid body mass was calculated using a mass of 101 kg and the known relationship for the impedance magnitude and phase of a rigid mass [8]. Both humans showed a primary or highest resonance peak between 6 and 7 Hz. Additional regions of resonance were observed at higher frequencies, particularly for the first human subject between 11 and 13 Hz, where a smaller peak was observed in all three magnitude response profiles. The impedance magnitudes for the humans remained relatively constant at frequencies

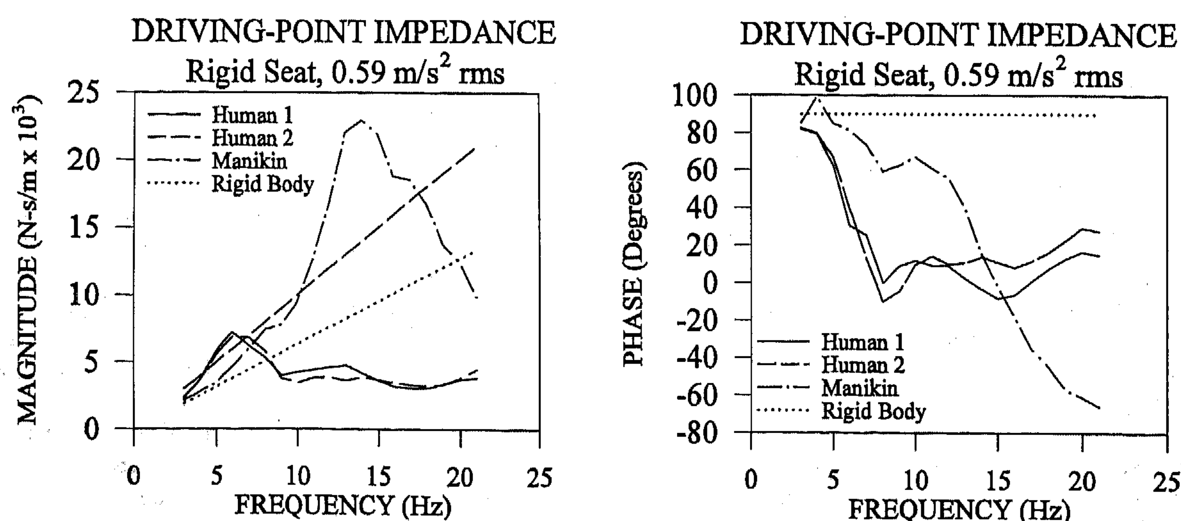

Figure 2 Driving-point impedance magnitude and phase frequency response profiles using the rigid seat.

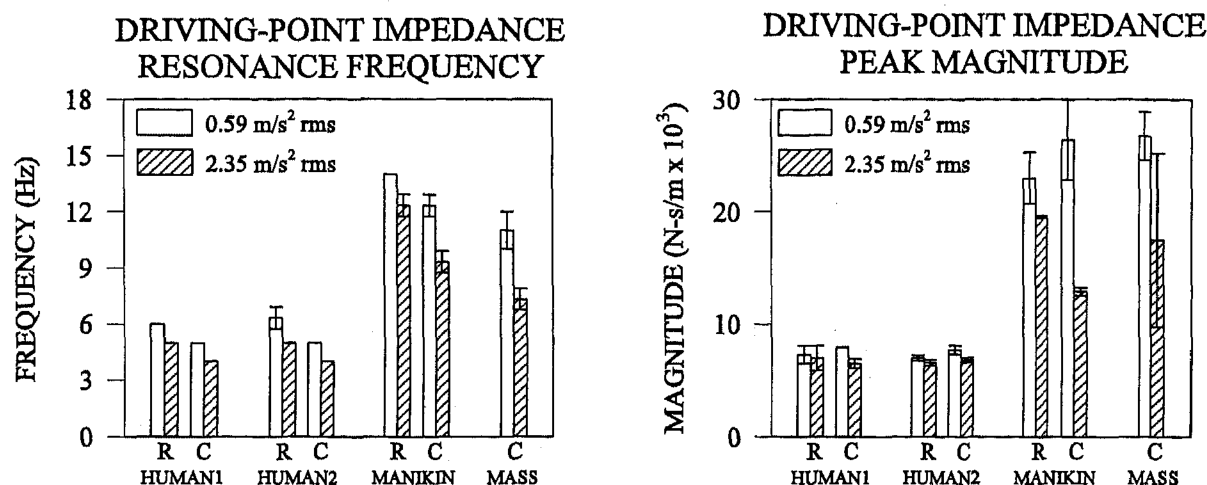

Figure 3 Driving-point impedance resonance frequencies and peak magnitudes (R = Rigid Seat; C = Cushion).

beyond the regions of resonance. For the humans, the phase declined rapidly through the primary region of resonance from about 90 degrees to around 0 degrees. There was a phase change through the second region of resonance observed for the first human subject as illustrated in Figure 2. The phases for the humans tended to remain within ± 20 degrees at frequencies beyond the primary peak. In contrast, the primary or highest impedance peak observed for the manikin occurred at a higher frequency around 14 Hz and was approximately four times the magnitudes of the human peaks. In addition, the majority of the manikin data showed smaller magnitude peaks at 8 and 17 Hz. As shown in Figure 2, the impedance magnitude decreased with increasing frequency beyond the primary region of resonance. The phase changed rapidly through the peak regions. For the manikin, the phase continued to decline at frequencies beyond the primary resonance (14 Hz) to between -60 and -70 degrees at 21 Hz. Figure 2 also shows the calculated magnitude and phase responses for the rigid body mass. Figure 3 shows that the primary impedance resonance frequency observed for both the humans and manikin decreased by 1 to 2 Hz at the higher acceleration level with the use of the rigid seat (labeled R in the figure). The two human subjects showed a peak at 5 Hz, while the manikin showed a peak around 12 Hz. The humans showed no significant difference in the magnitude of the primary peak at the higher acceleration level. The manikin did show a decrease in the primary peak at the higher acceleration level although less variability was observed in the data at this level. In contrast to the effects observed in the humans and manikin, the impedance of a rigid body mass is not affected by the input acceleration level. For both the humans and the manikin, the additional peaks observed in the impedance frequency response profiles appeared more attenuated or were shifted by several Hz at the higher acceleration level.

Figure 4 illustrates the mean magnitudes of the chest and head transmissibility frequency response profiles for the humans and manikin at the lower acceleration level using the rigid seat. Figure 5 shows the means ± one standard deviation for the primary resonance frequencies and peak magnitudes associated with the chest transmissibility, while Figure 6 shows the means ± one standard deviation for the primary resonance frequencies and peak magnitudes associated with the head transmissibility at both acceleration levels using the rigid seat (labeled R in the figures) and seat cushion (labeled C in the figures). The seat cushion effects are discussed later in the paper. The frequency location of the primary or highest chest and head transmissibility peaks coincided closely with the primary resonance frequency observed in the impedance data for both the humans (peaks occurring between 4 and 6 Hz) and the manikin (peaks occurring between 12 and 15 Hz) at the respective acceleration level. As shown in Figures 4 and 5, the magnitude of the peak chest transmissibility observed for the manikin was significantly higher as compared to the human at the lower acceleration level. Figures 4 and 6 show that the magnitudes of the peak head transmissibilities were more similar between the humans and manikin at the lower acceleration level. As depicted in Figure 4, the first human subject showed a relatively pronounced secondary peak between 12 and 15 Hz in both the chest and head transmissibility frequency response profiles, while the manikin showed a consistent peak at about 8 to 9 Hz. The secondary peaks occurred at frequencies which coincided closely with the secondary resonance peaks observed in the impedance frequency response profiles for these occupants. For the rigid seat, increasing the acceleration level had variable effects on the frequency location and magnitude of the primary resonance peaks for the chest and head transmissibilities. As shown in Figure 5, both the humans and the manikin showed a tendency for a decrease in the primary chest resonance frequency with the increase in acceleration level. The second human showed an increase in the magnitude of the peak chest transmissibility, while the manikin showed a decrease in the peak chest response. The first human showed no significant change in the magnitude of the peak chest response given the variability in the data. Figure 6 shows that both humans showed a slight tendency for a decrease in the head transmissibility resonance frequency while the manikin showed a larger decrease in the head transmissibility resonance frequency with the increase in acceleration level. Both humans showed a significant

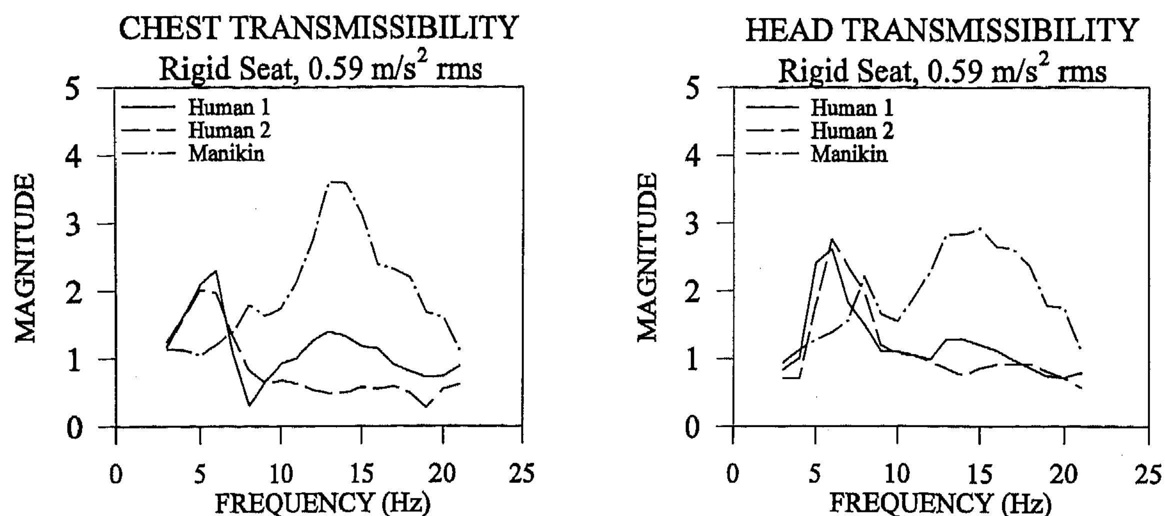

Figure 4 Chest and head transmissibility frequency response profiles using the rigid seat.

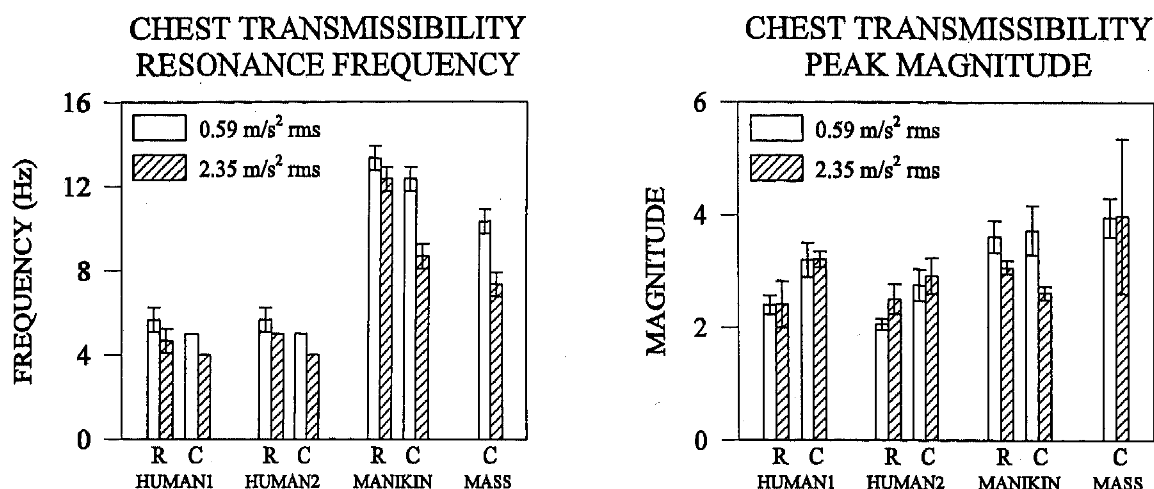

Figure 5 Chest transmissibility resonance frequencies and peak magnitudes (R = Rigid Seat; C = Cushion).

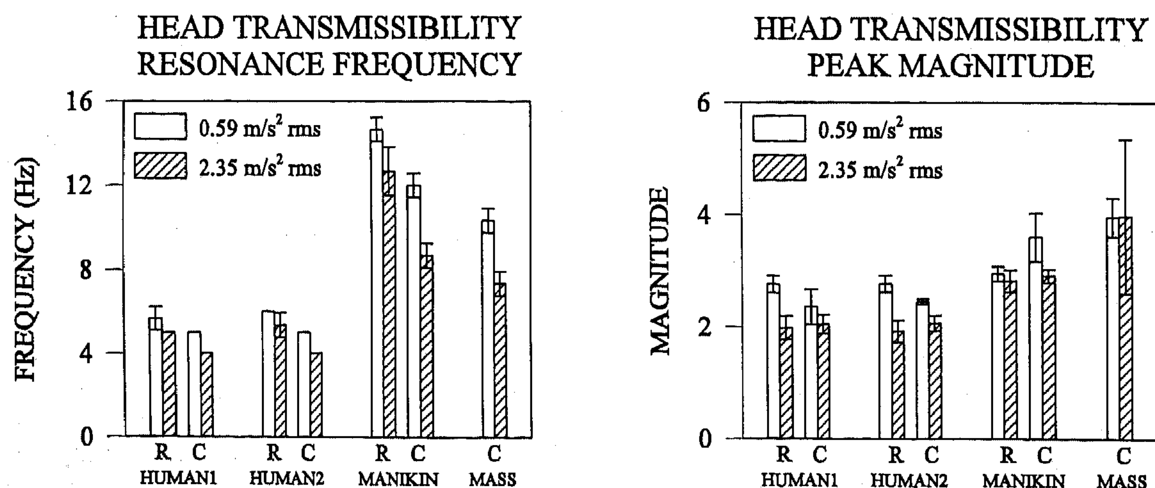

Figure 6 Head transmissibility resonance frequencies and peak magnitudes (R = Rigid Seat; C = Cushion).

decrease in the magnitude of the peak head transmissibility at the higher acceleration level, while the manikin showed similar peak responses at both acceleration levels.

For the rigid seat in general, the peak chest transmissibilities were higher in the manikin as compared to the human at the lower acceleration level, but more similar between the humans and manikin at the higher acceleration level. In contrast, the peak head transmissibilities were similar

between the humans and manikin at the lower acceleration level, but higher in the manikin at the higher acceleration level. The transmissibilities measured at the rigid seat interface were also unity for all occupants, i.e., the interface acceleration was equal to the input acceleration with the use of a rigid seat and no intervening cushion.

Hz). The associated magnitude peaks were also decreased for all occupants at the higher acceleration level with the most pronounced differences occurring for the manikin and rigid body mass. Large variability was observed in the rigid body data at the higher acceleration level. This may have been due, in part, to the relatively high acceleration peaks inherent in the sum-of-sines profiles at the higher level in combination with the cushion effects.

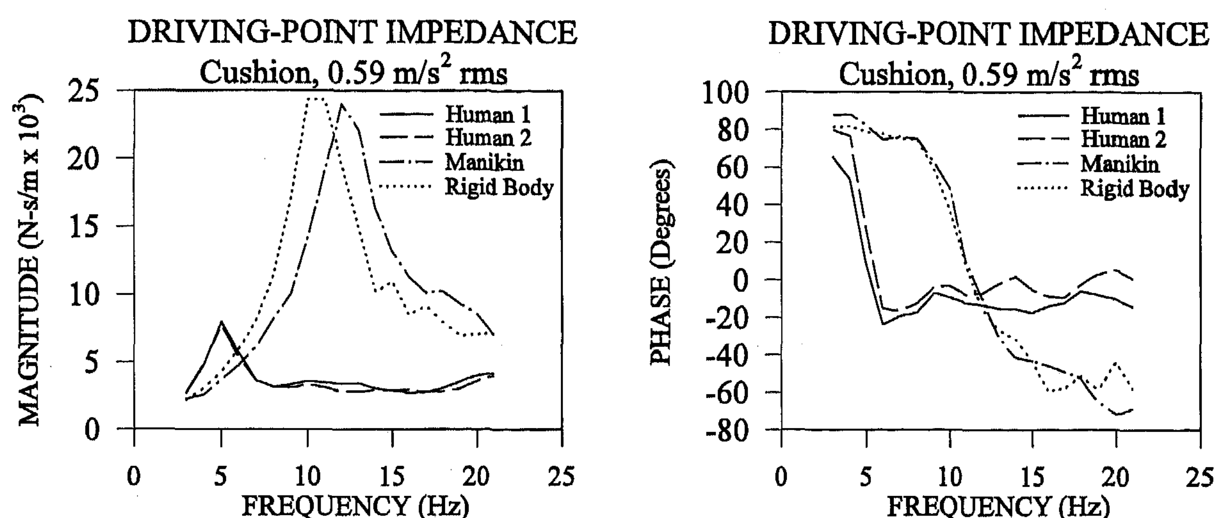

Figure 7 Driving-point impedance magnitude and phase frequency response profiles using the cushion.

SEAT CUSHION EFFECTS - Figure 7 illustrates the mean impedance magnitude frequency response profiles for the humans, manikin, and rigid body mass with the use of the cushion at the lower acceleration level. Figure 3 includes the mean resonance responses of the rigid body mass using the cushion. Figure 7 shows that, with the addition of the cushion located between the rigid body mass and the rigid seat, a prevalent impedance peak is observed at about 10 to 11 Hz at the lower acceleration level. Both the resonance frequency and peak impedance magnitude for the rigid body mass coincided more closely to the manikin data, with both showing a significantly higher resonance frequency and peak magnitude as compared to the human subjects, similar to the results observed using the rigid seat. Any additional resonance peaks appeared to be more attenuated with the use of the cushion for both the humans and manikin. As depicted in Figure 3, the primary impedance resonance frequency was decreased in both the humans and manikin with the addition of the seat cushion (labeled C in the figure) regardless of the acceleration level. The maximum decrease was 3 Hz. The addition of the seat cushion appeared to have a minimal effect on the peak impedance magnitude for the humans regardless of the acceleration level. Given the relatively large variability in the data, the addition of the cushion also had a minimal effect on the peak response of the manikin at the lower acceleration, however, the peak response was significantly reduced with the use of the cushion at the higher acceleration level. The acceleration effects observed with the use of the cushion were similar to the effects occurring for the rigid seat. The peak resonance frequencies were reduced by 1 Hz in the human with larger decreases being observed for the manikin and rigid body mass at the higher acceleration level (up to 4

Figure 8 illustrates the mean magnitudes of the chest and head transmissibility frequency response profiles for the humans and manikin using the cushion at the lower acceleration level. The figure also includes the mean transmissibility frequency response measured for the rigid body mass with the addition of the cushion. Figures 5 and 6 include the mean resonance responses of the rigid body mass with the use of the cushion. Figure 8 shows that the chest and head resonance frequencies and peak transmissibility magnitudes for the manikin were more similar to the responses observed for the rigid body mass. At both acceleration levels, the primary chest resonance frequency tended to decrease for the humans while the associated magnitude peak showed an increase with the use of the cushion as compared to the rigid seat. The manikin also showed a decrease in the resonance frequency with the use of the cushion. The decrease was more pronounced at the higher acceleration level. For the manikin, the peak chest transmissibility did not change significantly with the use of the cushion at the lower acceleration level given the variability in the data. At the higher acceleration level, the peak chest response tended to decrease with the addition of the cushion, in contrast to the results observed for the humans. The primary head resonance frequency showed a tendency to decrease with the use of the cushion for both the humans and manikin at both acceleration levels. The decrease was more pronounced in the manikin. Given the variability in the data, the magnitude of the peak head transmissibility tended to decrease for the humans and increase for the manikin at the lower acceleration level with no significant changes observed at the higher acceleration level with the addition of the cushion. For all occupants, the

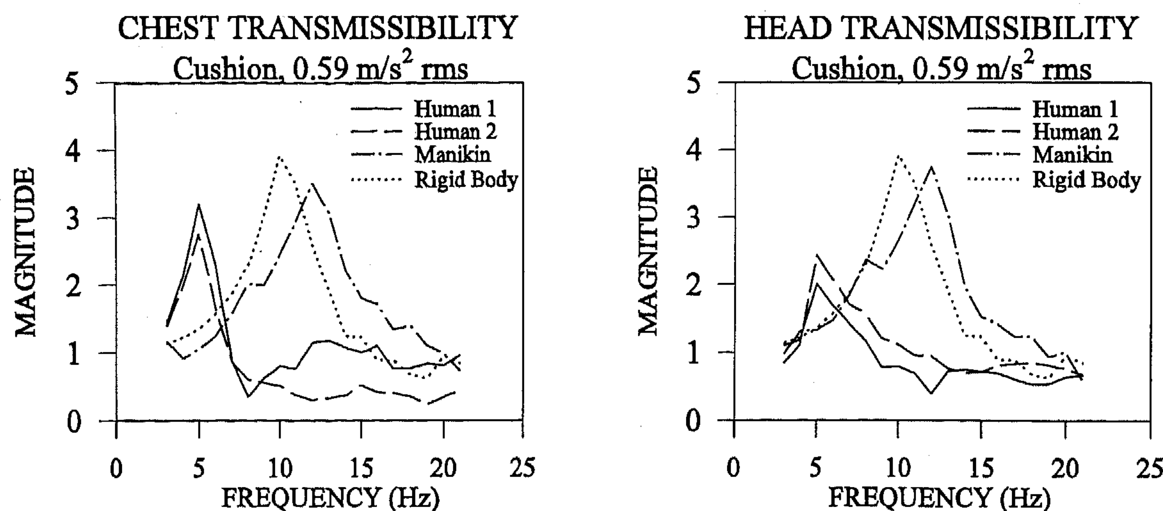

Figure 8 Chest and head transmissibility frequency response profiles using the cushion. Both graphs include the rigid body transmissibility frequency response profiles using the cushion.

effects of acceleration on the chest and head resonance frequencies were similar for the rigid seat and cushion showing a tendency to decrease at the higher level. The effects of the acceleration level on the magnitude of the peak chest transmissibility were minimal for both the rigid seat and cushion for the first human. The second human showed no significant effect of acceleration with the use of the cushion as compared to the tendency observed for the rigid seat. The manikin showed a more pronounced decrease in both the chest resonance frequency (up to 4 Hz) and peak magnitude response at the higher acceleration level with the use of the cushion as compared to the rigid seat. For the humans, the tendency for a decrease in the magnitude of the peak head response at the higher acceleration level was less pronounced using the cushion as compared to the results for the rigid seat. In contrast, the peak head magnitude response appeared to decrease in the manikin with the use of the cushion at the higher acceleration level as compared to the minimal effects observed for the rigid seat. The effects of acceleration on the magnitude of the peak head transmissibility were less pronounced in the humans as compared to the manikin with the use of the cushion as compared to the rigid seat. The peak resonance frequency was also decreased for the rigid body mass at the higher acceleration level. However, the magnitude of the peak responses were similar at both acceleration levels given the large variability in the data collected at the higher acceleration level. In general, the manikin resonance frequencies remained significantly higher than the humans with the use of the cushion. However, the peak chest transmissibilities were more similar between the humans and manikin, while the peak head transmissibilities showed higher responses in the manikin at both acceleration levels with the use of the cushion. The contrasting effects can be observed by comparing Figures 4 and 8 for the lower acceleration level.

For the transmissibility measured at the interface between the occupant and cushion, all occupants showed resonance frequencies which coincided closely with the resonance frequencies observed in the other measured responses. The peak magnitude responses at the interface for the humans and manikin were less than 2.0. The second human did show a slight increase at the higher acceleration level. As with the majority of responses, the manikin and rigid body mass showed a higher transmissibility peak at the interface as compared to the humans. For the manikin and the rigid body mass, the acceleration level did not appear to have a significant influence on the response. The rigid body mass did show a lower transmissibility at the interface than at the top of the mass. The placement of the metal shot bags on the cushion and the location of the accelerometer on top of the mass may have caused some off-axis motion in the mass.

DISCUSSION

HUMAN RESONANCE BEHAVIOR USING MANIKINS AND RIGID BODY MASSES - The results of this study showed that the whole-body vibration response characteristics of the human were different as compared to the response characteristics of the Hybrid III aerospace manikin and rigid body mass representation. The differences were specifically reflected in the dramatically higher resonance frequencies observed in the driving-point impedance and transmissibilities for the manikin as well as the rigid body mass regardless of the seating configuration (rigid seat vs cushion). Both the manikin and rigid body mass produced significantly higher impedance magnitude peaks as compared to the humans regardless of the seating configuration. Although the two human subjects were specifically selected to avoid response differences occurring due to body weight, the results strongly suggest that the distribution of the mass, stiffness, and damping characteristics are different between these humans and the manikin. In a recent study [7], in which the vibration response characteristics of a wide range of female and male subjects were compared, including the two males used in this study, the same conclusion was drawn about the distribution of structural properties. However, the differences between

the humans were primarily observed in the magnitudes of the peak responses and not on the location of the resonance frequencies. A comparison of these data shows that, in general, the manikin tested in this study produces significantly higher primary resonance frequencies as compared to humans, regardless of any structural differences occurring among the humans. Of particular concern for predicting cushion effects were the contrasting trends observed in the peak impedance and peak chest and head transmissibilities between the humans and manikin with the addition of the seat cushion.

There does appear to be some similarity between the primary resonance behavior observed in the manikin and the secondary resonance observed in the humans at higher frequencies. In the human, the primary impedance resonance peak occurring between 4 and 8 Hz has been considered to be strongly influenced by the dynamic behavior of the upper torso, including the shoulders and the soft tissues contained within the chest cavity [9]. The coincidence of the peak chest transmissibility and peak impedance in the frequency range of 4 to 8 Hz further supports this influence [7, 10]. In addition, these observations indicate that the resonance behavior observed for the head at the low frequencies was strongly influenced by the motions of the upper torso. The contrasting effects of the acceleration level and cushion between the head and chest peak responses requires further investigation of coupling effects in the human body. The majority of subjects tested in this laboratory have also shown a prominent transmissibility peak at C_7 at higher frequencies between 12 and 18 Hz [7]. These findings have strongly indicated that the spinal column structures may be a major contributor to the additional impedance resonance peak which has been observed at higher frequencies between 12 and 19 Hz [7, 10, 11]. The additional peak located at about 13 Hz for the first human coincided with the peak transmissibility measured at the seventh cervical vertebra (C_7) in this subject. A peak was also observed at C_7 for the second human used in this study but was lower as compared to the first human [7]. The second human did not show an identifiable impedance peak at the higher frequencies. While measurements were not made in the spinal column of the manikin, it appeared that the resonance frequency observed in the impedance and chest transmissibility frequency responses for the manikin coincided more closely with the spinal column resonance observed at the higher frequencies in the human. The magnitude of the peak chest transmissibility in the manikin did fall within the wide range of the peak spine (C_7) transmissibility magnitudes observed for humans and coincided closely with the magnitude peak observed at C_7 for the first human. The similarity between the resonance behavior of the human spine and the primary impedance and chest resonances observed in the manikin becomes even more apparent when considering the effects of the seat cushion on vibration response. The majority of current seat cushion designs have been shown to increase the transmission of vertical vibration to the human in the vicinity of the primary resonance (4 to 8 Hz) as demonstrated in this study and in previous studies [7, 10, 12, 13, 14]. In contrast, these cushions tended to attenuate the vibration at higher frequencies as shown in the tendency for a decrease in the peak spine (C_7) transmissibility occurring at higher frequencies for humans [7, 10]. Interestingly, the results of this study showed that the addition of the cushion decreased both the primary impedance and chest transmissibility peaks in the manikin, similar to the tendencies observed in the human spine transmissibility at higher frequencies.

Current biodynamic manikins are primarily designed for simulating the effects of short duration, high accelerative loading of the human body. These designs do not consider the low frequency, low amplitude human body sensitivity observed during vibration exposure. The manikin used in this study did appear to show the attenuating effects of cushions at higher frequencies which coincide with human spinal motion, however, the ability to simulate the resonance response of humans in the region of greatest sensitivity (4 to 8 Hz) is critical for developing improved seating systems.

PREDICTING HUMAN RESONANCE BEHAVIOR USING MATHEMATICAL MODELS - Lumped-parameter mathematical models have been used to predict the primary resonance behavior of the human body occurring between 4 and 8 Hz. These models use mass, spring, and damper elements to represent the dynamic response of 'lumped' anatomical structures or regions. A five degree-of-freedom (DOF) model was developed to simulate the multiple regions of resonance identified in the driving-point impedance response [11]. The model elements were selected to represent the dynamic responses of the upper torso (chest), spine, legs, and lower torso. The current model does not include the model elements for the head. The five DOF model was found to be effective in simulating human impedance response. Based on transmissibility data collected at specific anatomical sites, the model was also found to be quite effective in predicting the general resonance behaviors of the anatomical structures represented in the model [10]. The model was expanded to include seat cushion stiffness and damping properties estimated from rigid body mass tests. On comparing the predictions for two military cushions tested in this laboratory, the model was found to be effective in simulating the relative increases in the impedance and chest transmissibility peaks occurring at low frequencies (4 to 8 Hz), and the relative decreases in the impedance and spine transmissibility peaks occurring at higher frequencies (12 - 19 Hz) with the addition of the cushions [10]. A simplified three degree-of-freedom model, which lumped the torso and spine structures, was also shown to predict the relative effects of the seat cushions, but only in the low frequency region [10]. It appears that human models which are capable of predicting the low frequency response effects would be more appropriate as compared to manikins for evaluating the effects of seat cushions on humans, particularly if human testing is not feasible. The cushion stiffness and damping properties required by the model could be estimated from rigid body testing of the cushion or from known cushion material properties. Caution should be taken in using these models since differences in

vibration response have been observed between females and males of varying sizes [7]. It is important to consider the ability of a model to predict these differences. Specifically, the five DOF model developed in this laboratory requires further modifications and validation of its predictive capabilities before being used as a tool for optimizing seat cushion designs for a variety of occupants.

Recently there is demand for rotation sensors capable of high-accuracy detection and very low-speed detection of rotation at high temperature for automobile use. To meet this requirement, a rotation sensor using an InSb thin-film magneto-resistors with good thermal stability has been developed.

This sensor transduces magnetic flux change due to gear rotation to resistance change. It is composed of InSb thin-film magneto-resistors fabricated by a newly developed process and signal shaping circuits where resistor signals are converted to digital signals using no amplifier. Accordingly, the signals are independent of the measured frequencies, making possible very low speed (0 to 20 Hz) detection. The sensor stably operates in the temperature range from -40 to 150 degree C for thousands hours. There is no need for a shielded harness due to the digital output signal. It can be used for high temperature environments like in the engine compartments for rotation detection of ignition systems, electronically controlled AT systems, antiskid braking systems, etc.

INTRODUCTION

Trends, such as regulations for automobiles, like CAFE, OBD II, and LEV, along with energy and safety consciousness, and the need high-accuracy in navigation systems, etc., have increased demand for improved rotation sensors. These sensors need the following characteristics: (1) capability of very-low-speed detection at 0 - 20 Hz and (2) capability of high-accuracy detection at high temperature. In order to meet these requirements, we have been studying the "semiconductor magneto-resistor" that enables high-sensitivity sensor output and thus greatly-reduced peripheral circuits.

This semiconductor magneto-resistor (=semiconductor MR) was already reported in 1950's[1], especially in the period when the deposition process of InSb thin-film, as III-V family semiconductor thin-film, first became the subject of research[2]. The semiconductor MR, whose magnetic sensitivity is in proportion to electron mobility of semiconductor, limits its material to InSb and InAs. Therefore, it is an important point regarding how the crystalline semiconductor thin-film material is formed. Traditionally, slices of a bulk single-crystal wafer or those formed by the growth of the high-quality InSb thin-film on Mica substrate are transferred onto another substrate [3]. In either construction, because of the use of an adhesive layer, the problems, mainly caused by the difference in expansion coefficients, made it inadequate for the high-temperature specifications as in the electronic package applications. Therefore, we have developed the InSb thin-film MR based on the following basic technologies:

(1) The technology for the growth of InSb thin-films with excellent crystallinity directly on the Si substrate.

(2) The electrode material & process technology for ensuring reliable connections over a wide range of temperature.

(3) The heatproof packaging technology.

These technologies as well as the characteristics of a complete rotation sensor for automotive use are described below.

INSB THIN-FILM MAGNETO-RESISTORS

The basic structure of InSb thin-film magneto-resistors is shown in Fig. 1. It is basically constructed, after the growth of InSb thin-film on the substrate, by depositing a number of ladder-structure electrodes called, "shorting bar electrodes". In this construction, whose principle of operation is shown in Fig.2 (a), a phenomenon is used that the current path is elongated by the Lorentz

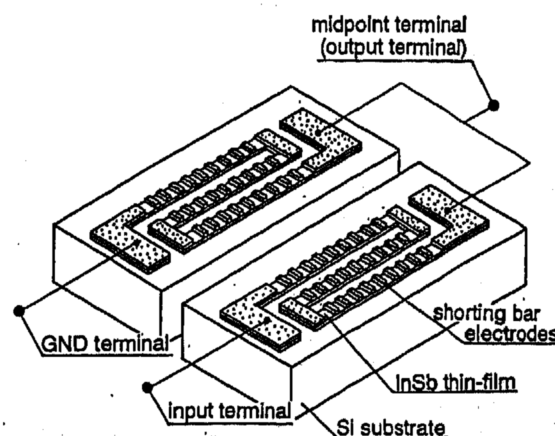

Fig.1 Basic structure of InSb thin-film magneto-resistors

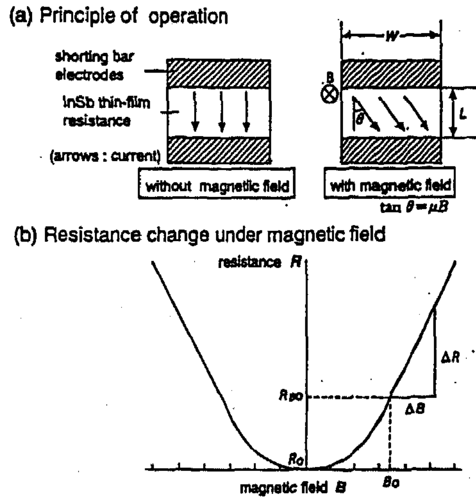

Fig.2 Principle and basic characteristics of InSb thin-film magneto-resistors
(a) Principle of operation
(b) Resistance change under magnetic field

force applied to the carrier when the magnetic field is applied in the transverse direction relative to the film surface of the InSb thin-film between the shorting bar electrodes. Here, as shown in Fig. 2 (b), the resistance change against the magnetic field differs between the low magnetic field region and the high magnetic field region. With adequate accuracy it can be expressed by the following equations:

(low-magnetic-field characteristics)

$$R_B / R_0 = \frac{\rho_B}{\rho_0}(1+g(\mu B)^2) \qquad (1)$$

(high-magnetic-field characteristics)

$$R_B / R_0 = \frac{\rho_B}{\rho_0}(G+\frac{W}{L}\mu B) \qquad (2)$$

where, R_B: resistance with magnetic field, R_0: resistance without magnetic field, μ: electron mobility of the semiconductor, B: applied magnetic field, g and G: functions of element's shape (L/W) respectively, L: element length, W: element width, ρ_B / ρ_0: magneto resistive effect (nearly equal to 1).

Generally, the change over point from square-law characteristics to linear characteristics is given by the following empirical equation:

$$\mu B = 0.65 \quad \text{(SI units)} \qquad (3)$$

As is obvious in Fig. 2 (b), the resistance change of this element is greater in the high-magnetic-field region, and accordingly it is necessary, in practical use, to set the point of operation in the linear (high field) region by placing a magnet on the backside of the element.

Furthermore, as is obvious in Equation 2, in this semiconductor magneto-resistor, the magnetic sensitivity or the magnitude of resistance change is in proportion to the element's shape (*W/L* ratio) and the electron mobility of semiconductor used. Since the magnitude of electron mobility, in particular, is a key factor of the element's characteristics, InSb, which has the highest value of μ among semiconductors, is used. In addition, as regards the merits of thin-films, the following points are indicated: (1) capability of high impedance, (2) improvement in heat resistance ,and (3) great reduction in the material (wafer) cost.

We have developed the technology for the growth of InSb thin-film with excellent crystallinity and thus realized the InSb thin-film magneto-resistors with high sensitivity and high heat resistance. The fabrication process is described below.

FABRICATION PROCESS OF INSB THIN-FILM MAGNETO-RESISTORS - The fabrication process of InSb thin-film magneto-resistors is shown in Fig. 3. As for the fabrication technology for the InSb thin-film with high electron mobility or excellent crystallinity, studies have been reported by several groups. Studies about heteroepitaxy on the InSb on GaAs substrate are the most popular, and as for growth technology, MBE [4,5], MOCVD [6,7], and sputtering [8] have been reported. In addition, examples of growth on CdTe [9] and sapphire [10] have also been reported. As a fabrication technology of InSb thin-film in practice, the method that, after the deposition on the Mica substrate, transfers it onto another substrate via an adhesive layer is being used in manufacturing hall elements [11]. Among them, taking into account the substrate cost, heat resistance, and the priority of proper orientation of the surface of the InSb thin-film, we have decided to use the Si(111) substrate.

Prior to the growth of the InSb thin-film, the surface washing treatment of Si substrate is an important point. Traditionally, in heteroepitaxy of InSb thin-film on Si substrate, a method that obtains an atomically clean surface by heating the substrate at high temperature above 900°C in a vacuum chamber and sublimating SiO existing on the surface is used [12]. In this method, the high-temperature and the ultra-high vacuum that are required, results in poor mass-productivity. Since the optimum temperature in the growth of the InSb thin-film is relatively low (430°C), we adopted the hydrogen termination treatment where the Si surface structure can be maintained sufficiently stable up to this temperature.

In the fabrication process, we use the 4-inch Si(111) substrate (resistivity ≧ 1 kΩ·cm). After treatment of the substrate surface by RCA washing, it is immersed in dilute HF solution. The hydrogen termination treatment is applied removing the oxidized layer on the substrate surface and terminating the unoccupied valence on the Si surface with hydrogen atom. After that, the substrate is rinsed with ultra pure water and introduced into the vacuum chamber.

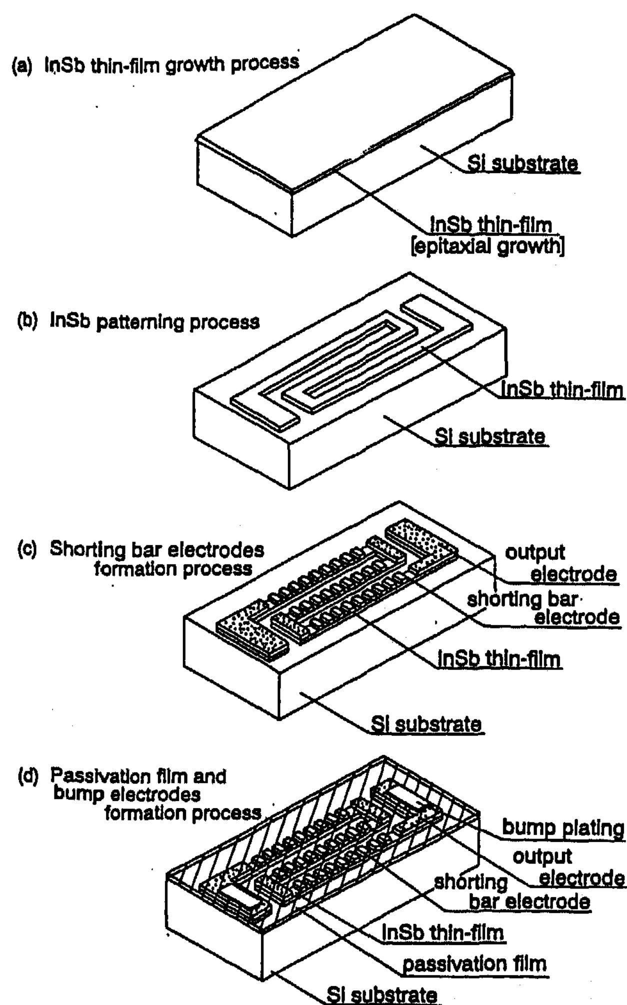

Fig.3 Fabrication process of InSb thin-film magneto-resistor

Then, the growth process of the InSb thin-film starts. In this process, since the lattice mismatch between InSb and Si is as great as about 19%, a simple one-step growth technology will result in a polycrystalline thin-film, the two-step growth technology is adopted where in (1) after the preliminary growth layer is deposited at low temperature, (2) the main layer is grown at normal growth temperature. In addition, in this growth technology, the vacuum evaporation method (three temperature method) is used where In and Sb are separately evaporated by

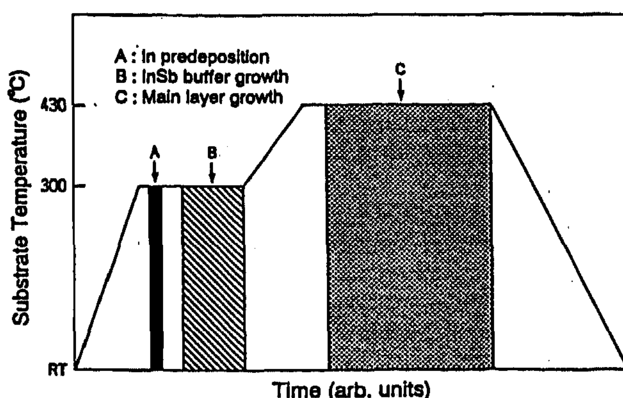

Fig.4 Typical substrate temperature profile for growth of InSb film on Si(111)

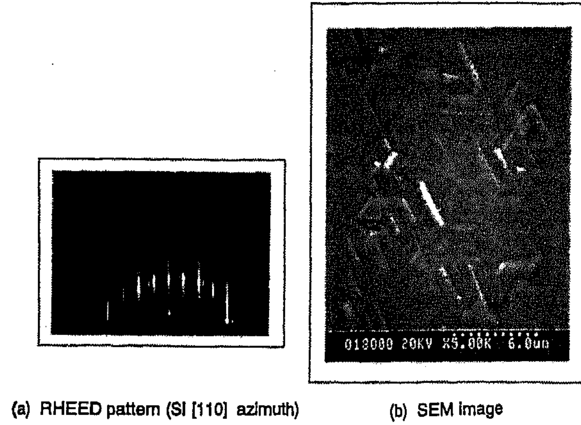
resistance heating. At the first stage of study, the typical substrate temperature profile for growth was a simple two-temperature type with low temperature and high temperature, as shown in Fig. 4.

<u>(1) Deposition of the preliminary growth layer</u> - The hydrogen-terminated Si(111) substrate described above is introduced into the vacuum chamber and, after lowering the vacuum pressure below 5×10^{-5} Pa, the substrate temperature is raised to 300℃. Then, as shown in Fig. 4 A, about 0.5 nm thick of In film is predeposited under the pressure of less than 1×10^{-4} Pa at the deposition rate of about 0.1 nm/s. Here, if the substrate temperature is too low, judging from the observation of the surface morphology of the InSb thin-film after the following main growth, a discontinuous mass crystal will be formed. Therefore, it is necessary to maintain the appropriate temperature. If the predeposited In film is too thin, it will not play a sufficient role as the core formation material, and if it is too thick, flocculation will be caused. Therefore, it is necessary to control the appropriate thickness.

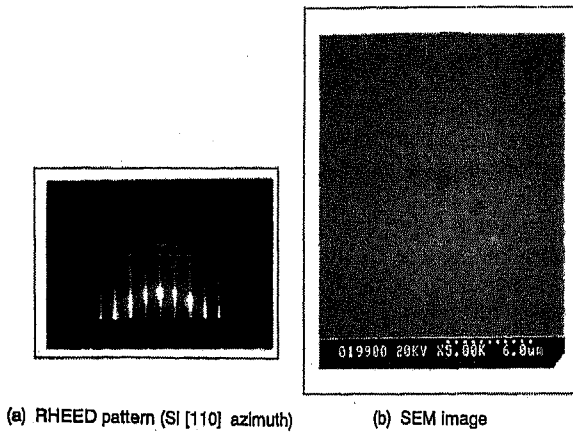
After pre deposition of In, maintaining the substrate temperature at 300℃, In and Sb are co-evaporated as shown in Fig. 4 B. Here, with the atomic ratio Sb/In = 3 and the In deposition rate of approximately 0.1 nm/s, the approximately 25 nm-thick InSb thin-film is deposited. The change of reflection high-energy electron diffraction (RHEED) pattern of a series of low-temperature preliminary growth layers from the early stage of growth is as follows:



As In is fed from the early stage of growth, the pattern intensity of the substrate Si(111) gradually decreases and, on the coevaporation of In and Sb, the intensity of Si(111) rapidly decreases and finally disappears. On the other hand, InSb(111) gradually emerges and finally the complete orientation pattern of InSb(111) is observed.

Here, the epitaxial growth of InSb(111)//Si(111), InSb<110>//Si<110> is confirmed. After that, as shown in Fig.4 B → C, the substrate temperature is elevated to 430℃ for the main growth.

<u>(2) Deposition of the main growth layer</u> - After maintaining the substrate temperature at 430℃, as shown in Fig. 4 C, an approximately 3 μm-thick InSb thin-film is deposited with the atomic ratio Sb/In = approximately 2.5 and the In deposition rate of approximately 0.3 nm/s (the InSb growth rate 0.75 nm/s).



The RHEED pattern and SEM image after completion of the main growth are shown in Fig. 5 (a)(b). Fig 5 clearly shows that, in the film after the two-step growth with the two-temperature profile with low temperature and high temperature as shown in Fig. 4, although strong and clear streaks are observed, the boundary exists between the domains of epitaxial growth. That is, although the epitaxial growth is achieved satisfying InSb(111)//Si(111), InSb<110>//Si(110), domains with two direction exist: one is the exactly same direction as Si and the other is the direction rotated by 180deg around the Si(111) plane. In measurement of electron mobility (μ) of the film in this state using the van

der Pauw technique, μ was found to be $\mu = 3.63\mathrm{m}^2/\mathrm{V \cdot s}$, which is not fully satisfactory.

(a) RHEED pattern (Si [110] azimuth) (b) SEM image

Fig.5 Structure of InSb film after typical growth process

(a) RHEED pattern (Si [110] azimuth) (b) SEM image

Fig.6 Structure of InSb film after optimized growth process

In this regard, we particularly focused on the temperature profile during the predeposition to clarify the relation between this profile and the crystallinity of the growing film and thereby optimized the conditions of the main growth. Thus, as shown in Fig.6 (a) (RHEED pattern) and (b) (SEM image), we realized the epitaxial growth of InSb thin-film on the Si substrate where clear streaks of InSb(111) with Kikuchi lines are observed and the domain boundary shown in Fig. 5 disappears to form the nearly single domain with excellent surface smoothness.

For the completed InSb thin-film, μ was measured and the value nearly equal to the theoretical value[13] was obtained (maximum value $\mu = 5.99\mathrm{m}^2/\mathrm{V \cdot s}$). In addition, this growth process of the InSb thin-film is well reproducible and enables the consistent fabrication of thin-films with excellent crystallinity and high electron mobility.

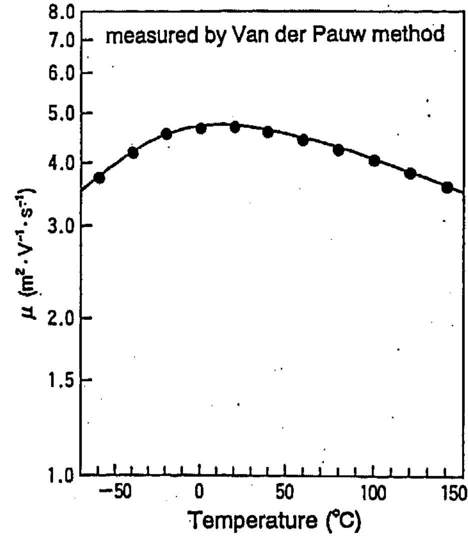


Fig.7 Temperature dependence of mobility of typical InSb thin-film

Fig. 7 shows an example of the temperature dependence of electron mobility of typical InSb thin-films (thickness: 3 μm) fabricated by this process. Electron mobility has its maximum value near room temperature and decreases in both high temperature and low temperature regions. The temperature dependence of electron mobility, with carrier concentration at room temperature of approximately $1\times10^{22}\mathrm{m}^{-3}$, is shown by the following theoretical equations[14,15], where electron mobility under scattering by ionized impurity is μ_I, electron mobility under scattering by lattice is μ_L, electron mobility under scattering by dislocation is μ_D, resultant electron mobility under these scattering mechanisms is μ_H, electron mobility considering surface scattering on the thin-film is μ_{TH}:

$$\mu_I = 1.10T^{0.73} \qquad (4)$$

$$\mu_L = 1.09\times105T^{-1.68} \qquad (5)$$

$$\mu_D = 8.165\times10^{11}\frac{T}{N_D} \qquad (6)$$

$$\mu_H = \left(\frac{1}{\mu_I}+\frac{1}{\mu_L}+\frac{1}{\mu_D}\right)^{-1} \qquad (7)$$

$$\mu_{TH} = \frac{\mu_H}{1+\dfrac{2.06\times10^{-3}\cdot\mu_H T^{0.5}}{d}} \qquad (8)$$

N_D: dislocation density, d: thickness of the InSb thin-film.

Based on Equations 4-8, the theoretical values of the temperature dependence of electron mobility are obtained and, by comparison between the theoretical values and our measurement values, the dislocation

density is considered to be approximately $10^{13}m^{-2}$. This is because dislocations generated by interfacial mismatch with the Si substrate still remain in the growing thin-film. In addition, it is found that scattering by dislocations in the low-temperature region and scattering by the lattice in the high-temperature region are dominant factors of electron mobility respectively. The differences in electron mobility due to thin-film quality is great mainly in the low-temperature region, and the better quality of thin-film results in smaller decreases in the low-temperature region. In the high-temperature region, since scattering by the lattice is dominant and nearly uniform, the differences are not very great.

After completion of growth of the InSb thin-film, through the photo lithograph process shown in Fig. 3 (b), the InSb thin-film is processed in the longitudinal direction of the element by the wet process, then the formation process of shorting bar electrodes with the ladder-structure shown in Fig. 3 (c) starts. After the uniform coating of electrode material, the desired ladder shape of electrodes is obtained by the photo lithograph process. In this process, since a number of ladder-structure electrodes are formed on the InSb thin-film, the important points are as follows:

(1) to minimize contact resistance between the electrodes and the InSb thin-film,

(2) to minimize stress by the electrode material on the InSb thin-film, and

(3) to prevent erosion of InSb thin-film in processing the electrodes (wet process).

We formed the ohmic contact with low contact resistance on the InSb thin-film and, from the viewpoint of chemical selectivity (on InSb) during the wet process, adopted the Cu/Cr laminated electrode. As for the above-mentioned point (1), in addition to HCl solution treatment used in the removal treatment of the InSb oxidized layer prior to the electrode formation, $(NH_4)_2S_x$ (ammonium polysulfide) treatment was introduced to keep the surface of the InSb thin-film in an unoxidized condition and to realize low contact resistance and, as for (2), for the evaporation formation, total stress was reduced mainly by the electrode thickness control and, as for (3), the process was stabilized by an appropriate selection of treatment solution.

After the formation of shorting bar electrodes, as shown in Fig. 3 (d), a passivation film electrodes was formed over the electrodes. For the passivation film, low-expansion polyimide ($\alpha: 5\times10^{-6}$ /deg) was used.By using the low-expansion material, as previously described, we minimized the stress on the InSb thin-film and suppressed the change of the forbidden band width shown in the following equation. In particular, expansion coefficient of the upper layer material is great to increase the forbidden band width when tensile stress is applied and to increase effective mass of electron and to deteriorate the magnetic characteristics of the element.

$$\frac{dE_g}{dP} = 1.58\times10^{-10}\,eV\cdot m^2\,/\,N$$

(Left side: change of forbidden band width per unit stress, stress dependence: tensile (+), compressive (-))

Stress applied to the InSb thin-film in burning this polyimide is at most approximately (tensile stress) and, in the wide range of temperature, has no adverse effect on the element's characteristics. After spin coating of this polyimide material, plating windows are made through the conventional photo lithograph process and it is burnt in vacuum. By the polyimide passivation film thus formed, under specifications for electronic packaging reliability, sufficient reliability is assured. Then, by electrolytic plating, Au/Ni is plated to complete the element.

Fig. 8 shows the characteristics of resistance change with magnetic field of the completed element (μ:4.5m^2 /V·s, room temperature value). Under 0.4 T, the resistance is three times as high as the resistance without a magnetic field.

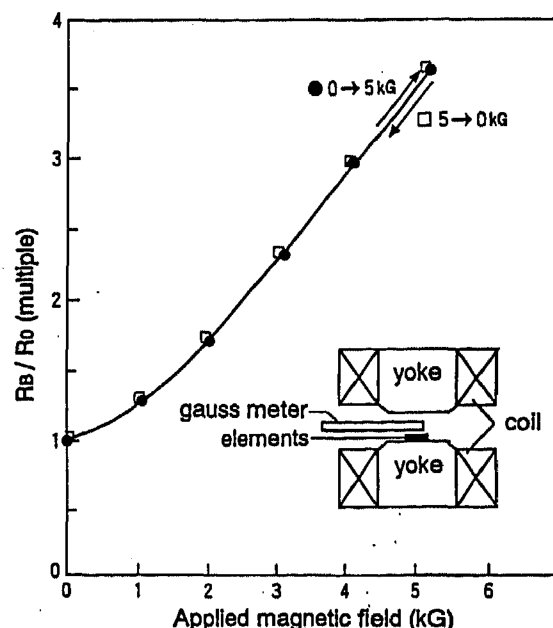

Fig.8 Characteristics of resistance change under magnetic field of InSb thin-film magneto-resistors

Fig. 9 shows the relation between the output voltage and the air gap (between the detection gear and the element surface) at room temperature in the differential element. A differential wheatstone bridge configuration is used to compensate for the large temperature dependence of the InSb element's impedance characteristic. It is understood that output voltage of SMR is sufficiently high under the usual condition (air gap is about 1.5mm).

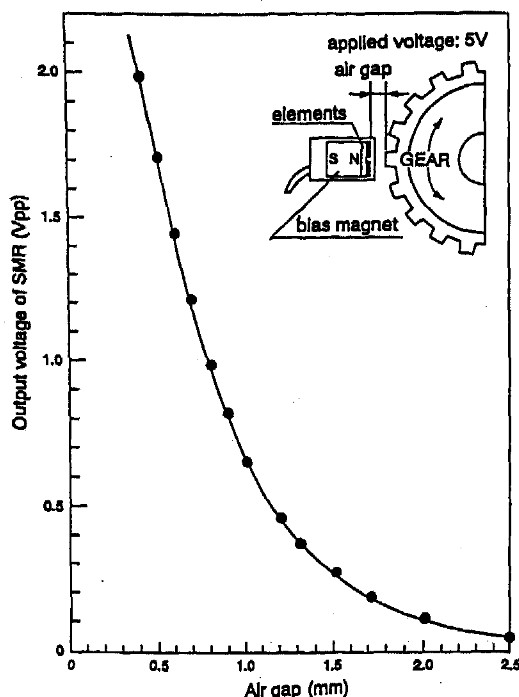

Fig.9 Characteristics of output voltage vs. air gap (at 5V applied)

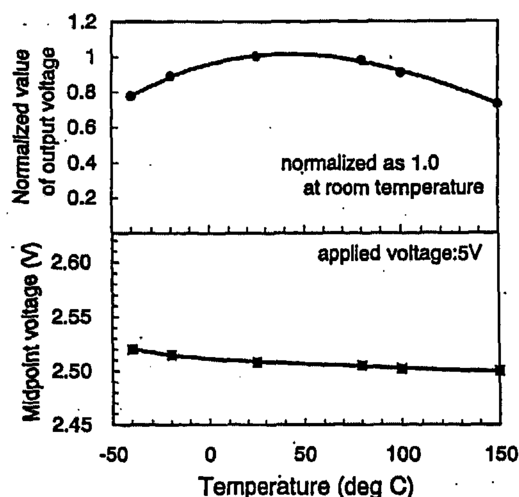

Fig.10 Characteristics of dependence of output voltage (normalized at 1 at 25 degree C value) on temperature

In addition, Fig. 10 shows the typical characteristics of temperature dependence of output voltage (normalized at room temperature value) and midpoint voltage in the differential element. Output voltage has a similar temperature dependence to that of electron mobility and has its maximum value near room temperature. It also tends to decrease in both the low-temperature and high-temperature regions. Midpoint voltage tends to slightly diverge in the low-temperature region and converge in the high-temperature region. This is caused by heterogeneity of the element including differences in the thin-film quality between the two elements. This needs to be further reduced in the future.

HEAT-PROOF PACKAGING TECHNOLOGY - When the InSb thin-film magneto-resistors are used as a rotation sensor for automobiles, the packaging technology is important factor.

The construction of inner lead bonding parts is shown in Fig. 11. In packaging, important points are as follows:

(1) to assure the stable connection in the temperature range of -40 ~150℃ as required for automotive use, and

(2) to reduce the package thickness (including mold) of the upper surface of the element (in order to allow the distance between the element and the detection gear to be as small as possible).

Usually, in sensor elements for automobile use, wire-bonding→transfer products such as hole IC are popularly used. However, we require the upper surface package thickness to be less than 200 μm as described in (2) and transfer products do not necessarily satisfy this requirement. In this regard, we adopted the TAB packaging that enables a thinner package.

As shown in Fig.11, since the InSb thin-film magneto-resistors form the detection part with two-chip differential type, two device holes are made to keep the two chips at a certain distance (to fit the detection gear pitch) and, as for the ILB (Inner Lead Bonding) connection, a Au-Sn eutectic is formed between Sn plating on the Cu foil lead of TAB and Au electrodes on the element connection parts. After that, a resin coating is applied in order to protect the element surface and the ILB parts. This completes the detection element.

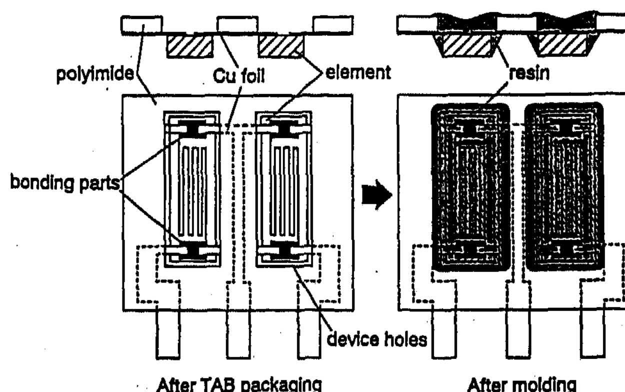

Fig.11 Construction of inner lead bonding parts to InSb thin-film MR

Since TAB packaging has not been applied to automotive area so far, durability verification was needed. In order to assure the stability of the connections, as previously described in (1), the design assurance of the structure particularly in terms of its consistency was an important point. Regarding the design assurance, we performed theoretical analyses in terms of thermal factor (thermal stress), vibration factor (resonance resistance), and connection factor (lead disconnection). Fig. 12 shows the evaluation models for analyzing thermal stress. In this figure, (a) is the face structure model of TAB and (b) is the cross-sectional structure model. Using this

model, the stress distribution was obtained. According to the analytical results, the maximum stress occurs on the Cu foil in the OLB (Outer Lead Bonding) parts indicated with the dotted line in this figure, but breakage will not occur because it is below the breaking strength at the use temperature limit of 150°C. At this point, in terms of equivalent safety ratio at 150°C, as shown in Table 1, a safety ratio greater than 1.5 will be assured by the forming height more than 0.1 mm. As for the vibration factor, a resonance frequency more than 20 kHz shall be assured in design and, as for the connection factor, the connection conditions shall be defined to avoid breakage of the lead. Thus, the suitability of the design was theoretically evaluated and it was found that it is sufficiently reliable in specifications for automobile use. This was confirmed by reliability tests.

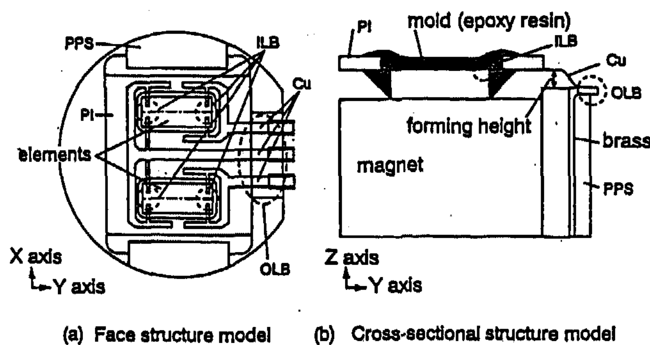

Fig.12 Model for analyzing thermal stress to TAB structure

Table 1 Safety ratio thermal stress analysis for TAB structure

forming height (mm)	safety ratio by thermal stress analysis	
(a) TAB face structure model		
	X-axis direction	Y-axis direction

ROTATION SENSOR WITH INSB THIN-FILM MAGNETO-RESISTORS

CONSTRUCTION OF ROTATION SENSOR - The construction of rotation sensor with the above-mentioned InSb thin-film MR as the detection part is shown in Fig. 13.

The InSb thin-film magneto-resistors are placed on the Sm-Co bias magnet. The peripheral circuit parts are constructed on the flexible printed circuit (FPC), and the OLB connection is made by welding at the junction terminal connecting the element and the peripheral circuit. After that, by ultrasonic bonding, the resin cap is integrated with the functional parts to complete the sensor

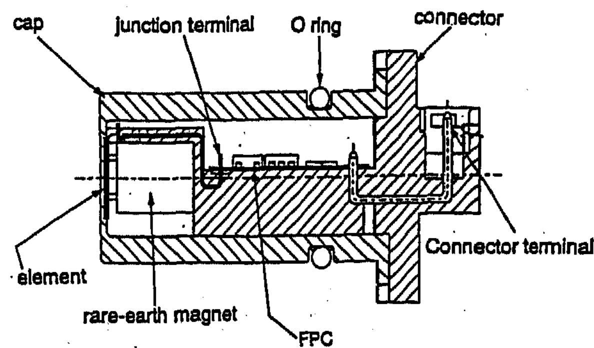

Fig.13 Construction of rotation sensor with InSb thin-film MR

unit. In this rotation sensor, construction of the peripheral driving circuit is shown in Fig. 14. Since output sensitivity of the InSb thin-film MR is high, the waveform shaping circuit (for converting into a rectangular wave) is constructed without an amplifier, using a simple circuit consisting only of a single comparator. For this peripheral circuit, each component is chosen to sufficiently meet the required heat resistance, pressure resistance, etc.

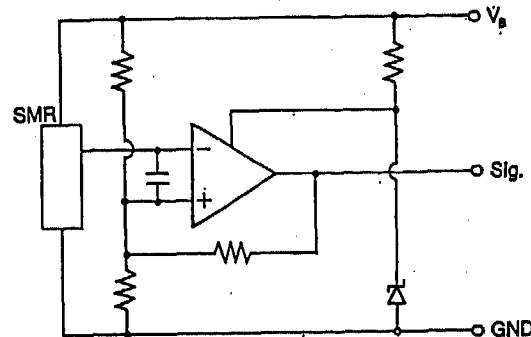

Fig.14 Construction of peripheral driving circuit

Since an amplifier is not used, the following important points must be considered.

(1) to optimize the magnetic circuit part,

(2) to reduce the gap between the element surface and the unit surface within the sensor unit,

and in order to assure reliability such as heat resistance,

(3) to assure structural reliability.

As for (1), optimization of the pitch between the two elements and the shape of magnet and clarification of optimum operating magnetic field of the element (resistance change per unit magnetic flux is greatest in the range of 0.3~0.4 T) were performed to increase the difference in resistance between the two parts of the differential element as much as possible. As for (2) and (3), as previously described about TAB, it was designed to assure theoretically sufficient reliability.

ROTATION SENSOR CHRACTERISTICS - Fig. 15 shows the output signal of the InSb thin-film MR and the sensor output signal after signal shaping at

temperatures of -40, 25, and 150°C. In addition, Fig. 16 shows the resistance change of the element after the heat cycle test between -40°C and 150°C under 5V drive. Then Fig. 17 shows the resistance change of the element after the high-temperature voltage bias test at 150°C, 5V. The InSb thin-film magneto-resistors have sufficient temperature stability (and achieve stable operation) for use as a rotation sensor.

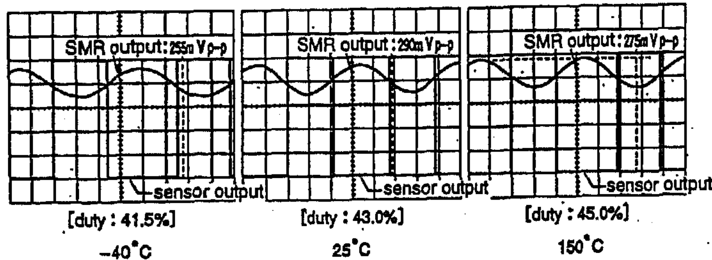

Fig.15 Output signal of InSb MR and sensor output signal after signal shaping

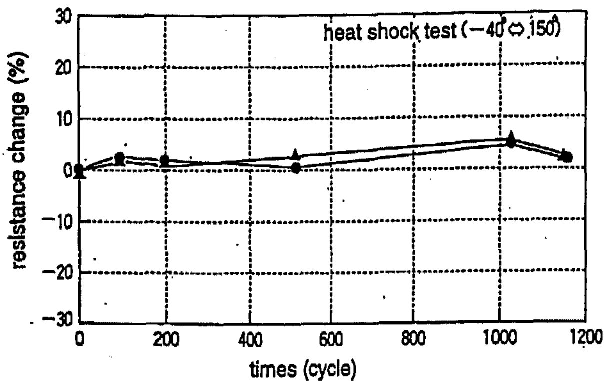

Fig.16 Resistance change of InSb MR after heat shock test

Table 2 shows the reliability test results as a rotation sensor for automobile use. Table 3 shows the basic specifications of this InSb thin-film MR type rotation sensor. Considering the absence of fatigue deterioration, it clearly has sufficient performance for use as a rotation sensor for automotive applications.

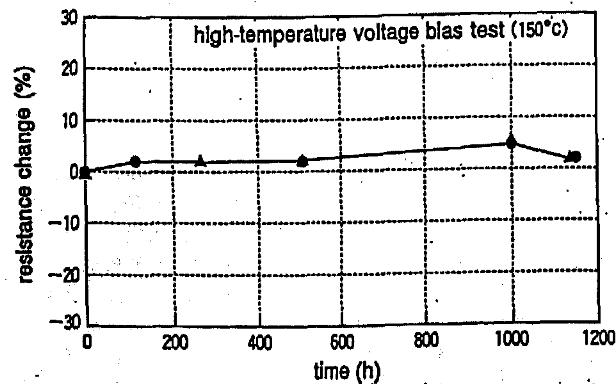

Fig.17 Resistance change of InSb MR after high-temperature voltage bias test

Table 2 Reliability test results of rotation sensor

test items	conditions	results
high temperature	150°C, 500h	1000h OK
low temperature	-40°C, 500h	500h OK
high temperature and high humidity	85°C, 90~95%, 500h	500h OK
heat shock	-40°C, 150°C, 1h each, 1000cycle	2400cycle OK
high temperature voltage bias	150°C, 5V, 1000h	1000h OK
electrostatic charge	±1kv, 10 times for each terminal	OK
surge durability	70V, 200ms	OK
EMI test (strong electric field)	2~200 MHz, 100 V/m	OK

Table 3 Specification of InSb thin-film MR type rotation sensor

[Basic Specifications]

operating temperature	-40~150°C
operating voltage	5±0.25V
consumption current	10 mA or less
output voltage	High:4.8 V, Low:0.8 V
output current	10 mA or less
duty	50±20%
air gap	1.5 mm or less
detection frequency	15kHz or less
insulation resistance	500M ohm or more

CONCLUSION

We have developed the technology for the epitaxial growth of InSb thin-films with high electron mobility directly on Si substrates and , using this technology, have realized InSb thin-film magneto-resistors with high heat resistance and high sensitivity and incorporated these into a rotation sensor with sufficient reliability for automobile use. In the future, we plan to establish the technology for mass production for automotive applications such as electronic control AT system, engine ignition system, and ABS.

ACKNOWLEDGMENTS

Finally, we greatly appreciate the staff of Ion Engineering Center K.K., whose facilities were used in developing this InSb thin-film MR rotation sensor, particularly in the basic study on InSb/Si epitaxial growth technology.

Applications of Magnetoresistive Sensors in Navigation Systems

Michael J. Caruso
Honeywell Inc.

ABSTRACT

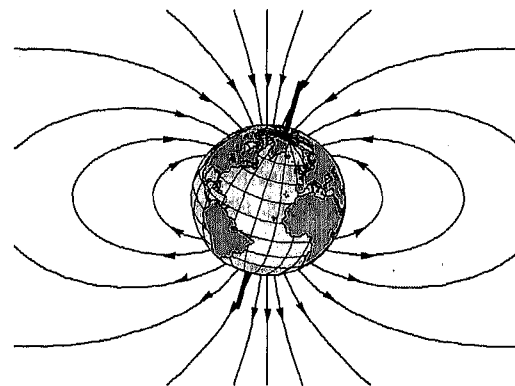
Most navigation systems today use some type of compass to determine heading direction. Using the earth's magnetic field, electronic compasses based on magnetoresistive (MR) sensors can electrically resolve better than 0.1 degree rotation. Discussion of a simple 8-point compass will be described using MR sensors. Methods for building a one degree compass using MR sensors will also be discussed. Compensation techniques are shown to correct for compass tilt angles and nearby ferrous material disturbances.

INTRODUCTION

The magnetic compass has been used in navigation for centuries. The inventor of the compass is not known, though evidence suggests that the Chinese were using lodestone—a magnetic iron ore—over 2000 years ago to indicate horizontal directions. It appears that Mediterranean seamen of the 12th century were the first to use a magnetic compass at sea [1]. Today, the balanced needle compass is only a slight variation of this early discovery. Advances in technology have led to the solid state electronic compass based on MR magnetic sensors and acceleration based tilt sensors. Electronic compasses offer many advantages over conventional "needle" type or gimbaled compasses such as: shock and vibration resistance, electronic compensation for stray field effects, and direct interface to electronic navigation systems. Two types of compasses will be discussed in this paper—a basic eight-point compass and a one-degree compass.

EARTH'S MAGNETIC FIELD

The earth's magnetic field intensity is about 0.5 to 0.6 gauss and has a component parallel to the earth's surface that always point toward magnetic north. This is the basis for all magnetic compasses. The key words here are "parallel to the earth's surface" and "magnetic north".



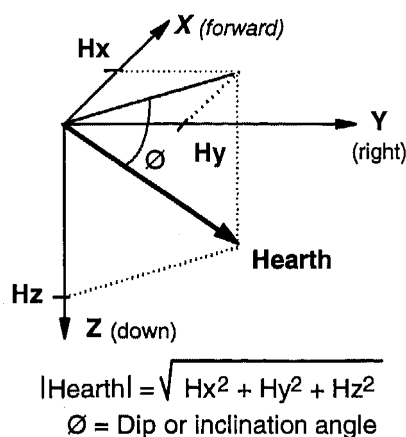


Figure 1 - Earth's Magnetic Field vs. True North

The earth's magnetic field can be approximated with the dipole model shown in Figure 1. This figure illustrates that the earth's field points down toward north in the northern hemisphere, is horizontal and pointing north at the equator, and point up toward north in the southern hemisphere. In all cases, the direction of the earth's field is always pointing to magnetic north. It is the components of this field that are parallel to the earth's surface that are used to determine compass direction. The angle of the magnetic field to the surface of the earth is called the dip, or inclination, angle (see Figure 2). In the northern hemisphere, the dip angle is roughly 70° down toward the north. Only the X and Y components of the earth's field is used when determining the azimuth, or compass direction. The vertical portion of the earth's magnetic field is ignored.

The term magnetic north refers to the earth's magnetic pole position and differs from true, or geographic, north by about 11.5 degrees. True north is at the earth's rotational axis and is referenced by the meridian lines found on maps. At different locations around the globe magnetic north and true north can differ by ±25 degrees, or more as shown in Figure 3. This difference is called the declination angle and can be determined from a lookup table based on the geographic location.

$$|Hearth| = \sqrt{Hx^2 + Hy^2 + Hz^2}$$

Ø = Dip or inclination angle

Figure 2 - Earth's Field in X, Y, Z Coordinates

The key to accurately finding a compass heading, or azimuth, is a two step process: 1) determine the Hx and Hy horizontal components of the earth's magnetic field and 2) add or subtract the proper declination angle to correct for true north.

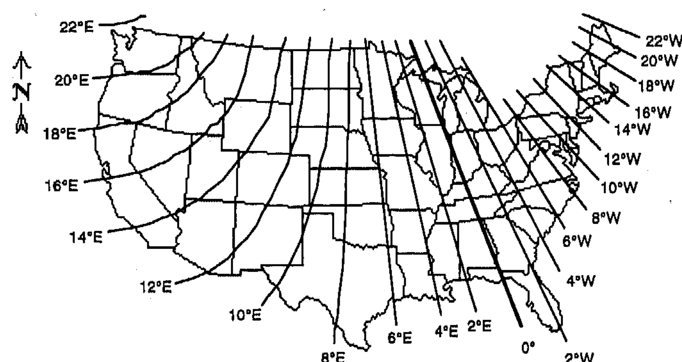

Figure 3 - Declination Angle To Correct For True North

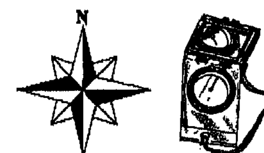

BASICS OF MAGNETIC SENSING

Today, there are several types of electronic compasses to chose from: fluxgate, magnetoresistive, magnetoinductive, and others. A common type of magnetic compass for navigation systems is the fluxgate sensor. The fluxgate sensor consists of a set of coils around a core with excitation circuitry that is capable of measuring magnetic fields with less than 1 milligauss resolution. These sensors provide a low cost means of magnetic field detection; they also tend to be bulky, somewhat fragile, and have a slow response time. Sometimes, fluxgate sensors in motion can have a reading response time of 2-3 seconds. This reading delay may be unacceptable when navigating a high speed vehicle or an unmanned plane.

Another type of magnetic sensor is the magnetoresistive (MR) sensor. This sensor is made up of thin strips of permalloy (NiFe magnetic film) whose electrical resistance varies with a change in applied magnetic field. These sensors have a well defined axis of sensitivity and are mass produced as an integrated circuit. Recent MR sensors show sensitivities below 0.1 milligauss, come in small solid state packages, and have a response time less than 1 microsecond. These MR sensors allow reliable magnetic readings in moving vehicles at rates up to 1,000 times a second.

A magnetoresistive sensor will be used in the remainder of this paper to detect both the sign and magnitude of the earth's field as a voltage output. The sensor will also detect any stray field or field anomaly superimposed onto the earth's field. The magnetic sensor output will have an X, Y, and Z component referenced to the magnetic sensor, or compass, package. For our navigational reference: the X component will be in the forward looking direction, the Y component to the right, and the Z component will be down as shown in Figure 2.

COMPASS DESIGN

There are many forms of compasses used in navigation systems. Two forms will be discussed here that use magnetoresistive magnetic sensors—the eight point compass and the one-degree compass.

EIGHT-POINT COMPASS—A simple eight point compass depicts the cardinal points (N, S, E, W) and the midway points (NE, NW, SE, SW). This type of compass may be used for basic automotive use where the driver needs to know the general direction of travel. For this application, the magnetic sensor can be reduced to a two-axis sensor using only the X and Y axis. An automobile usually travels on a level surface, barring any hills or potholes, so that the X and Y sensors will directly measure the earth's Hx and Hy magnetic fields. The compass can be mounted on the dashboard with the X axis pointing straight ahead and the Y axis to the left. For now, ignore the magnetic effect of the car on the earth's field.

The compass design can be broken into eight regions to indicate the cardinal directions. To analyze the magnetoresistive sensor response, plot the X and Y outputs while the car travels in a circle as indicated in Figure 4. Knowing that the earth's magnetic field is always pointing toward the north, start the analysis with the X axis (and the car) directly pointing north. The X output will be at its maximum value while the Y output will be zero—since no part of the earth's field is pointing to the left, or west. As the car turns clockwise toward the

east, the X axis will diminish to zero while the Y axis will decrease to its maximum negative value. With the car continuing its clockwise turn to point due south, the X axis will decrease to its most negative value while the Y axis will return to zero. This effect is illustrated in Figure 4 and shows the complete circular cycle for the X and Y axis outputs. The X and Y outputs of the magnetometer can be modeled by the cos(Ø) and sin(Ø) functions where Ø is the azimuth, referenced to magnetic north.

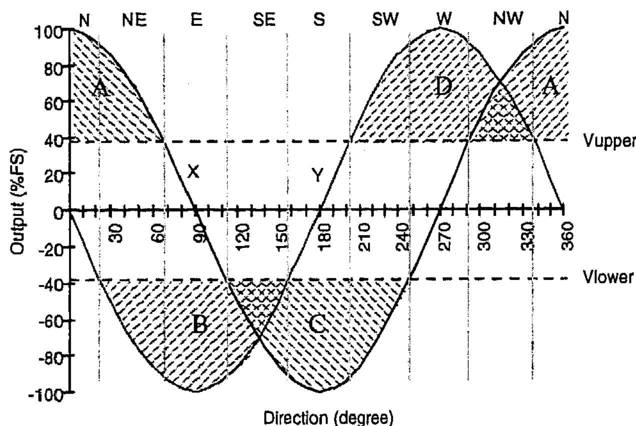

Figure 4 - Magnetic Outputs X And Y For 360° Rotation

The X and Y curves in Figure 4 can be split into eight regions representing the four cardinal and four midway points. A combination of these curves can be formed to represent each region. Two crossover points, Vupper and Vlower, are necessary to distinguish the boundaries of the eight compass direction headings. The crossover points can be determined by knowing the full scale (FS) values for X and Y as:

Vupper = 100*sin(22.5°) (%FS) = 38 %FS (1)
Vlower = -100*sin(22.5°) (%FS) = -38 %FS

Voltage comparators can be used to detect Vupper and Vlower levels to divide the X and Y curves into four regions: A, B, C, and D. The eight points of the compass can be determined by combining the A, B, C, and D using Boolean logic gates, four comparators, and a two axis magnetic sensor as shown in Figure 5. This circuit requires a two axis magnetometer with a signal sensitivity of 1-2 milligauss. Magnetic hysteresis and linearity must be less than 1-2%FS with good repeatability. There are three limitations to consider while using this design: 1) there is no tilt compensation so the compass must be held level, 2) there should be no nearby ferrous material to create magnetic distortions, and 3) the declination angles are difficult to add to this design. These limitations will be addressed in the one-degree compass discussion below.

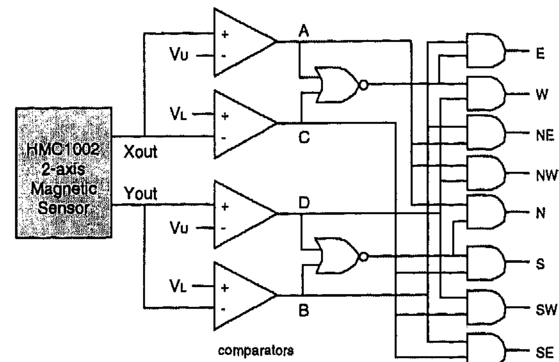

Figure 5 - Eight Point Compass Circuit

ONE-DEGREE COMPASS—Some navigation systems require more than just an eight point compass. For instance, the Global Positioning System (GPS) has led to a sophisticated tracking of vehicle position on video maps with accuracy better than 10 meters. These systems rely on telemetry contact from four satellites, sometimes aided by a system radio tower. It is essential to keep a line of sight with these satellites for position determination. Backup systems are required in cities and tunnels to maintain a course of direction during short blackouts. This is where a more accurate compass can help in GPS based navigation systems. During the loss of GPS signals, knowing the vehicle's speed and heading direction can maintain proper vehicle tracking. Gyros can be used to maintain direction but a lower cost MR based compass is preferred. For these systems, a compass accuracy of one degree is desirable.

To achieve a one degree accurate compass requires a magnetic sensor that can reliably resolve angular changes to 0.1 degrees. The sensors must also exhibit low hysteresis (<0.05%FS), a high degree of linearity (< 0.5%FS error) and be repeatable. The magnetic fields in the X and Y plane will typically be in the 200 to 300 milligauss range—more at the equator, less at the poles. Using the relationship:

Azimuth = arcTan (y/x) (2)

the required magnetometer resolution can be estimated. To resolve a 0.1° change in a 200milligauss field would require a magnetic sensitivity of better than 0.35 milligauss. Solid state MR sensors are available today that reliably resolve 0.07 milligauss signals giving a five times margin of detection sensitivity.

Using the simple magnetic sensor shown in Figure 6, the azimuth can be calculated by using the X and Y outputs in a horizontal plane. To account for the tangent function being valid over 180° and not allowing the y=0 division calculation, the following equations can be used:

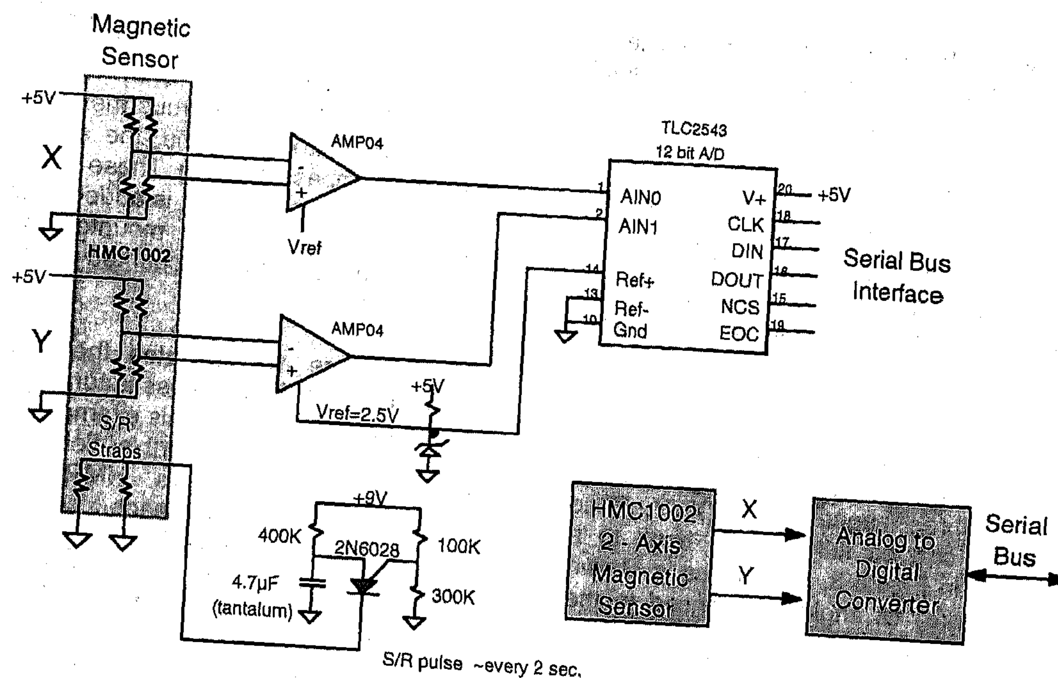

Figure 6 - One Degree Compass System without Tilt Compensation

Azimuth (x=0, y<0) = 90.0 (3)
Azimuth (x=0, y>0) = 270.0
Azimuth (x<0) = 180 - [arcTan(y/x)]*180/•
Azimuth (x>0, y<0) = - [arcTan(y/x)]*180/•
Azimuth (x>0, y>0) = 360 - [arcTan(y/x)]*180/•

The set/reset (S/R) circuit shown in Figure 6 is a current pulse generator used to eliminate the effects of past magnetic effects and temperature drift [4]. The serial bus output can readily interface to a low cost microprocessor for azimuth computation. Equations (3) provide continuous azimuth angles from 0° to 360° in the forward direction relative to magnetic north (H_{North}), see Figure 7. In this example, there is no compensation for tilt and nearby ferrous distortion effects on the azimuth.

COMPENSATING FOR TILT—Most often compasses are not confined to a flat and level plane. They are often hand held, attached to an aircraft, or on a vehicle in an uneven terrain. This makes it more difficult to determine the azimuth, or heading direction, since the compass is not always horizontal to the earth's surface. Errors introduced by tilt angles can be quite large depending on the amount of the Dip angle. A typical method for correcting the compass tilt is to use an inclinometer, or tilt sensor, to determine the roll and pitch angles. The terms roll and pitch are commonly used in aviation: ROLL refers to the rotation around the X, or forward direction, and PITCH refers to the rotation around the y, or left-right, direction (see Figure 8).

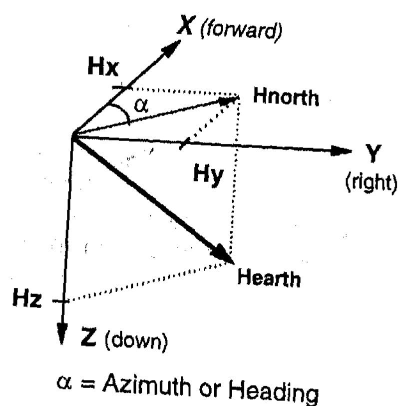

Figure 7 - Azimuth Defined In The X-Y Plane

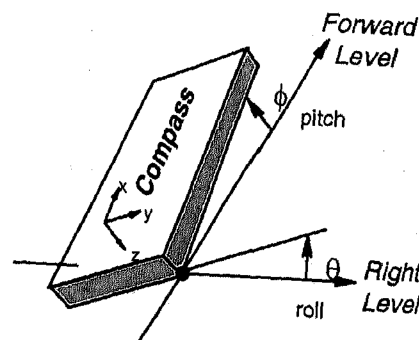

Figure 8 - Compass Tilt Referenced To The Earth's Horizontal Plane

Common liquid filled tilt sensors resemble a glass "thimble" that uses electrodes to monitor the fluid movement as the sensor changes angles. Newer solid state accelerometer tilt sensors are available that measure the earth's gravitational field by means of an electromechanical circuit [5]. The output of these devices are an electrical signal equivalent to the angle of tilt. During compass assembly, the tilt sensor directions must be carefully aligned with the X,Y,Z magnetic axis. Several manufacturers offer these tilt sensors as stand alone circuit boards that provide the roll and pitch angles as outputs.

To compensate a compass for tilt, knowing the roll and pitch is only half the battle. The magnetometer must now rely on all three magnetic axes (X, Y, Z) so that the earth's field can be fully rotated back to a horizontal orientation. In Figure 8, a compass is shown with roll (θ) and pitch (ϕ) tilt angles referenced to the right and forward level directions of the observer or vehicle. The X, Y, and Z magnetic readings can be transformed back to the horizontal plane (X_H, Y_H) by applying the rotational equations shown below:

$$X_H = X^*\cos(\phi) + Y^*\sin(\theta)^*\sin(\phi) - Z^*\cos(\theta)^*\sin(\phi)$$

$$Y_H = Y^*\cos(\theta) + Z^*\sin(\theta) \qquad (4)$$

$$\text{Azimuth} = \arctan(Y_H / X_H)$$

Once the X and Y magnetic readings are in the horizontal plane, equations (3) can be used to determine the azimuth. For speed in processing the rotational operations, a sine and cosine lookup table can be stored in program memory to minimized computation time.

A block diagram for a tilt compensated compass is shown in Figure 9 with a serial bus interface. After the azimuth is determined, the declination correction can be applied to find true north according to the geographic region of operation.

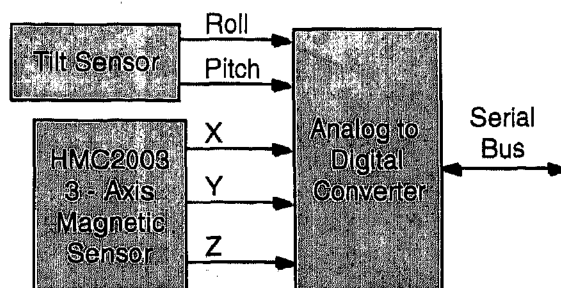

Figure 9- Tilt Compensated Compass System

COMPENSATING FOR NEARBY FERROUS EFFECTS—When a compass is operating in a open area in the absence of any ferrous metals there is no distortion effects on the earth's magnetic field. In reality, though, compasses are mounted in vehicles, aircraft, and platforms that most likely have ferrous materials nearby. The effects of ferrous metals (iron, nickel, steel, cobalt) will distort, or bend, the earth's field which will alter the compass heading. These effects can be thought of as a magnetic field that is added to the earth's field. If the compass is securely mounted in the vehicle, the ferrous effects can be accounted for and removed from the magnetic readings.

Figure 10 illustrates the X and Y magnetic readings when the compass is turning around in a circle in a horizontal plane. In this example, there is no ferrous interference with the earth's field. The readings are taken from Honeywell's HMR2300 Smart Digital Magnetometer where each count represents 67 microgauss. The earth's field magnitude in the X and Y plane reads 2800 counts which is approximately 190 milligauss. When the X and Y readings are plotted with each other they form a circle centered about the 0,0 point. An azimuth can be determined for each reading using equations (3) as show in Figure 10. This plot shows a sine and cosine output response for the X and Y directions during rotation.

If the magnetometer is mounted in a car, the effect of the engine and car body would distort the earth's magnetic field. Driving the car in a circle would produce the curves shown in Figure 11. Note here that the X,Y plot is not a circle (slightly ellipsoid) and that it is offset from the 0,0 point by -480 and -795 counts. This offset and ellipsoid effect are a result of the fixed distortion of the car on the earth's magnetic field. This distortion can be determined systematically and applied to subsequent X,Y readings to eliminated the effects of the car.

To compensate for the vehicle's distortion, two scale factors Xsf and Ysf can be determined to change the ellipsoid response to a circle. Offset values Xoff and Yoff can then be calculated to center the circle around the 0,0 origin. The X,Y values used to compute the azimuth when compensating for the vehicle's distortion are:

$$\text{Xvalue} = \text{Xsf} * \text{Xreading} + \text{Xoff} \qquad (5)$$

$$\text{Yvalue} = \text{Ysf} * \text{Yreading} + \text{Yoff}$$

Here, the scale factors Xsf and Ysf scale each reading to change the ellipsoid to a circle and Xoff and Yoff values shift the center back to the 0,0 origin. The result of this compensation is shown in Figure 12 and should be compared to the 'no interference' curves in Figure 10.

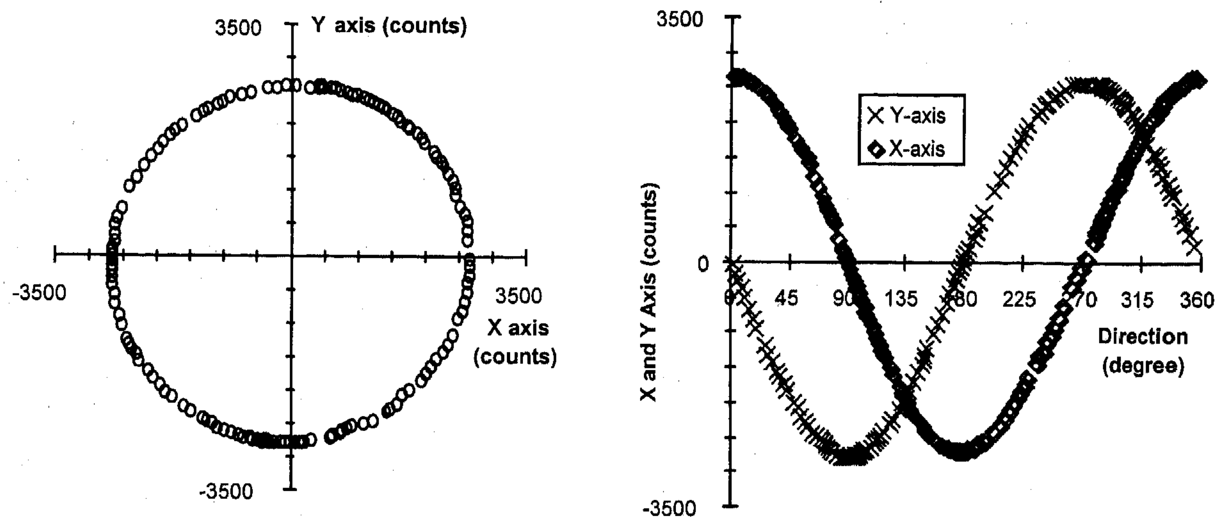

Figure 10 - No Interference Of Magnetometer Readings For 360° Rotation In Level Plane

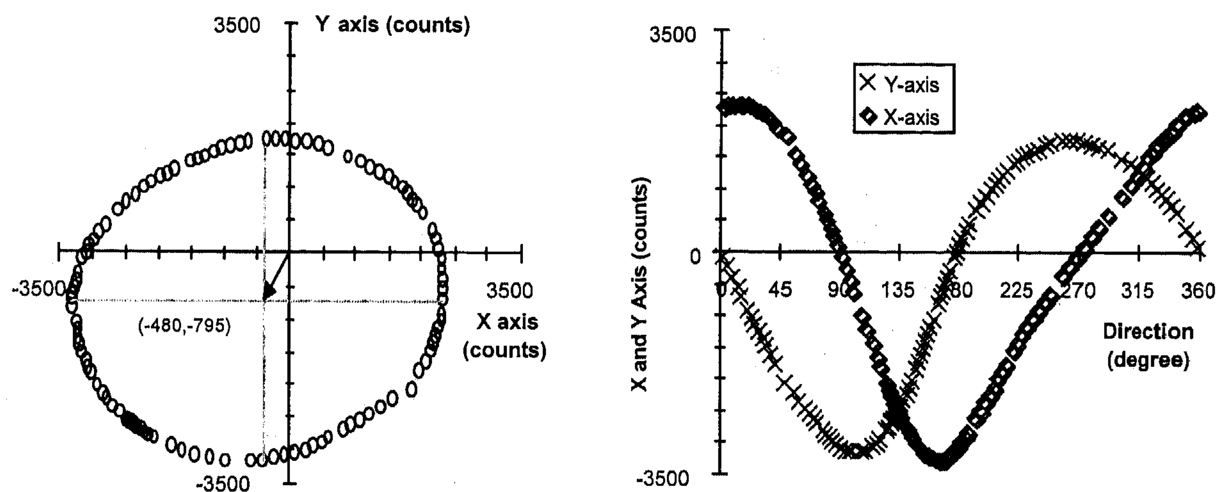

Figure 11 - Car Engine/Body Interference Of Magnetometer Readings For 360° Rotation In Level Plane

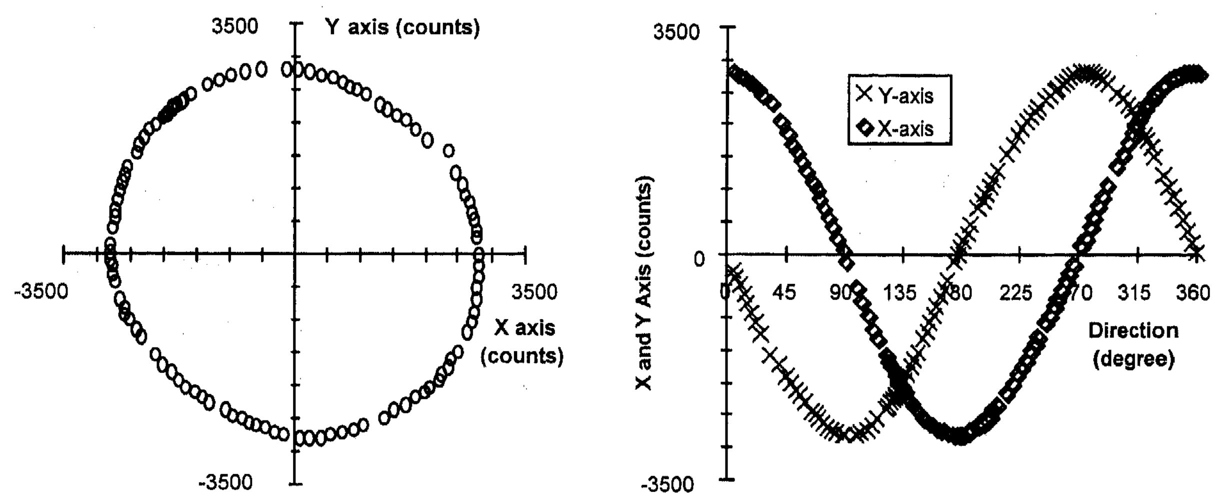

Figure 12 - Car Engine/Body Compensation Of Magnetometer Readings For 360° Rotation In Level Plane

A simple calibration method can be used to determine the offset and scale factor values:

- Mount the compass in the car and drive the car in a circle on a horizontal surface.
- Find the maximum and minimum values of the X and Y magnetic readings.
- Using these four values determine the X and Y scale factors (Xsf, Ysf) and the zero offset values (Xoff, Yoff).

Xsf = 1 or (Ymax - Ymin) / (Xmax - Xmin) (6)
whichever is greater

Ysf = 1 or (Xmax - Xmin) / (Ymax - Ymin)
whichever is greater

Xoff = [(Xmax - Xmin)/2 - Xmax] * Xsf (7)

Yoff = [(Ymax - Ymin)/2 - Ymax] * Ysf

The following example will show how the compensation values are determined. A compass is mounted in a car that has traveled a circle in a vacant parking lot. The magnetic X and Y counts (15,000 counts=1 gauss) from the magnetometer are scanned and the minimum and maximum readings are:

Xmin = -3298 Xmax = 2338

Ymin = -3147 Ymax = 1763

Set the X scale factor (Xsf) to one since (Ymax - Ymin)/(Xmax - Xmin)< 1, according to equation (5). Next, determine the Y scale factor (Ysf) by dividing the X reading span by the Y reading span.

Xsf = 1

Ysf = (Xmax - Xmin) / (Ymax - Ymin) = 1.15

Calculate the offset correction values by taking one-half the difference of the max. minus min. readings and apply the scale factors, Xsf and Ysf.

Xoff = [(Xmax - Xmin)/2 - Xmax] * Xsf = 480

Yoff = [(Ymax - Ymin)/2 - Ymax] * Ysf = 795

Store these values and apply them to every tilt compensated reading—X_H and Y_H. The Xvalue and Yvalue numbers used in the azimuth calculations, equations (3), to determine compass heading are:

Xvalue = X_H + 480

Yvalue = 1.15 * Y_H + 795

CONCLUSION

Compass headings are determined from the earth's magnetic fields in a horizontal plane. In a compass system each magnetometer reading must first be corrected for tilt. Then each reading must be compensated for the effects of nearby ferrous materials. Once the compass reading is tilt compensated and nearby ferrous material corrected, the declination angle should be applied to adjust magnetic north to true north.

Magnetoresistive sensors provide a solid state solution for building compass navigation systems. Their high sensitivity and good repeatability, along with small size, results in a high accuracy and easy to integrate magnetic sensor. There are many other techniques than the ones shown here for tilt and ferrous distortion compensation. The method for compensation depends on the application requirements: accuracy, resolution, speed, size, and cost.

ABSTRACT

Large changes in resistance with magnetic field exhibited by recently discovered thin-film multilayer structures offer new opportunities in the sensors field. Compatibility of these Giant Magnetoresistive (GMR) materials with conventional semiconductor processing technology and semiconductor underlayers allows the production of inexpensive, ultra-small, smart sensors with enhanced magnetic sensitivity. The action of GMR materials is described along with their application to sensor configurations for detecting magnetic fields, magnetic field gradients, and magnetic fields from currents. Characteristics of these sensors are discussed and compared to conventional magnetic field sensors. Finally, the exciting combination of GMR materials with semiconductor underlayers in smart sensors with linear or digital (switched) outputs is explored.

INTRODUCTION

The discovery of any new physical phenomenon which relates some condition imposed on a material to a measurable property of that material often leads to a new class of sensors. Such is the case with Giant Magnetoresistive (GMR) materials. Initial observations of large magnetic field dependent changes in resistance of thin-film ferromagnet/nonmagnet metallic multilayers in 1988, were followed by the commercial introduction of magnetic sensors based on GMR materials in 1994[1, 2]. Intense research continues on a wide variety of new materials which utilize the phenomenon of spin-dependent conduction electron scattering as well as research understanding the phenomenon itself. Efforts to develop applications using GMR materials include not only magnetic field sensors, but also read heads for high density magnetic data recording and memory elements for magnetic random access memory (MRAM).

This paper first describes the properties of some of the GMR materials which have already proved useful for sensors as well as a brief discussion of how GMR works. Various sensor configurations using GMR materials are examined as well as the integration of GMR elements with semiconductor materials. Finally, utilization of GMR sensors in specific applications is discussed and GMR sensors are compared with conventional magnetic field sensors.

GMR MATERIALS

BASIC PRINCIPLES - Resistance of metals depends on the mean free path of their conduction electrons. The shorter the mean free path, the higher the resistance of the metal. A voltage applied to a conductor results in an electrical field in the conductor which accelerates the conduction electrons. Current density in the conductor depends upon the average velocity of conduction electrons and on their number density. The more frequently they are scattered and lose their momentum, the lower their average velocity. Scattering can occur in the bulk or at surfaces. The resistivity of thin films can be considerably larger than the bulk resistivity if the film thickness is less than the mean free path of the conduction electrons.

Ferromagnetic materials introduce an additional complication to the behavior of conduction electrons. Electrons can be either *spin up* if their spin is parallel to the magnetic moment of the ferromagnet or *spin down* if they are antiparallel. In nonmagnetic conductors there are equal numbers of *spin up* and *spin down* electrons in all energy bands. However, due to the ferromagnetic exchange interaction, there is a difference between the number of *spin up* and *spin down* electrons in the conduction sub bands of ferromagnetic materials. Therefore, the probability of an electron being scattered when it passes into a ferromagnetic conductor depends upon the direction of its spin. If two thin ferromagnetic layers are separated by a thin nonmagnetic conducting layer, we can change the resistance by simply changing whether the moments of the ferromagnetic layers are parallel or antiparallel. Layers with parallel magnetic moments will have less scattering at the interfaces and, therefore, longer mean free paths, and lower resistance. Layers with antiparallel magnetic moments will have more scattering at the interfaces and, therefore, shorter mean free paths, and higher resistance. In order for this

spin dependent scattering to be a significant part of the total resistance, the layers must be thinner than the mean free path of electrons in the bulk material. For many ferromagnets the mean free path is tens of nanometers, so the layers themselves must each be typically less than 10 nm (100 Å). For a more complete treatment of spin-polarized transport see the recent article by G. Prinz in *Physics Today*[3]. Figure 1 illustrates the concept of spin dependent scattering at interfaces.

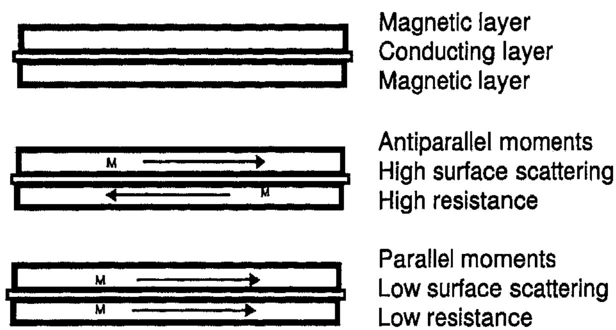

Fig. 1. Scattering from two different alignment of magnetic moments in a two magnetic layer GMR sandwich.

GMR STRUCTURES - There are several methods of obtaining antiparallel alignment of the magnetic layers. In this paper we will discuss the two which are currently used in GMR sensors: *sandwich* GMR materials sometimes called unpinned spin valves, and antiferromagnetically coupled *multilayer* GMR materials. Both of these materials are typically RF diode sputtered onto atomically flat substrates such as silicon nitride on single crystal silicon wafers common in the integrated circuit industry.

Unpinned sandwich GMR materials - consist of two soft magnetic layers of iron, nickel and cobalt alloys separated by a layer of a nonmagnetic conductor like copper. With magnetic layers 4 to 6 nm (40 to 60 Å) thick separated by a conductor layer typically 3 to 5 nm thick there is relatively little magnetic coupling between the layers. For use in sensors sandwich material is usually patterned into narrow stripes. The magnetic field caused by a current of a few mA per µm of stripe width flowing along the stripe is sufficient to rotate the magnetic layers into antiparallel or high resistance alignment. The right hand rule for magnetic fields from currents provides antiparallel alignment of the moments of the magnetic layers with the moments perpendicular to the current direction. An external magnetic field of 3 to 4 kA/m (35 to 50 Oe) applied along the length of the stripe is sufficient to rotate both the magnetic moments parallel to the external field lowering the resistance. A positive or negative external field parallel to the stripe will produce the same change in resistance. An external field applied perpendicular to the stripe will have little effect due to the demagnetizing fields associated with the narrow dimensions of a magnetic object. The value associated with the GMR effect is the percent change in resistance normalized by the saturated or minimum resistance. Sandwich materials have values of GMR typically 4 to 9 %. Figure 2 shows a typical resistance *vs.* field plot for sandwich GMR material.

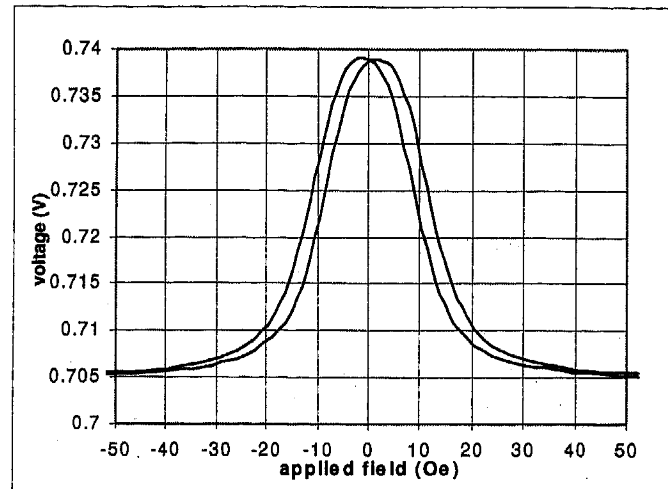

Fig. 2. Voltage *vs.* applied field for a 2 µm wide stripe of unpinned sandwich GMR material with 1.5 mA current. GMR = 5 %.

Antiferromagnetic multilayers - consist of multiple repetitions of alternating conducting magnetic layers and nonmagnetic layers. A typical multilayer structure used in magnetic sensors is shown in Figure 3.[4 5]

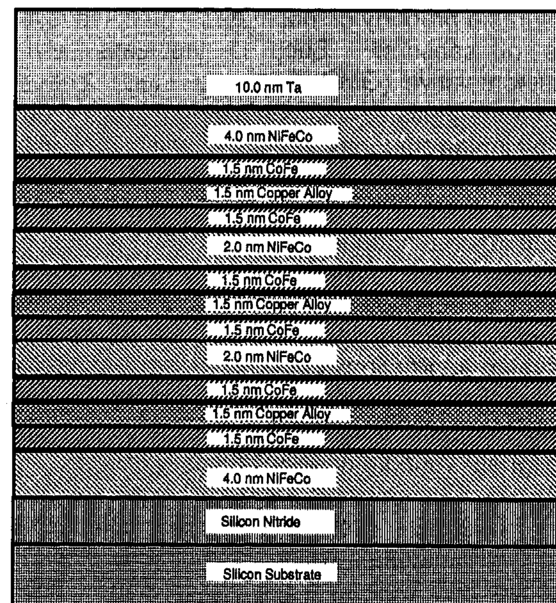

Fig 3. Layer structure of a typical commercial GMR multilayer.

The subdivision of the magnetic layers into two different alloy compositions improves the performance. With more interfaces than sandwiches, the size of the GMR effect is larger. The thickness of the nonmagnetic layers is less than that for sandwich material (typically 1.5 to 2.0 nm) and is quite critical. At the proper thickness, the polarized conduction electrons cause antiferromagnetic coupling between the magnetic layers. In other words, each magnetic layer has its magnetic moment antiparallel to the moments of the magnetic layers on each side – exactly the condition needed for maximum spin dependent scattering. Again, an external field can overcome the coupling which causes this alignment and can align the moments in all the layers parallel reducing the resistance. If the conducting layer is not the proper thickness, the same coupling mechanism can cause ferromagnetic coupling between the magnetic layers resulting in no GMR effect.

A plot of resistance *vs.* applied field for a multilayer GMR material is shown in Figure 4. Note the higher GMR value, typically 12 to 16 % for structures shown in Figure 3, and the much higher external field required to saturate the effect. Multilayer GMR materials have better linearity and lower hysteresis than typical sandwich GMR material.

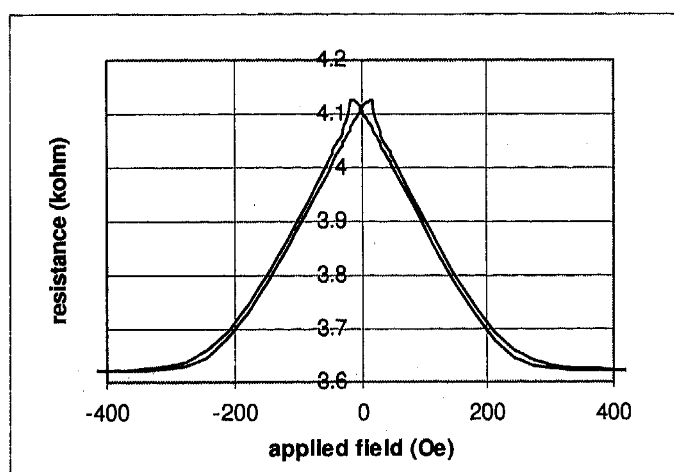

Fig. 4. Resistance *vs.* applied field for a 2 μm wide stripe of antiferromagnetically coupled multilayer GMR material. GMR = 14 %.

MATERIAL CHARACTERISTICS - Besides the basic characteristic of resistance *vs.* applied field, there are several other characteristics of GMR materials which are of importance when applying them to sensors.

Resistivity - Many sensor applications are power limited. This limitation is most severe in battery powered applications. Therefore, a high sensor resistance is desirable. GMR materials are thin film and, therefore have relatively high resistance measured in ohms per square. Typical values are between 12 and 16 ohms per square. Resistors can be patterned in very small areas. A serpentine 10 kΩ resistor can easily be fit into a square 100 μm space using GMR stripes with a 2 μm linewidth. In wafer-scale sensor fabrication, die size has a large influence on sensor cost.

Temperature coefficient of resistivity - Both sandwich and multilayer GMR materials have temperature coefficients of resistivity (TCR) of 0.14 to 0.16 %/°C (1400 to 1600 ppm/°Cz0 which are relatively linear with temperature. This value is about one-half that of nickel-iron permalloy used in other magnetoresistive sensors. The surface scattering which dominates the resistance in thin film GMR materials is less temperature dependent that is bulk scattering. The GMR effect itself is temperature dependent. The field at which the effect saturates decreases slightly with temperature as does the change in resistance. However, as will be shown in a later section, constant current drive can be used to produce a sensor which is quite temperature independent.

High temperature endurance - Sensors materials must not only endure use temperatures which are on the move upward above 150 °C in automotive applications, but also processing temperatures during packaging. The addition of semiconductor processing temperatures place an even greater short term high temperature limit on the sensor materials.

Unpinned sandwich GMR materials have relatively thick copper interlayers and have demonstrated stable properties to about 250 °C. Antiferromagnetically coupled multilayers with much thinner copper alloy interlayers have shown decrease in their GMR above 175 °C and degrade rapidly above 200 °C. Packaged multilayer sensors have survived 1000 hour dry storage tests. Figure 5 shows changes in GMR of multilayer and sandwich materials after 1 hour anneals at various temperatures.

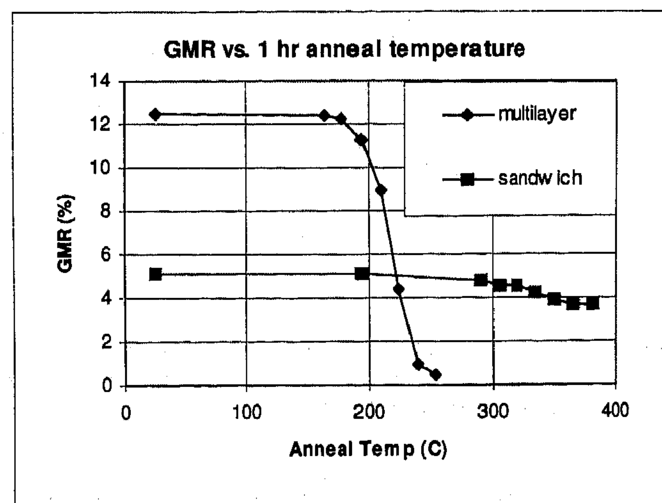

Fig. 5. GMR of sandwich and multilayer materials after 1 hour anneals at various temperatures.

SENSOR CONFIGURATIONS

FIELD SENSORS - Although simple GMR resistors and GMR half bridges can be fabricated from GMR materials, the best utilization of these materials appears to be in a traditional Wheatstone bridge configuration. Electroplated soft magnetic permalloy structures on top of many GMR sensors accomplish two objectives – shielding and flux concentration. Small magnetic shields plated over two of the four equal resistors in a Wheatstone bridge, say the resistor connected to power on one side and the resistor connected to ground on the other side, protect these resistors from the applied field and allow them to act as reference resistors. Since they are fabricated from the same material, they have the same temperature coefficient as the active resistors. The two remaining GMR resistors are both exposed to the external field. The bridge output is therefore twice the output from a bridge with only one active resistor. The bridge output for a 10% change in these resistors is approximately 5% of the voltage applied to the bridge.

Additional permalloy structures plated onto the substrate act as flux concentrators. The active resistors are placed in the gap between two flux concentrators as is shown in Figure 6. These resistors experience a field which is larger than the applied field by approximately the ratio of the gap between the flux concentrators, D1, to the length of one of the flux concentrators, D2. In some sensors the flux concentrators are also used as shields by placing two resistors beneath them as is shown for R3 and R4 in the figure below.

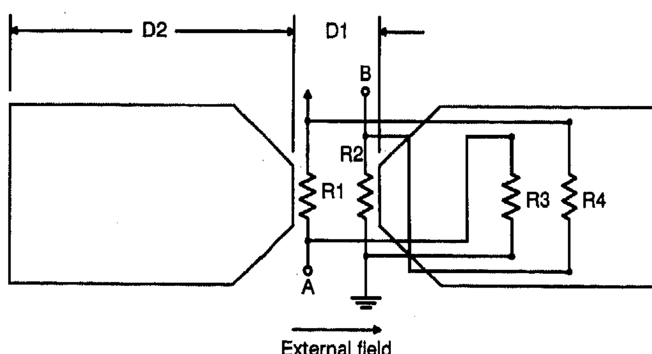

Fig. 6. Configuration of GMR resistors in a Wheatstone bridge sensor. Flux concentrators are shown as well as output between A and B.

The sensitivity of a GMR bridge sensor can be adjusted in design by changing the lengths of the flux concentrators and the gap between them. In this way, a GMR material which saturates at approximately 300 Oe can be used to build different sensors which saturate at 15, 50, and 100 Oe.

An example of the output from a GMR bridge sensor is shown is Figure 7. The curves on the left side represent the output of the bridge at various temperatures with a constant voltage applied to the bridge. Only negative excursions of the external field are shown without crossing zero to avoid hysteresis. The curves on the right side of Figure 7 represent the output of the same bridge when a constant current supply is used. The maximum output still decreases with temperature, but not by as large an amount since the voltage across the bridge automatically increases as the bridge resistance increases with temperature. The output at any constant field which is less than saturation remains almost constant.

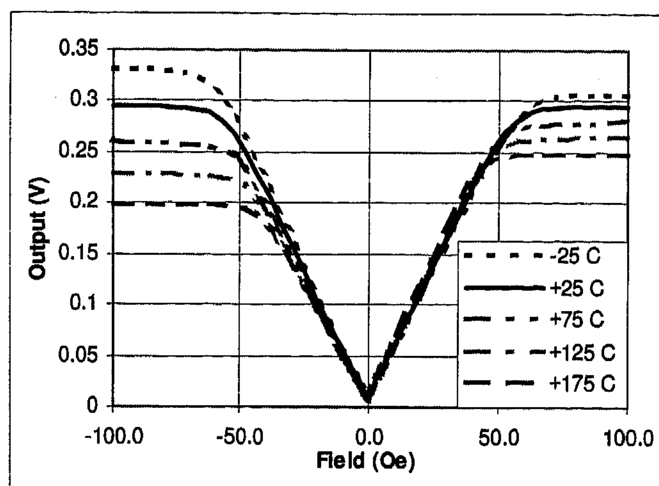

Fig. 7. Output of a GMR Wheatstone bridge *vs.* external field at various temperatures. The left side represents a bridge driven with a constant voltage, the right side a bridge driven with a constant current.

BIASING - Since the resistance of GMR material decreases when an external field is applied and the magnetic moments of the layers can be aligned in either direction for minimum resistance, a bridge circuit produces a symmetrical or omnipolar output. If a knowledge of the direction of a bipolar magnetic field is required, methods of biasing the sensor away from zero are necessary. This biasing can be done either with a small permanent magnet affixed to the top of the sensor package or by electromagnetic means using a coil or a current strap to apply a constant magnetic field to the sensor. Biasing the GMR material away from zero also decreases the hysteresis and non-linearity observed close to the zero field point. The offset caused by a bias can be handled either by ac coupling of the output if there is no dc signal of interest, or by building a negative offset (output at zero field) into the bridge by using

unequal resistors. An additional bias then brings the output back to zero.

GRADIENT FIELD SENSORS - A Wheatstone bridge can be made with GMR resistors without shields or flux concentrators. If the upper left and lower right resistors are located at one end of the chip and the other resistors at the other end of the chip the device becomes a gradiometer. The output of the bridge is due to the *difference* between the resistances of the two sets of resistors. A constant field will change all four resistors by the same amount leaving the bridge in balance. A non-uniform field, however, has a gradient and the two pairs of resistors will experience different fields resulting in an imbalance in the bridge; the bridge is sensitive to the field gradient. Such sensors respond to fields which change very rapidly with position such as those found near magnetized gear teeth. They are insensitive to uniform fields as long as the fields are not large enough to saturate all of the resistors. Gradient field sensors will be discussed under angular position sensing

Half bridges consisting of two GMR resistors separated in position and connected in series with a center tap can also be used as gradiometers. The zero field output at the center tap is one half of the applied voltage. In the presence of a non-uniform magnetic field, the output will vary above and below its zero field value by an amount proportional to the difference in field between the two resistors. In a uniform field both resistors will change by the same amount and the output will remain at the zero field value.

SENSOR APPLICATIONS

GENERAL COMMENTS - A magnetic field sensor can directly sense a magnetic field from a permanent magnetic, an electromagnet, or a current. In sensing the presence of a ferrous object, a biasing magnet is often used. The biasing magnet magnetizes the ferromagnetic object such as a gear tooth, and the sensor detects the combined magnetic fields from the magnetized object and the biasing magnet. A biasing magnet is affixed to the sensor in a position such that its direct influence on the sensor is minimal. Usually the biasing magnet is mounted on the top of the sensor with its magnetic axis perpendicular to the sensitive axis of the sensor. The biasing magnet can be centered such that there is little or no field in the sensitive direction of the sensor. In this way a reasonable large biasing magnet can be used. Occasionally a spacer is used between the sensor and the magnet to reduce the field at the sensor and, therefore, reduce how critically the magnet must be positioned. Figure 8 shows the relative positions of a sensor and a biasing magnet. The magnetic field lines are shown both in the absence and presence of a ferromagnetic object. Note the induced magnetic moment in the ferromagnetic object. The technique of using a biasing magnet can only be used if the ferrous object is in close proximity. In some applications such as detection of motor vehicles, the Earth field acts as a biasing magnet resulting in a magnetic dipole moment along the length of the motor vehicle.

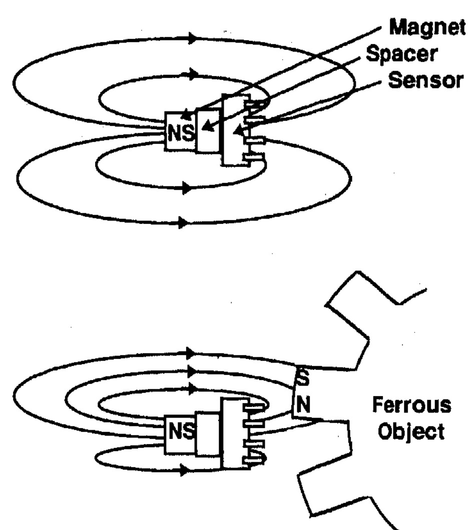

Fig. 8. Side view of biasing magnet and sensor in 8 pin package shown with and without a ferrous object present.

FIELD SENSING - GMR sensors can be used to measure or sense magnetic fields. As was pointed out in a section above, provisions for biasing the sensor away from zero field are necessary if bipolar fields are to be sensed. The high sensitivity of GMR sensors with high flux concentration ratios allow them to detect the fields from small magnetized particles such as those included in the ink on various countries' currencies and the magnetic layer on Microtaggant particles.[6]

DISPLACEMENT SENSING- GMR bridge sensors can be effectively employed to provide position information from small displacements associated with actuating components in machinery, proximity detectors, and linear position transducers. Due to the nonlinear characteristic of dipole magnetic fields produced by permanent magnets, the range of linear output may be limited. A dipole field decreases as the reciprocal of the distance cubed. Figure 9 shows the position and motion of a sensor relative to a cylindrical permanent magnet. In both cases the sensitive axis of the sensor is in the X direction. Sensors A and B can both detect motion in either the X or Y direction but not both at the same time. The sensitive axis of the sensor is indicated by the double headed arrow on each sensor. The rate of change of the X component of the magnetic field (the sensitive axis of both sensors) with position can be

approximated from the formula for the magnetic field from a dipole if the sensor is at least one or two diameters away from the permanent magnet.

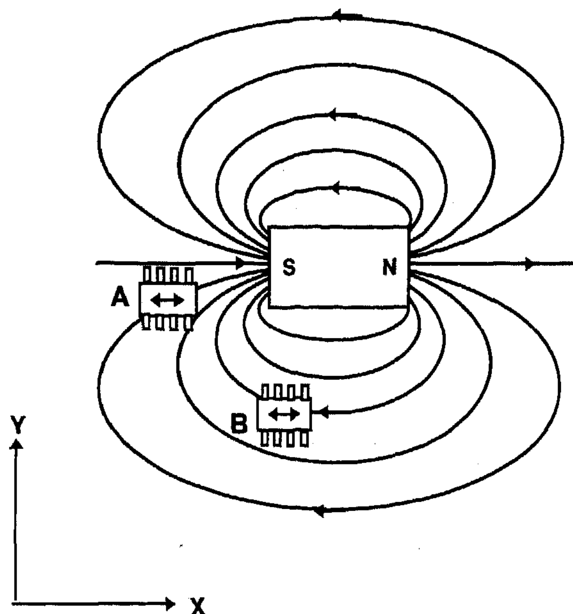

Fig. 9. Sensors positioned to measure displacement relative to a permanent dipole magnet. Sensitive axis indicated on sensors **A** and **B**.

ANGULAR POSITION SENSING - GMR sensors offer a rugged, low cost solution to rotational reference detection. High sensitivity and dc operation afford the GMR bridge sensor an advantage over inductive sensors which have very low outputs at low frequencies and can generate large noise signals when subjected to high frequency vibrations. GMR sensors are field sensors and do not measure the induced signal from the time rate of change of fields as do variable reluctance sensors. The output from a GMR bridge sensor will have a minimum when the sensor is centered over a tooth or a gap and a maximum when a tooth approaches or recedes. Figure 8 shows a bridge sensor in position for angular position sensing.

Higher accuracy sensing of the edge of a gear tooth can be achieved by using a gradiometer. A properly biased gradiometer will produce a maximum and a minimum at each tooth edge and minima over the center of each tooth and gap. Figure 10 shows the output from a gradiometer biased with a permanent magnet.

CURRENT SENSING - Currents in wires create magnetic fields surrounding the wires or traces on printed wiring boards. The field decreases as the reciprocal of the distance from the wire. GMR bridge sensors can be effectively employed to sense this magnetic field. Both dc and ac currents can be detected in this manner. Bipolar ac current will be rectified by the sensors omnipolar sensitivity unless a method is used to bias the sensor away from zero. Unipolar and pulsed currents can be measured with good reproduction of fast rise time components due to the excellent high frequency response of the sensors. Since the films are extremely thin, response to frequencies above a megahertz is possible. Figure 11 shows the relative position of a GMR bridge sensor and a current carrying wire to detect the current in the wire. A wire placed immediately over or under the sensor will produce a field of approximately 0.080 A/m (one mOe) per mA of current. The sensor can also be mounted immediately over a current carrying trace on a circuit board. High currents may require more separation between the sensor and the wire. Low currents may be best detected with the current being carried by a trace immediately over the GMR resistors.

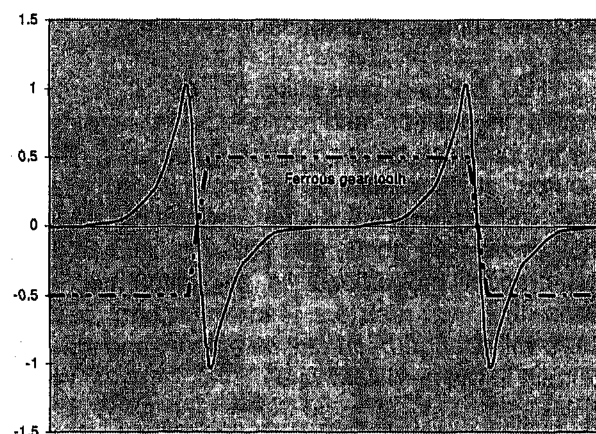

Fig. 10. Output from a biased gradiometer used for gear tooth detection. The relative position of the gear tooth is shown superimposed on the output.

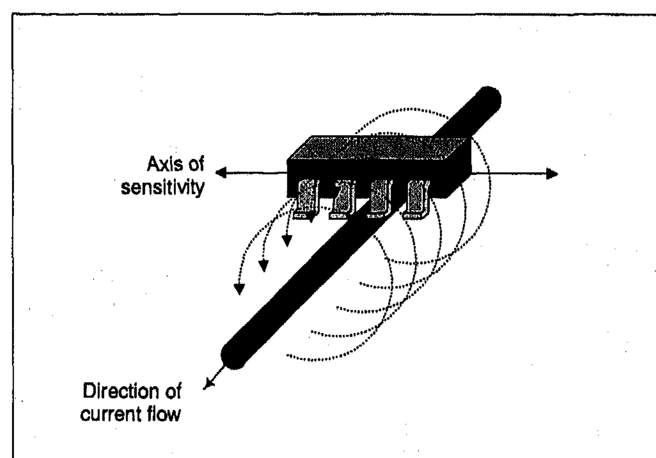

Fig. 11. Proper position of a GMR bridge sensor to detect the magnetic field created by a current carrying wire.

SENSOR COMPARISONS

Various methods of magnetic field sensing which have been developed over the years have their advantages and disadvantages. The oldest technique, variable reluctance (VR) sensors, are basically coils of wire. A change in magnetic field induces a voltage in the coil by Lenz's law. They are relatively large, sensitive to vibration, and do not sense dc fields. Hall effect sensors have been available since shortly after the second world war. A current driven through a slab of semiconductor material develops a voltage perpendicular to the current when a magnetic field is applied perpendicular to the slab due to the Lorentz force on the electrons. These voltages are very small, about 5 mV/100 Oe. Hall effect sensors can be very small and can be integrated with semiconductor circuitry to produce inexpensive sensors which can measure magnetic fields up to 1000 Oe. Anisotropic magneto-resistive (AMR) sensors utilize the change in resistance in metals when the current is parallel to the magnetic moment compared to the resistance when the current is perpendicular to the magnetic moment. The maximum change in resistance in the nickel-iron alloys typically used is about 2.5% compared to 4 to 16% for current commercial GMR materials. The relatively wide stripes of material necessary in AMR resistors made from NiFe films require much larger chip areas than do the resistors from GMR materials to produce high resistance sensors. High sensitivity sensors can be made but the maximum field that they can detect is only tens of Oe. In addition, high magnetic fields can reverse the polarity of the output of the sensor unless some means such as onboard flipping coils are used to periodically saturate the sensor in a given direction. Because of the relatively large areas occupied by the resistors used in AMR sensors, significant integration is impractical.

The best way to compare the relative merits of these magnetic field sensors is to list relevant properties in a table. Table I compares some properties of GMR, AMR, Hall, and VR sensors.

Table I. Comparison matrix for magnetic field sensors.

	GMR	AMR	Hall	VR
DC operation	Yes	Yes	Yes	No
Size	Small	Large	Small	Very large
Signal size	Large	Medium	Small	Varies with size
Sensitivity	Very high	High	Low	Varies
Relative cost	Low to Medium	High	Low	Medium to High
Stability over Temperature	Good	Good	Fair	Good

INTEGRATED SENSORS

GENERAL CONSIDERATIONS - Smart sensors with both sensing elements and associated electronics such as amplification and signal conditioning on the same die are the latest trend in modern sensors. GMR materials are deposited on wafers with sputtering systems and can, therefore, be directly integrated with semiconductor processes. The small size sensing elements fit well with the other semiconductor structures and are applied after most of the semiconductor fabrication operations are complete. Due to the topography introduced by the many layers of polysilicon, metal, and oxides over the transistors, areas must be reserved with no underlying transistors or connections onto which the GMR materials can be deposited. In actuality the GMR materials are deposited over the entire wafer, but the etched sensor elements remain only on these reserved, smooth areas on the wafers[7].

The typical functions which can be included in an integrated sensor include regulated voltage or current supplies to the sensor elements; threshold detection to provide a switched output when a preset field is reached; amplifiers; logic functions including divide by 2 circuits; and various options for outputs. Using such elements, a two-wire sensor can be designed which has two current levels – a low current level in the absence of a gear tooth and a high current level in the presence of a gear tooth.

ADVANTAGES - There are many advantages of manufacturing sensors with on-board electronics. They usually center on size, cost, and performance. In the automotive industry cost is often the most powerful driver. In semiconductor devices, size and cost are always related. The more chips which fit on a wafer, the lower the final cost. In sensor assemblies a single chip solution is almost always less expensive and more reliable that a multi-chip assembly or a hybrid assembly. A two wire smart sensor is preferable to a multi-wire sensor with remote electronics.

On-sensor electronics can increase signal levels to significant voltages with the least pickup of interference. It is always best to amplify low-level signals close to where they are generated. Converting analog signals to digital (switched) outputs within the sensor is another method of minimizing electronic noise. The use of comparators and digital outputs makes the nonlinearity in the output of sandwich GMR materials of less concern. Even the hysteresis in such materials can be useful, since some hysteresis is usually built into comparators to avoid multiple triggering of the output due to noise.

INTEGRATION PROCESS - GMR materials have been successfully integrated with both BiCMOS semiconductor underlayers and Bipolar semiconductor underlayers. The wafers are processed with all but the final layer of connections made. GMR material is deposited on the surface and patterned followed by a

passivation layer. Windows are cut through the passivation layer to allow contact to both the upper metal layer in the semiconductor wafer and to the GMR resistors. The final layer of metal is deposited and patterned to interconnect the GMR sensor elements and to connect them to the semiconductor underlayer. The final layer of metal also forms the pads to which wires will be bonded during packaging. A final passivation layer is deposited and windows are etched through to the pads.

CUSTOM AND SEMI-CUSTOM CHIPS- The process of designing, laying out, and fabricating a semiconductor chip can take several months and requires a significant investment which may be uneconomical for low volume applications. A custom chip provides the minimum size and cost since it is tailored to the specific requirements of the application. An alternative to custom designs for prototypes and for small volume applications is the semi custom design for which a standard semiconductor underlayer has been designed with a variety of semiconductor structures in place. These wafers can be stocked with all but the final metal layer completed. A prototype sensor can be designed to use combinations of these electronic components to deliver its desired performance. GMR material under a magnetic shield can even be used for any resistors required by the circuit. Only the masks for the last few layers need be designed, and the lead time for manufacturing new semiconductor wafers is reduced. On the down side, the chip may be larger than a custom designed chip, but for low volume applications and prototypes the slightly higher per chip cost is more than made up for by lower up front design costs and lead time. Figure 12 shows the layout of a semi-custom chip. Both the transistor underlayers and the GMR and plated magnetic layers are shown.

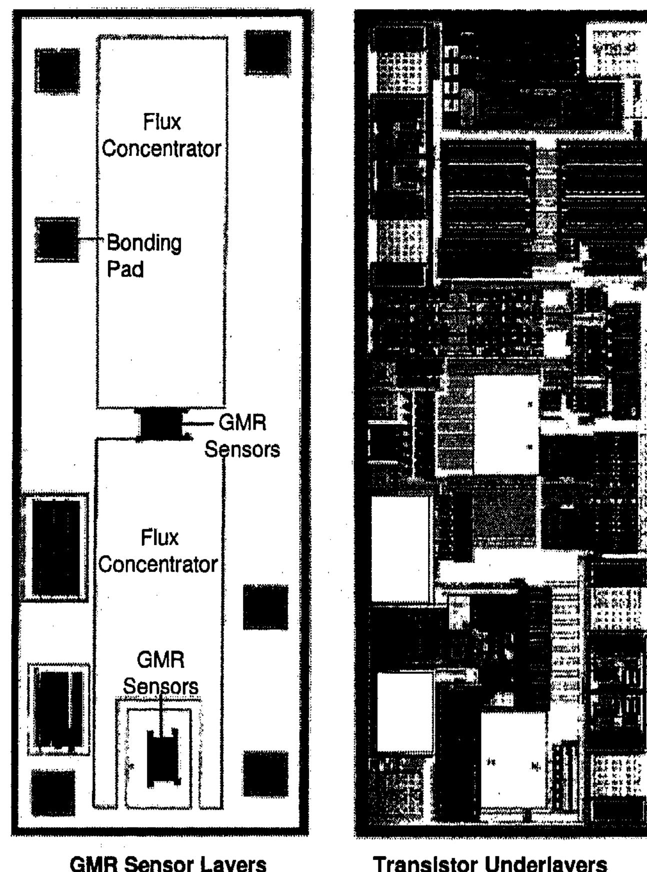

Fig. 12. Layout plots of a semi-custom integrated chip incorporating GMR sensor material. Views of the transistor underlayers without the GMR material and the final chip with GMR and magnetic layers are shown.

CONCLUSION

The discovery of the giant magnetoresistance effect has provided a new and exciting magnetic field sensing material with many applications. The methods of fabricating these multilayer thin films are directly compatible with both BiCMOS and Bipolar semiconductor technologies. Integrated sensors using GMR materials deposited on semiconductor underlayers show great promise for a new generation of sensors with improved cost and reliability for the automotive and other industries.

ABSTRACT

The development of a transducer for sensing the torque on the output shaft of a four speed rear wheel drive automatic transmission is described. Magnetoelastic polarized ring technology was selected based on its independence from shaft properties and its non-contact mode of sensing. The ring and several intermediate sleeves were attached by press fits onto an experimental shaft. The magnetic field arising from the ring with the application of torque was sensed by flux gate sensing elements. Ability to accurately measure the output torque of an engine driven transmission over its full range of torque and speed was demonstrated by dynamometer tests.

INTRODUCTION

Automotive transmissions serve to match the available torque and speed of the vehicle's engine (or other on-board prime mover) with the tractive effort required at the wheels to attain or maintain the speed and direction of travel desired by the driver. With a *manual* transmission, the driver, on the basis of experience and mastery of the required skills, willfully selects the gear ratio deemed most suitable for the specific driving circumstance (e.g., drive-away, acceleration, hill climbing). With an *automatic* transmission, the driver's desires, relative to the speed of the vehicle, are primarily signaled by manipulation of the throttle. The gear selection lever is repositioned only for directional control and to accommodate special driving conditions, e.g., descending long or steep hills. Based on the engine's response to motion and position of the throttle, as well as to incline and other conditions of the road, the transmission must be automatically guided to quickly select the *most appropriate* gear ratio. The determination of when best to shift from one gear ratio to another and the control of the complex series of events that actually effect the shift require a variety of sensory inputs and a stored knowledge (map) of the engine's speed-torque-throttle position characteristics. The driver's non-involvement with the actual mechanics of shifting results in a heightened awareness of accompanying sounds, vibrations and irregular accelerations. Thus it is the burden of the designer of an automatic transmission to not only ensure that the ratio best able to provide the efficient transfer of power from the engine to the wheels is selected, but that the actual shifting events will take place in a manner that is also smooth and maximally transparent to the driver.

The problem is complicated by variations in the engine map with engine temperature, barometric pressure (altitude), engine wear and between individual engines. It would appear that these problems could be simplified if the actual tractive effort was factored into the control of the transmission since this is the quantity most actively involved in executing the driver's speed demands. In the absence of braking, and except for the rotational inertia of intervening parts, the tractive effort at the wheels has a fixed (for any one vehicle) numerical relationship with the torque on the output shaft of the transmission. Thus, knowledge of the actual value of the instantaneous torque on this shaft should enable the development of improved shift control systems.

The potential for improving shift quality and other aspects of vehicle performance from signals representative of the torque on transmission shafts is well recognized [1-5]. Appreciation of the value of such information has stimulated many investigations into *estimating* this torque from indirect sources, e.g., computations involving engine and torque converter maps [4] or changes in shaft rotational speed [5]. Nevertheless no reports on the development of a *direct* torque sensing means that is sufficiently accurate, reliable and economical for use on production vehicles have yet appeared. This paper reports on the details of such a development.

DEVELOPMENT PROGRAM

A program aimed at developing a torque sensor to a stage sufficient to allow determination of its suitability for the intended use was outlined as follows:

1. Establish a *tentative* specification for the torque sensor. Consider the requirements in sufficient detail to identify preferred sensor locations, expected measurement range, operating environment and performance targets.
2. Critically examine known torque sensing technologies and select the one considered most appropriate for this application. (During this phase it was deemed important to maintain a constant awareness of the goal: a suitably accurate, extremely reliable, economically justifiable and mass producible torque sensor.)
3. Design experimental hardware.
4. Fabricate and assemble necessary parts.
5. Test experimental assemblies under static (non-rotating) loads and under unloaded rotational conditions.
6. Load test an assembled transmission on a dynamometer.

In-vehicle testing was not considered to be part of this development phase since such would clearly require the kind of preparation that would not be undertaken without encouragement from step 6 results. Because of the need to schedule dynamometer testing well in advance, static and unloaded spin testing of the shaft and skeletal sensor constructions were to be relied on to avoid seriously unpleasant surprises during dynamometer testing of the assembled transmission.

SPECIFICATION

The output shaft of a four speed automatic transmission used in front engine, rear wheel drive, light trucks and utility vehicles was selected for installation of a first generation torque sensor. A photograph of the targeted shaft as it normally exists without a sensor is shown in Fig. 1. The sensor was to be located in the region, forward of the speedometer take-off gear, indicated as A A on the photo.

Tentative target specifications were as follows:

- Location: Overdrive unit output shaft of Chrysler Model 44RE/42RE transmission.
- Shaft Diameter: 35 mm at sensor location.
- Shaft Material: Forged AISI/SAE 8620, Carburized, OQ & T (0.040/0.070" case, HRC 58/62) [6].
- Torque Range: 0-2700 N·m.
- Overload: 4700 N·m forward, 2700 N·m reverse.
- Speed Range: 0-5000 rpm (highest accuracy expected to be required in middle ranges).
- Resolution: <7 N·m (1 part in 400).

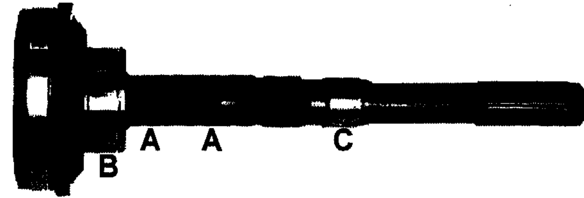

Fig. 1. Transmission output shaft. A A indicates torque sensing region. The shaft is supported in the overdrive housing by ball bearings at B and C.

- Linearity: Desired, monotonicity required.
- Hysteresis: TBD (rezeroing in neutral acceptable).
- Output Signal: 0.2 - 4.8 Vdc corresponding to 0-2700 N·m. CW or CCW directionality to be independently determined.
- Environment: Cast aluminum enclosure. Exposure to transmission fluids. Temperature range: -40 to +150 °C.
- Response: 30 Hz bandwidth (opening estimate).
- Power Supply: 12 Vdc system, as per SAE - J1211.

SELECTION OF TORQUE SENSING TECHNOLOGY

BROAD CLASSIFICATION - A wide variety of sensing technologies are embodied in the many available instruments for measuring the torque being transmitted by a rotating shaft. By one means or another these *torque transducers* all serve to provide an electrical signal that is a linear analog of the torque. All operate by sensing some manifestation of the shear stress which effectively transmits the torque along the shaft. While these devices are more commonly categorized according to their underlying operating principles, for the purposes here we find it more suitable to divide all torque transducers into only two, constructionally distinct categories, namely: those that utilize shaft mounted electrical components and those that do not. In consideration of the rigors of the present application, including circumstances that may arise during manufacture, assembly and repair of the transmission as well as the conditions of actual use, technologies utilizing shaft mounted electrical components were felt to be insufficiently robust. It was also felt that designs utilizing shaft mounted electrical components would be too labor intensive to be cost competitive. In fact, constructions relying on adhesively bonding any components to the shaft were deemed inappropriate. Thus, although strain gauges have been suggested for other automotive applications [7] and capacitive elements have been investigated for use on automotive axles [8], these technologies were not considered further. For similar reasons, as well as the absence of reports on their use in automotive applications, SAW devices [9] were also excluded from more detailed examination.

TORSION BAR - Technologies based on measurement of shaft twist angle were briefly considered. The angle of twist, θ, for a 35 mm diameter (*d*), SAE 8620 steel shaft (*G* = shear modulus = 80 GPa) under the full range torque, *T* = 2700 N·m, was found from

$$\theta = \frac{32LT}{\pi d^4 G} \tag{1}$$

to be only 0.0131° per mm of shaft length. Even if a clear gauging region 100 mm in length (*L*) could be made available, the angle measurement system would need to discriminate displacements as fine as 0.00328° in order to provide the desired 1 part in 400 resolution. Such resolution challenges even instrument grades of "torsion bar" torque transducers, e.g., those based on the light passing through axially spaced optical shutters [10]. It was judged as unlikely that variable reluctance systems, such as those developed for automotive power steering applications (wherein typical twist angles are between 4° and 7° [11]), could be sufficiently refined for use with shafts having the required torsional stiffness. While this difficult angular resolution requirement could be relaxed by reducing the shaft diameter in the gauging region, this would risk plastic yielding of the shaft under peak torque conditions. Also, increasing shaft compliance would alter the spectrum of torsional oscillations in the drive train, with possibly serious adverse consequences. For these and other reasons associated with the manufacturability of needed high precision components, this approach was not considered further.

MAGNETOELASTIC (PERMEABILITY) - Detailed attention was directed to magnetoelastic (often called, "magnetostrictive") torque sensing technologies. It is well known that stress acts to alter the orientation of the *spontaneous magnetization,* the presence of which characterizes a material as ferromagnetic [12]. (Magnetomechanical effects due to stress manifest an intrinsic magnetoelastic interaction generally present in this class of materials.) Among the consequences of this stress induced magnetization reorientation are changes in the permeability of a stressed sample from measured values when in the unstressed condition. The utility of this phenomenon for the measurement of torque on a rotating shaft can be readily appreciated since magnetic coupling enables the determination of properties such as permeability without any need to physically contact the stressed body. The further attractiveness of utilizing changes in the magnetic properties *of the shaft itself* in order to determine the torque being transmitted is obvious. Fleming [13] has studied and compared three common configurations of torque transducers that develop their output signals from stress induced permeability changes.

Although well understood and seeming to be ideally appropriate, reported efforts to use these methods on powertrain shafts nevertheless fail to demonstrate suitable accuracy over the required torque and temperature ranges. The underlying problem stems from the fact that powertrain shafts are designed to fulfill demanding mechanical functions.

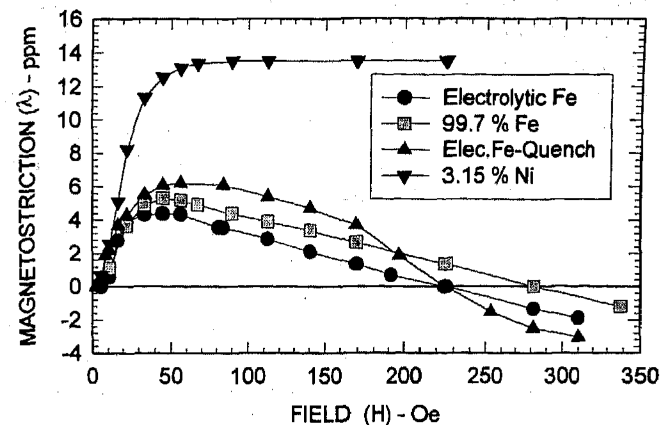

Fig. 2. Effects of composition and thermal history on the magnetostriction of iron and dilute alloys.

Except for those instances when torque sensing is the overriding concern, e.g., in commercial torque transducers, the choices of shaft size, material, fabrication methods, heat treatments and other processing steps are all aimed at meeting mechanical performance and cost criteria. The influences of composition and processing conditions on magnetic and magnetoelastic properties of the shaft are only rarely considered [2, 14]. One generally ignored property, *magnetostriction* (λ), plays an essential role in determining both the direction and amplitude of changes in permeability with stress [15]. While *saturation* magnetostriction (λ_s) [16] is an intrinsic material property, the variation of permeability with stress follows from the variation of magnetostrictive strain ($\delta l/l = \lambda$) with applied field (H), and this is a sensitive function of microstructure as well as composition. Data plotted in Fig. 2 (taken from Schulze [17]) for some dilute alloys of iron clearly shows these dependencies. The reversal in sign of λ seen in all but the 3.15% Ni-Fe alloy is reflected in a variable *direction* of change in permeability with stress in these materials (the *Villari* reversal [18]). Shaft materials exhibiting a Villari reversal are clearly not good choices for this means of torque sensing. SAE 8620 [6] has too little Ni, Si, Al or Co to squelch the non-monotonic λ vs H characteristic found in iron, its principal constituent.

The effective permeability of a shaft surface, even in the absence of stress, varies significantly with temperature as well as with composition and microstructure. Moreover, the term, "permeability" does not define a single, material dependent property, since its value, and the manner and range of its variability with stress, depends on the amplitude and frequency of the measuring field (as well as on other, more incidental influences on shaft magnetization, e.g., the earth's field). Thus, such performance characterizing features as linearity, hysteresis, dynamic range and temperature effects are all dependent on the excitation field parameters in this class of torque sensors.

Additional complications pertinent to this specific application include the potential for drifting calibration caused by *irreversible* changes in permeability associated with stress excursions beyond the endurance limit of the shaft material during peak overloads. Similar drifts would accompany even

subtle microstructural changes associated with prolonged time at temperatures in the tempering range. These, in addition to concerns with normal shaft to shaft variations in characteristics affecting calibration, were considered serious enough to eliminate "permeability" forms of magnetoelastic torque transducers from further consideration. (The existence of the problems associated with the inappropriate and inconsistent magnetoelastic properties of typical shaft materials are well recognized [1, 2, 3, 7, 14, 19, 20, 21]. Persistent attempts at solving these problems, by e.g., characterizing individual shafts [19], ad hoc material development [20], attachment of sleeves of more suitable materials [21] or even remote variations on this basic sensing theme such as inducing eddy currents in Cu conductors electroplated on the shaft [3], have yet to demonstrate adequate performance for this demanding application.)

MAGNETOELASTIC (POLARIZED RING) - By avoiding dependence on permeability, inconsistent or unstable magnetic properties of the shaft do not affect the operation of magnetoelastic torque transducers employing magnetically polarized ring constructions [22]. Figure 3 shows the arrangement of functional elements comprising this type of transducer. The transducer consists only of a ring of magnetoelastically active material attached to the shaft in such manner as to assure that they act as a single mechanical unit and a proximate magnetic field sensor. (Mechanical attachment of the ring to the shaft is most often accomplished by a simple press fit.) As indicated in the figure, the ring is magnetically divided into two regions having oppositely directed circumferential polarizations. When torque is applied to the shaft these polarizations become more or less steeply helical; the ring effectively develops magnetic "poles" uniformly distributed around its central band (indicated in gray) and, of opposite polarity, at its ends. The strength and polarity of the magnetic field associated with these poles is linearly analogous to the magnitude and CW or CCW

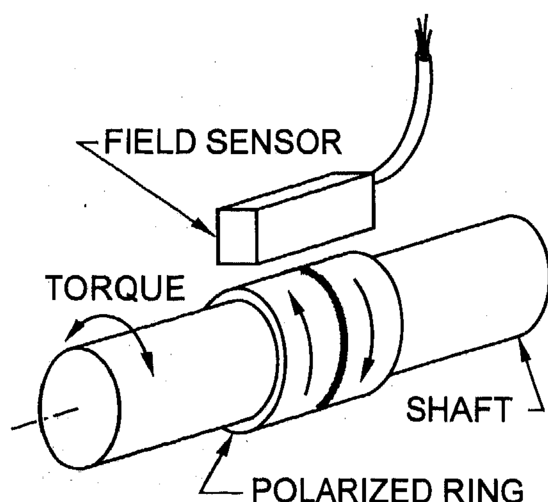

Fig. 3. Functional elements of a polarized ring torque transducer. The arcuate arrows indicate the directions of remanent magnetization (i.e., polarization) in each ring region. When torque is applied, magnetic poles develop along the gray band and at each of the ring ends.

directionality of the applied torque. The output signals from one or more magnetic field sensors thereby provide the measure of the torque. (Further explanation of the operating principles and related details can be found in the referenced technical and patent literature [22-25].) The sensitivity, i.e., the field intensity per unit of torque in this type of transducer is based primarily on the size and *intrinsic* material properties of the polarized ring. This, in combination with other features, including the complete absence of any form of excitation field, greatly simplifies (or may even eliminate) individual transducer calibration. A properly constructed transducer of this type will, by its nature, generate no field (i.e., zero) with zero applied torque, independent of its temperature. Hence, temperature compensation, if needed at all, would be limited to transducer sensitivity (i.e., the "span") and would expectedly be generic for any one design. Calibration drift due to thermally induced microstructural changes in the ring is unlikely since typical rings undergo final heat treatments at 483 °C (for 3 hours), far above the specified maximum operating temperature. The simplicity of the construction portends a reliable and economical device. All of these clearly desirable features, together with advances in the technology development and experience in its use since first suggested for electric power steering applications [25], directed its selection for this application

TRANSDUCER DESIGN AND CONSTRUCTION

GENERAL - Although the functional elements shown in Figure 3 comprise a complete torque transducer, two factors associated with the existing transmission shaft (Fig. 1) necessitated the use of additional components, at least at this experimental stage of development. Firstly, as with all applications involving shafts made of ferromagnetic steels, it is found desirable to interpose a non-magnetic spacing ring between the magnetically polarized ring and the shaft. Spatial separation of the field generating ring from the shaft allows more of the magnetic flux to follow paths through the space on the outside of the ring where the field sensor(s) are located. If the ring is mounted directly on a typical ferromagnetic shaft, nearly 90% of the generated flux will take lower reluctance paths through the shaft and thus not be available for sensing. Besides reducing this loss, spatial separation minimizes any effects that incidental shaft magnetization may have on the operation of the transducer. It has been found in some applications that an austenitic stainless steel "insulating" ring having a radial thickness as small as 1 mm reduces the flux loss to less than 25%. Greater thickness will naturally be even more efficient.

The size (diameter in the sensing region) of the presently available transmission shaft made it necessary to add still another component (ring) to the basic construction. Since the polarized ring generates a magnetic field in proportion to the torsional (shear) stresses over its cross section, it is important to ensure that these stresses accurately reflect the *applied* torque and *only* the applied torque. Should there be any plastic yielding within the shaft or ring, or any slip at their interface under any conditions of applied torque, the stresses will not uniformly relax to zero when the torque is removed.

Under such inelastic conditions there will be a *residual* stress distribution over the cross section with the ring stressed in the opposite direction to that which existed when the high torque was applied. The magnetic field arising as a result of this residual stress will be sensed as a torque even though the applied torque is zero. The field sensor output signal at zero applied torque will thus be different (i. e., there will be *hysteresis*) depending on whether inelastic events occurred during CW or CCW applied torques. Hysteresis will also be manifested as differing values of output signal for the same value of torque, depending on whether the torque is increasing to, or decreasing from, a torque high enough to cause inelastic events. While zero shifts at zero torque can be electronically eliminated (by resetting the signal when in neutral) and minor hysteresis is of little practical concern, it is clear that yielding of the shaft and interfacial slip would best be avoided.

MECHANICAL DETAILS - The extent of this problem and its solution are readily understood from the following analysis. The shear stress associated with the transmission of a torque, *T*, through a shaft of diameter, *d*, varies from zero at the center to a maximum value (τ_m) at the surface, found from

$$\tau_m = \frac{16T}{\pi d^3}. \tag{2}$$

For $d = 35$ mm, under the peak overload torque of 4700 N·m, τ_m will reach 558 MPa. While no torsional yield strength data for carburized 8620 steel has been found, considering that the tensile yield strength (0.2% offset) for the core of a bar of this size is almost certainly ≤ 800 MPa [6], and that the torsional yield strength of steels is typically about 57% of the tensile value (i.e., $\tau_y \leq 456$ MPa), yielding of some portion of the cross-section under overload conditions seems likely. An obvious solution is to enlarge *d* in the region where the ring is to be installed and such would expectedly be the eventual course of action. Presently limited by the existing shaft dimensions, it would appear that *d* could be effectively increased by simply increasing the wall thickness of the spacing ring. After a moment's reflection, it will be realized that the shear stress in each ring is transferred to it via frictional forces arising from the contact pressure at all underlying interfaces. Without unlimited, independent control of friction coefficients, high interfacial contact pressures are required. Except for some exotic (read: expensive) Ni based alloys, non-magnetic materials have insufficient strengths to act elastically under the required contact pressures. Hence it was considered necessary to build up the effective diameter of the shaft in the sensing region by pressing on a heat treated steel sleeve. The problem was further complicated by the fact that the shaft in region AA (Fig. 1) was not sufficiently larger than the bearing journal at C to obtain the desired interference. The shaft was thus built up to the desired diameter by means of *two* hardened steel sleeves, sized such that mounting,, by pressing on the outer one, increased the contact pressure between the inner one and the shaft. To avoid distortion under the heavy press-on forces required, and to provide better control of the alignment of the parts during their assembly, each interface was machined to a shallow taper (typical

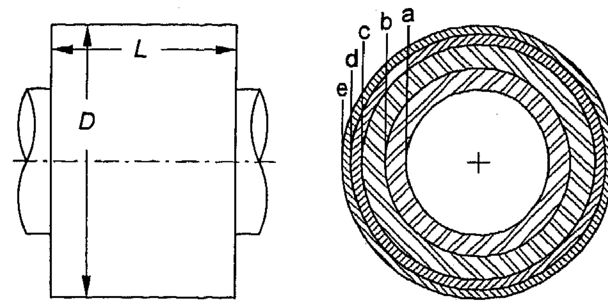

Fig. 4. Details of experimental ring assembly. Inner two rings - OQ & T AISI 4340; "Insulator" ring - Carpenter 22 Cr 13 Ni 5 Mn; Outer ring - Teledyne Vasco C-250, aged 3 h @ 483 °C. Axial length L = 45.7 mm. Outside diameter = 66.0 mm. Nominal radii at each indicated interface: a = 17.6; b = 22.9; c = 28.7; d = 31.2; e = 33.02.

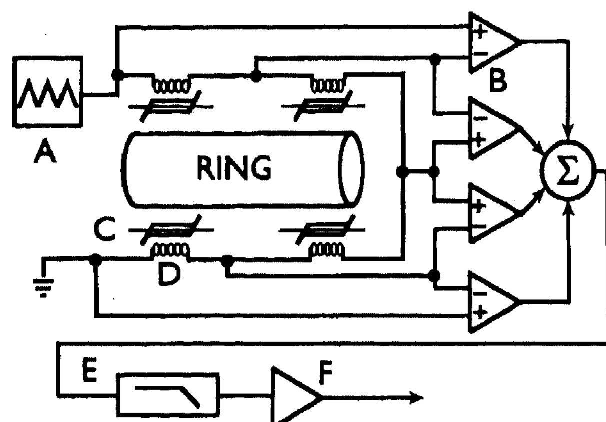
included angle ≈ 1°). Figure 4 shows the details of the final assembly design.

It is of course, only the outermost ring of the four ring set that has an active role in the torque *sensing* function. The use of an interference fit for this ring served the dual purposes of assuring the mechanical integrity of its attachment to the underlying "shaft" and instilling a circumferential tensile (hoop) stress. This is needed to establish the circumferential direction as the stable orientation for the remanent magnetization. An 18% Ni maraging steel was chosen for this ring on the basis of its high strength and desirable magnetic properties [26]. Although it was not considered necessary for the magnetically polarized ring to be any longer than 20-25 mm in order to fulfill its transducing function, it was thought best at this stage to keep all rings the same length in order to reduce the possibility of slippage at any of the interfaces.

MAGNETIZATION - The two, oppositely polarized regions in the outer ring were instilled by simply holding a North-South/South-North pair of bonded ferrite magnets close to the ring surface while rotating the shaft (for about 100 revolutions) [22]. The polarizations were circumferentially homogenized by passing an approximately 300 peak ampere, 60 Hz current, axially through the shaft.



FIELD SENSOR - In general, the magnetic field that arises when torque is applied to the shaft can be sensed by any of several suitable means. Both Hall effect and "flux gate" sensors [27] were used for static load and unloaded spin testing of the experimental transducer shaft. Since the output signals from presently available Hall effect devices often drift with temperature, a flux gate design, having an inherently stable and temperature independent zero field output signal, was chosen for installation into the transmission housing. At this stage in the development it was thought prudent to avoid possible problems from shaft runout, bending stresses or other sources of circumferential inhomogeneity by combining the signals from two, diametrically opposed, sensor pairs. The actual sensors consisted of small diameter, solenoidal windings of high temperature insulated magnet wire, each encircling a single strand of near zero λ_s amorphous wire

(Unitika DC2T). These core/coil "assemblies" were cemented into grooves machined into an aluminum ring that had been turned to fit an axially concentric bore already existing in the overdrive housing. The radial air gap between the ring and sensor surfaces was 0.5 mm.

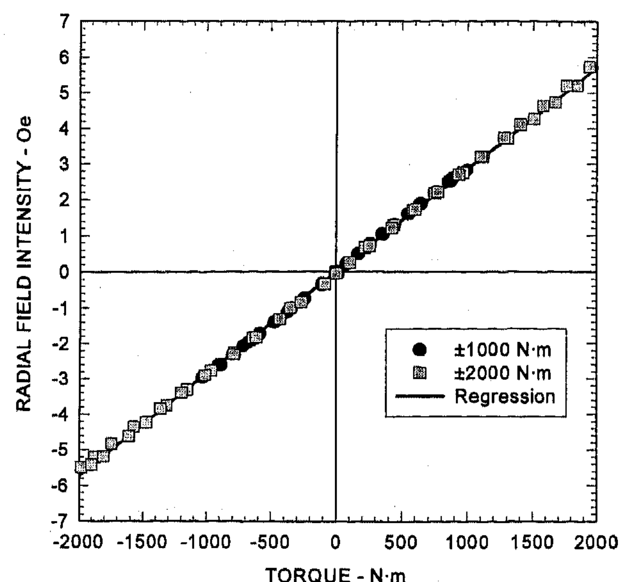
ELECTRONICS - Figure 5 shows a block diagram of the circuit used with the core/coil assemblies to obtain a field (hence torque) dependent signal. Details of its operation are described in the (lengthy) caption.

TESTING

STATIC TESTS - An apparatus for applying controlled and accurately measurable torques to the stationary shaft was constructed. The shaft was firmly clamped at the forward (large) end, while, through a system of links and levers and a yoke having a matching internal spline, torque in the form of a force couple was applied to the free end. The push and pull forces comprising this couple were applied through tension/compression strain gauge load cells. The forces were

A - Triangle Wave Oscillator
B - Comparators
C - Square loop wire cores
D - Coils
E - Low Pass Filter
F - Output Buffer
Σ - Summing Amplifier

Fig. 5. Block diagram of electronic circuit used with the flux gate field sensors. The triangle wave current (≈ 13 kHz) through the coils sweeps the core wires through major hysteresis loops. In the absence of torque, the magnetization within each of the cores reverses at the same amplitude of coil current. When torque is applied, the associated magnetic field adds to the excitation field on the cores adjacent to one region of the ring while subtracting on those adjacent to the other. Since all core magnetizations reverse at one characteristic value of *effective* field, the cores adjacent to each region now reverse at different current amplitudes, i.e., at different times in the triangle wave. The comparators, which in the absence of torque spend equal (half) periods with high and low outputs, now have asymmetrical high and low periods. Their average outputs, after summing, filtering and buffering, thereby vary up or down depending on the field amplitude and polarity, hence on the torque amplitude and direction.



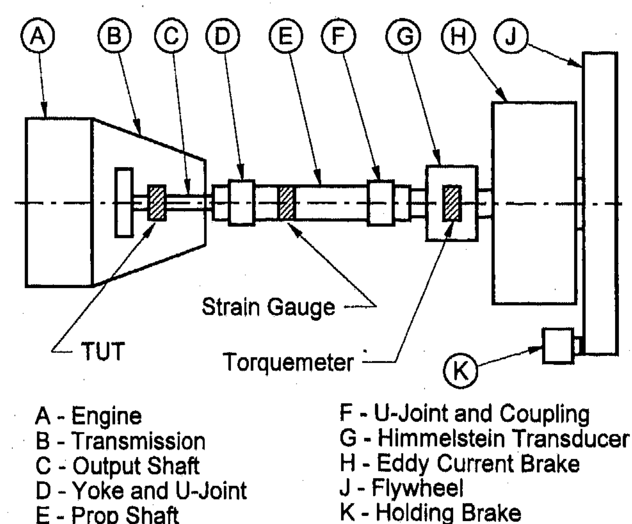


Fig. 6. Variation in the radial field intensity appearing near the axial center of the ring with applied torque. (Distortion of the yoke and load cell limitations prevented accurate exploration at much higher torques.)

produced by a hydraulic "jack" which, by its placement at one or the other end of a lever, provided for the application of CW or CCW torques. A commercial gaussmeter with Hall effect probes was used to measure the actual radial and longitudinal field intensities in the space around the ring. Typical data obtained for complete cycles of increasing and decreasing torques in each direction are plotted in Fig. 6. The excellent linearity and minimal hysteresis are clearly indicated.

DYNAMIC TESTS - After assembly of the overdrive components to the shaft and further assembly into the housing, the overdrive unit was attached to a Chrysler 44RE transmission. The transmission, coupled to a 4.0 liter 6 cylinder in-line engine, was installed in a fully instrumented

J - Flywheel
K - Holding Brake

Fig. 7. Arrangement of apparatus used for dynamic tests. The shaded areas indicate the three torque measuring devices.

dynamometer test cell. The driveline arrangement is schematically illustrated in Fig. 7. In addition to the measurement of the output signal from the transducer under test (TUT), torque was measured by a custom built and calibrated strain gauge bridge installed on the prop shaft and by a Himmelstein Model MCRT 8-02TA Torquemeter (rated for 50,000 lb.·in. up to 5000 RPM). Other measured parameters included: engine speed, throttle position, output shaft speed and transmission oil temperature.

All measurement data was sampled at rates appropriate to the specific test and acquired by computer. All details of the test regimens were under computer control except for the selection of the transmission gear ratio. This was either allowed to change automatically by the normal operation of the transmission or else continuous operation in first gear was manually selected. Testing followed several different regimens. For example, while the transmission was kept in first gear, targeted values of speed and output torque were established by interactive adjustments of the throttle position and dynamometer brake current. While some data was collected in this way at various output shaft speeds and torques, one limitation or another prevented the attainment of steady state operation at high enough torques to fully test the transducer. Automatic test cycles provided more interesting data. Prior to the beginning of each such cycle, the output shaft was held stationary by the holding brake on the flywheel while the engine idled. The test was launched by simultaneously releasing the brake and snapping the throttle to a preestablished opening. The engine would accelerate more or less rapidly depending on throttle position and the transmission stepped through its gear ratio changes as the flywheel reached appropriate speeds. After reaching the limiting output speed, the throttle was cut and the flywheel was brought to a halt by the eddy current brake. Tests of this nature were performed for approximately 10% increments in throttle position. Data (at 100 samples/s) from one test run at full throttle (nominally 100%) are shown in Figures 8-12.

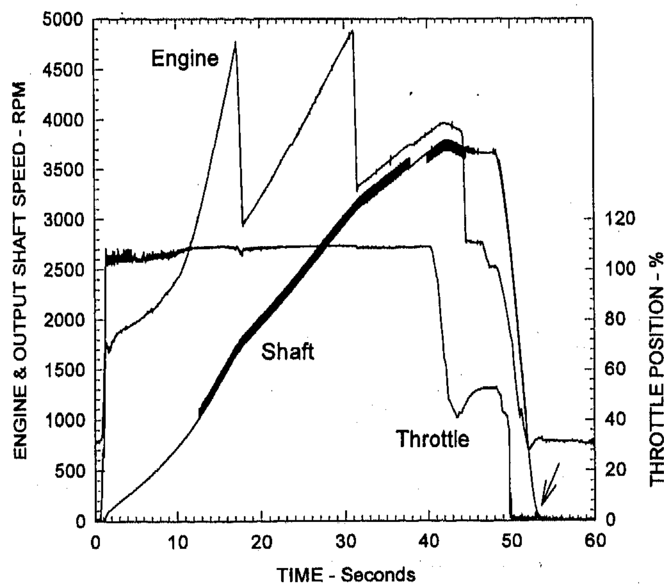

Fig. 8. Variations in engine and output shaft speeds (and throttle position) during 100% throttle automatic test cycle.

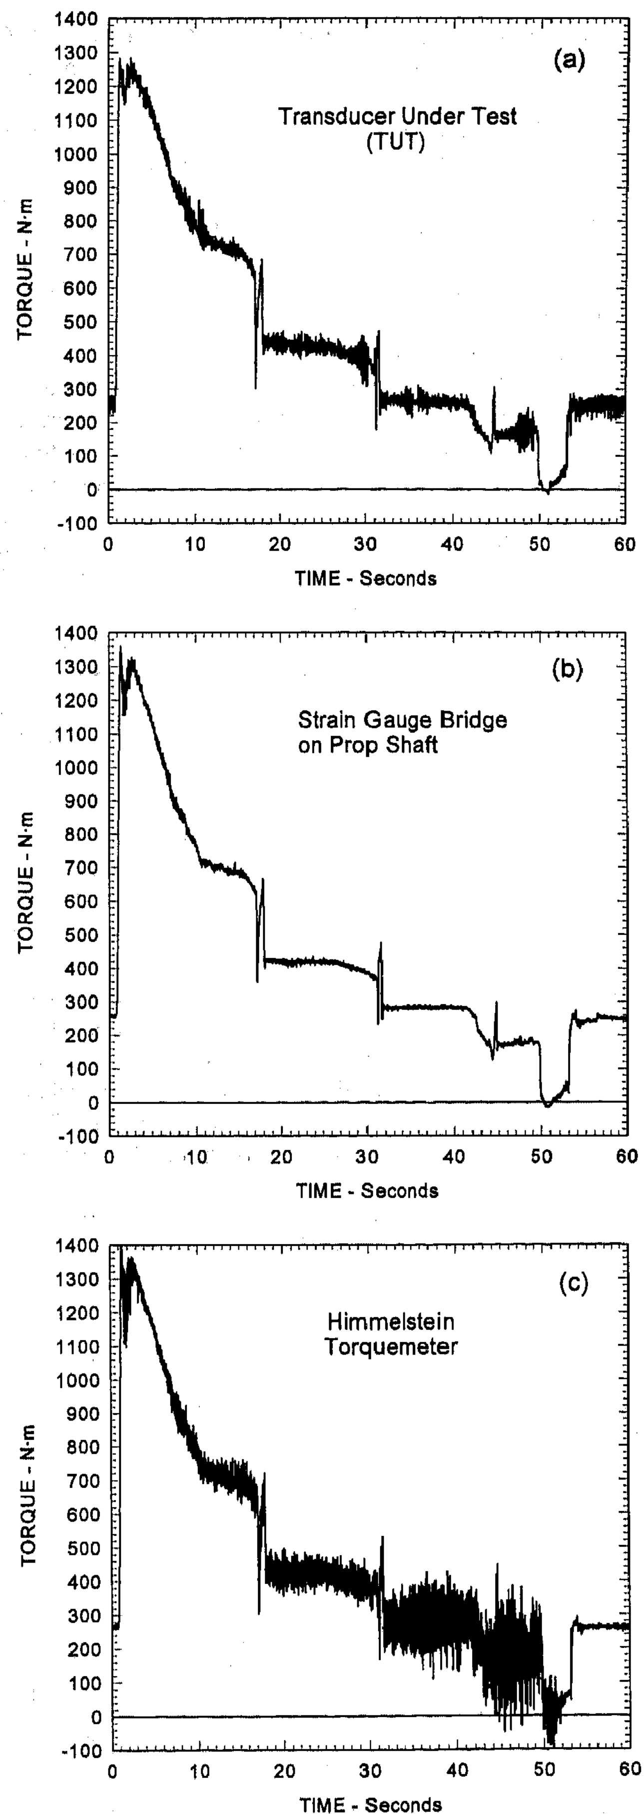

Fig. 9. Torque as measured by: (a) the TUT; (b) the strai gauges on the prop shaft; (c) the torquemeter.

The progression of active events throughout the 60 second duration of the automatic test cycle is shown in Fig. 8. Following the opening of the throttle, which effectively starts the test, the output shaft is seen to undergo a continuous acceleration as the transmission steps between first and second and second and third gears, while decelerating slightly prior to the shift into overdrive. The throttle was cut to about half open just before the shift into overdrive, near 45 seconds into the test, after which the eddy current brake was applied and the throttle shut (near 49 seconds) bringing the shaft to a halt slightly after 54 seconds.

Figure 9 shows the variation in the output torque as indicated by each of the three measurement devices shown in Fig. 7. This figure shows that the measurement of torque under the dynamic conditions found in engine/transmission drivelines is not a simple matter. The precise answer to the question, "What is the magnitude of the torque?" is seen to depend on the type and location of the sensor. While this complicates the performance assessment of any torque measuring device under study, it also shows that there is a wealth of information that torque measurement can provide.

The "noise" seen to be present in varying degrees in these three figures is not noise in the classical sense but represents actual torque variations experienced by each sensor; different in each due to torsional oscillations. It is quite normal for the dynamic torques on a distributed system containing elements of varying compliances and inertial masses to vary from location to location. This is readily seen by examining the expanded data shown in Figs. 10-12. While the TUT is seen to provide an average signal that for the most part accurately follows the prop shaft strain gauge data, a superposed oscillatory signal of $\approx$ 9 Hz is seen to be pervasive. This signal component is believed to have arisen from oscillations of the engine on its mounts, a conclusion supported by its presence even when the output shaft was stationary, e.g., as seen in Figs. 9 and 10 during the first one

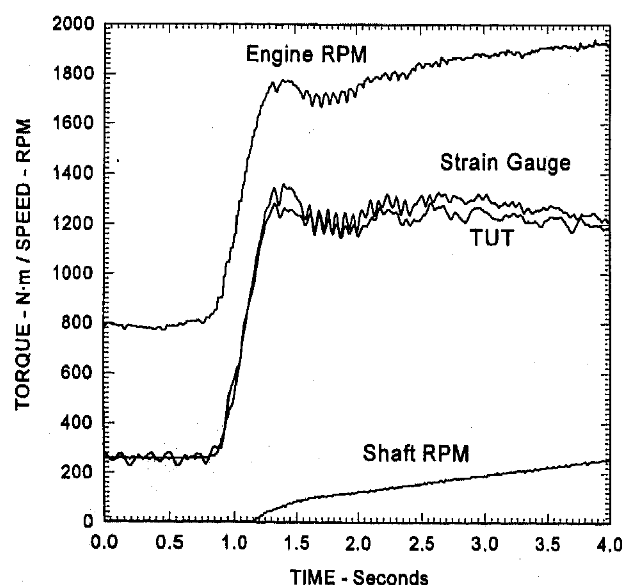

Fig. 10. Variations in engine RPM, shaft RPM and torque, as indicated by both the strain gauges on the prop shaft and the TUT on the transmission output shaft, during the first 4.0 seconds of the automatic test at full throttle.

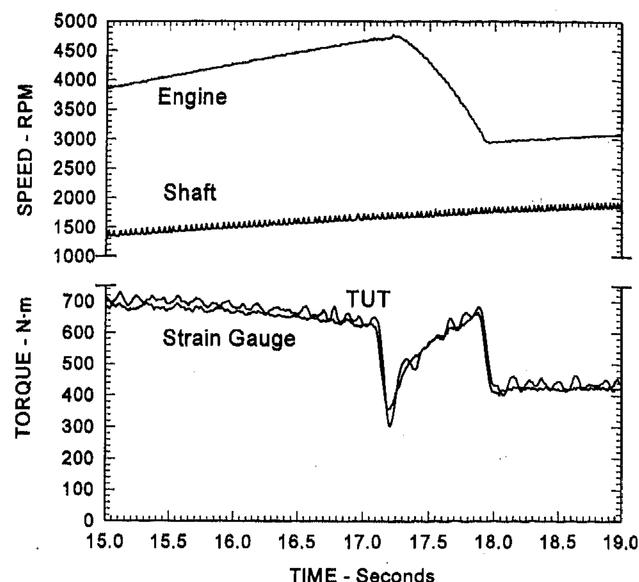

Fig. 11. Variations in engine RPM, shaft RPM and torque, as indicated by both the strain gauges on prop shaft and the TUT, during shift from first to second under full throttle conditions.

second of the test and in Fig. 9 (and the right end of Fig. 12) during the last 6 seconds of the test cycle. These oscillations are seen to be stimulated to substantial amplitudes, both in particular engine speed ranges and during rapid changes in engine acceleration accompanying shifting events and throttle changes. Chaotic and severe bouncing of the engine and transmission was observed during the tests but no records were made to correlate the timing and extent of such events.

Torsional oscillations in the torquemeter records are seen in Fig. 9(c) to be even more severe, but these were of a higher frequency ($\approx$ 13.5 Hz), reflecting a resonant association of the torquemeter compliance with the flywheel and dynamometer

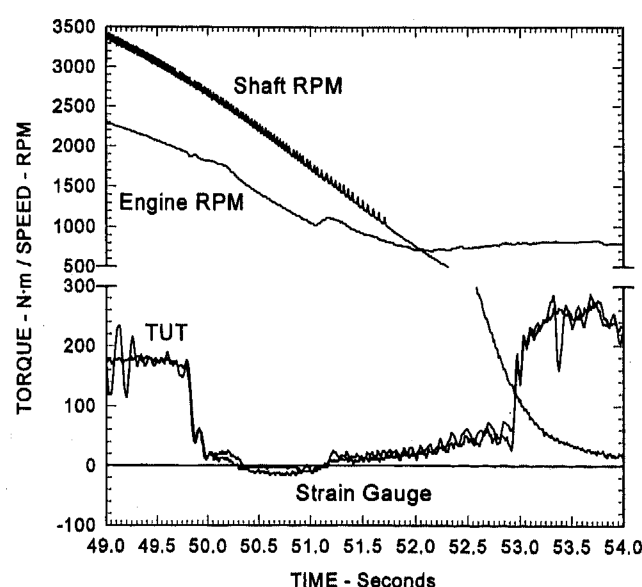

Fig. 12. Variations in engine RPM, shaft RPM and torque, as indicated by both the strain gauges on the prop shaft and the TUT, during final throttle shut down. As seen by the arrow in Fig. 8, the throttle "bounced" to almost 5 % near 53 seconds.

rotor inertias. These oscillations are seen to have been absent (as would be expected) when the output shaft was stationary at the beginning and end periods of the test cycle. The prop shaft is seen to be largely free of the large oscillatory torques found at both ends of the driveline. This too is expected since this shaft is insulated by the compliance of the U-joints and the non-linearity of the torque and velocity transfers associated with the angularity of the coupled shafts.

Other than for the additional oscillatory torque, the TUT signal is seen to track the prop shaft data quite accurately at all torque levels except those over about 1200 N·m. The torque indicated by the TUT is clearly seen, by the expanded data in Fig. 10, to be consistently low from 1.2 - 4 seconds into the test. Since no such fall-off in sensitivity is seen in the static data plotted in Fig. 6, it would appear that a saturation problem may exist in the transfer function of the flux gate sensor. While this certainly needs to be investigated, it is also interesting to note that, as indicated in Fig. 9, the peak torque indicated by the torquemeter *exceeds* that shown by the prop shaft by a similar amount in the same region.

The expanded data in Figs. 10-12 provide an opportunity to examine both the ability of the TUT to follow transient torques and to observe the large amplitude that the oscillatory torques can reach when stimulated, as well as the rapidity with which these are damped.

During the many tests that were performed, over a period of several hours, the transmission oil temperature varied only from RT (≈ 20 °C) to 76 °C, only a small fraction of the specified operating range. Nevertheless, within this limited range no significant changes in the performance of the TUT were observed.

CONCLUSION

It is recognized that the developments reported here are but the first steps towards the ultimate application of torque transducers in automotive transmissions. Even at this early stage of development the described transducer clearly shows the ability to accurately measure the actual transmitted torque using simple and reliable hardware. As the technology advances, it can be reasonably expected that performance will be even further improved. A possible additional benefit from the use of this polarized ring technology is the reduction in overall sensor count, since adaptations of the basic technology have already been shown to provide rotational speed information in the transducer signal [28].

Next steps in the development will include further dynamometer tests utilizing a larger engine and more sophisticated loading means. This will allow dynamic testing up to the full specified CW and CCW torques, including excursions into the overload range. Following this, there will undoubtedly be extensive in-vehicle testing to provide the data necessary for the development of suitable control algorithms. Only then can it be determined whether actual torque measurement on automotive transmission shafts can provide the anticipated benefits.

ACKNOWLEDGMENTS

We would like to express our thanks to Hong Liu for her invaluable assistance with the FEA design and stress analysis of the ring system and to David Cripe for his design and construction of the field sensors and associated electronics. We would also like to thank the managements of our respective organizations for their support and encouragement.

Adaptive Light Pattern - A New Way to Improve Light Quality

Henning Hogrefe and Rainer Neumann
Robert Bosch Corp.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

In most cases of night time driving the low beam light function is used for the road illumination in front of the car. This conventional low beam function has a constant light pattern: no matter whether the driver is actually driving on a straight or curvy road, whether the road is wet or dry, always the same beam pattern is applied. Test experiences of the last years prove that a headlamp with an „adaptive light pattern“ having different optimum light pattern adapted to different driving situations should give a better illumination than the conventional constant low beam pattern which can only be a compromise.

In this paper an outline of the basic idea of the „adaptive light pattern“ is given. Different driving situations and their corresponding optimum light pattern, basic technical concepts and the legal situation regarding homologation of such an advanced lighting system will be discussed.

INTRODUCTION

Automotive headlamps provide for each of the basic light functions (low beam, high beam and fog beam) a fixed static light pattern. Some thirty years ago 200-300 lumen were a good total luminous flux for a low beam headlamp. This amount of light was at best enough to illuminate the most important parts of the driver's night time viewing zone.

All lighting regulations and techniques were set up to ensure a minimum light quality using available light sources.

The introduction of halogen bulbs around 1965 greatly improved the light quality. In the eighties two-reflector-headlamps for separate low and high beam and advanced reflector technologies further increased the amount of light available for the street illumination.

Now, a low beam light volume of 500 lumen and more can be achieved using halogen bulbs in combination with advanced reflector techniques or even 1000 lumen using gas discharge lamps (HID). Having reached this state of lighting performance the question arises, in which direction further development should be continued. Shall we add, as in the past, more and more light - if technically available - into the static light pattern giving more and more intense illumination in the hot spot or broader side illumination? Recent HID-light pattern applications have shown very good results on this way (Ref. 1, 2).

Another very promising alternative is to direct the available light dynamically into the direction where it is actually needed. Why illuminating the hot spot with full power while driving with low speed on a windy road? Why wasting many lumen on large lateral side illumination while driving with high speed on a straight highway? Hence, the idea is to have a dynamic or „Adaptive Light Pattern“ (ALP) which always supplies an adapted, optimal light performance for the actual driving situation.

The legal regulations are not yet completely ready for this innovative concept but the technique is now under full development. The ALP topic can cover a wide range of lighting aspects. We want to concentrate here mostly on the main headlamp functions, especially the low beam, because there seems to be the highest potential for improvement of night time traffic safety.

ALP - AN INNOVATIVE LIGHTING CONCEPT

During night time driving the automotive lighting equipment is responsible for illuminating the driver's viewing field under many different driving situations, street and traffic conditions. The following parameters characterize most of these situations:

- Speed:	low - medium - high
- Road condition:	dry - wet - slippery
- Course of the road:	straight - curvy - intersection ...
- Road topography:	flat - hilly
- Road type:	highway - country - city...
- Viewing conditions:	clear - rain - fog - snow
- Ambient illumination:	dark - street lights ...
- Traffic density:	low - medium - high
- Driver:	age - driving skills ...
- Other parameters:	country, tunnel ...

At the same time the car must be visible to other traffic members without causing glare or other irritations. Regarding this complex task the conventional static headlamp light pattern can only be a compromise. Usually most of the flux available for static illumination is directed to the central parts of the viewing zone including the range zone of the low or high beam (approx. ± 5° hor./vert. of driving direction). In this zone we certainly have the highest demand for good illumination and therefore also the highest requirements by current ECE and SAE standards.
The rest of the available static beam flux is more or less scattered to the left and right sides of the viewing zone. This light pattern is a compromise in the sense that it fairly covers the most important viewing zones but only to some extent the special zones needed for example for curve illumination, fog conditions, etc. This compromise is only for those headlamps a very good overall solution that have a total flux almost as high as in the case of HID headlamps. But the general idea - even for high flux systems - is, that light (e.g. foreground illumination), which is beneficial in the static beam pattern under normal driving conditions is most likely undesirable in some other situations (e.g. wet roads).
These basic considerations about the static and dynamic light pattern seem to be obvious but they have to be verified by scientific investigations.The goal is to evaluate the potential benefits of a dynamic or adaptive light pattern compared to the conventional static light pattern. Independent from basic research, a few technical realizations using rotatable reflectors have been presented years ago (e.g. Ref. 3, 4). First internal field tests and other investigations (Ref. 5, 6, 7) now prove that for most of the above mentioned driving situations different light pattern must be required to obtain an optimal illumination.
The finding is, that no static light pattern, even the sum of all individual light pattern, can deliver the overall optimal headlamp beam pattern. The philosophy of „Adaptive Light Pattern" can achieve this goal by means of detection of the actual driving condition and subsequent switching to the well-adapted light pattern.

The European ECE regulations do not yet allow the realization of the ALP concept. Both, the application of multiple light sources in one headlamp and moving beams are considered as important technical realization possibilities for ALP as will be pointed out in the next section. But it is neither permitted to use more than 1 light source for the low beam function within one headlamp (and more than 2 light sources each for high beam and fog beam) nor is it generally allowed to apply a movable or rotatable reflector.
There is an exception of this practice: an additional secondary high beam may be horizontally rotatable. Reflector parts may also be movable as long as their optical axis is not moved. Also, it is not explicitly forbidden to have adaptive low, high or fog beam if the adapted light pattern always fulfills the current regulation.
A European EUREKA project called AFS (Advanced Frontlighting Systems) with all major European bulb, headlamp and vehicle manufacturers participating (Ref. 8) has been established to make studies and proposals for new regulations to overcome the current restrictive ECE homologation practice. In the second phase the AFS working group is now testing the basics and limits of adaptive lighting in order to propose new regulations in the third phase.
The US Federal Register, Part 571 (FMVSS 108), for automotive lighting is not as restrictive as the European ECE regulation but the subject also is not yet explicitly introduced.

Once we have realized the potential of adaptive lighting in general and supposed there will be some regulatory framework in a few years, what

what kind of variations can be introduced by ALP? Various adaptation possibilities can be thought of:

- Adaptation of low, high or fog beam pattern
- Integration or combination of low, high and fog beam into one beam
- Adaptation of a headlamp to different standards: ECE left hand drive, ECE right hand drive, USA, Japan
- Variation of shape of the cut-off of a low or fog beam
- Variation of beam inclination
- Variation of the signal image of a headlamp (the appearance to opposing traffic)
- Variation of brightness or colour
- On/off - automatic switching of beams

...

The first tests and investigations already mentioned above allow some preliminary conclusions which help to select the most important variations and parameters for „Adaptive Light Pattern" headlamps:

Experimental Experiences:

- Speed is a suitable control parameter
- Distinction between city traffic, 25 Mph-zones, rural roads and highway is meaningful
- Oncoming traffic on rural road: Enhanced SPOT is advantageous
- Turns at intersections: Increased side illumination is very much welcomed
- Driving in convoy: Spot illumination should be reduced in favour of large side illumination
- Wet roads: Reduced foreground illumination helps to reduce glaring reflections to oncoming traffic
- Switching between different light pattern components should be harmonic and not too abrupt

Some of these conclusions are nicely illustrated in Fig. 1 showing schematically different driving situations from the bird eye's view and their adapted light pattern. In the left part of Fig. 1 the corresponding active components of a multi-segment headlamp - one realization technique for ALP - are indicated. The most important control parameter, which is quite easily accessible in a modern car, is the driving speed. Driving with high speed requires the attention of the driver to be directed to the far field in the direction where the car is heading instead of being distracted by the foreground scenery or the outer left and right sides of the total viewing zone. It is well known that the driver's view is attracted by those parts of the scenery that have the highest luminance (Ref. 9). Hence, the adaptive light pattern should support to direct the concentration to the most important zone for the current driving situation. Therefore, at high speed, an additional far field spot illumination should be added, accompanied by reduced or normal side and foreground light.

When driving at low or medium speed usually the spot is not needed any more. In this case, the adapted optimum light pattern depends on other parameters: When there is an intersection ahead, a curve or a broad street in an urban area then an enhanced lateral side illumination to the left and/or right is needed. In

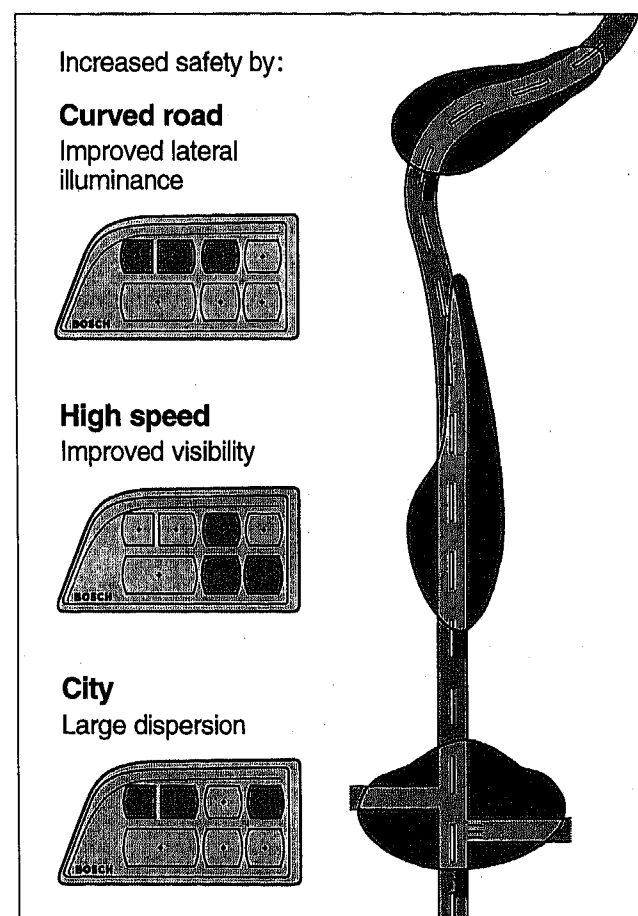

Fig.1: Three standard driving situations with adapted light pattern seen from the bird eye's view.

some cases, e.g. in a city, in a convoy or on wet roads without oncoming traffic (supposed there are means in the own car to detect oncoming traffic), an enhanced foreground illumination may be beneficial. Vice versa, on wet roads with oncoming traffic a reduced foreground diminishes specular reflection by the wet road ahead and therefore also reduces glare to other traffic participants. The transition between different adapted light pattern should always be harmonic and not too abrupt in a manner that has to be found out by detailed testing.

One important measure to assure safety and harmonic transitions is the idea to keep always a „basic light pattern" component static and switched on while the other beam pattern parts, e.g. spot, side illumination etc. will be adaptive.

ALP technique will be more complex than conventional headlamp technique is and it will be undoubtedly a challenge to incorporate it into modern car bodies. On the other hand it can also offer new styling opportunities as it is shown for example in Fig. 2. Recently, some show cars with such stylish model headlamps could already be seen on automobile shows around the world.

TECHNICAL REALIZATION ASPECTS

The design of a headlamp with „Adaptive Light Pattern" has to fulfill the same general requirements as the conventional lighting equipment: cost effectiveness, limited space, stability, life time etc. and it has to deal with the trend to more exotic vehicle front shapes, inclined lenses and low profile reflectors. Additionally, it has to incorporate the ALP-functions.

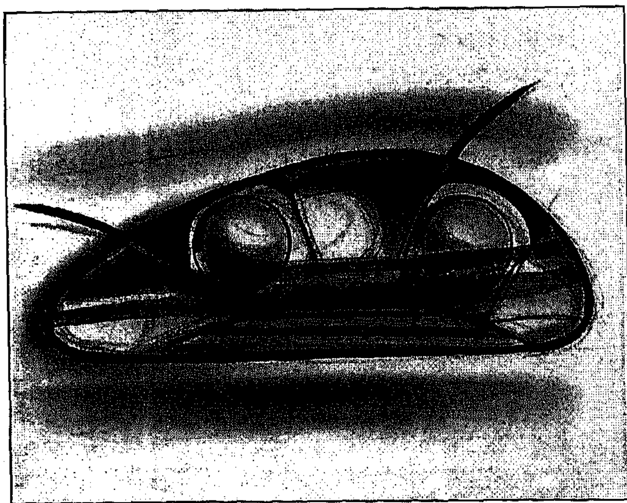

Fig. 2: Example for styling opportunities of ALP headlamps

Once the available space of an ALP headlamp and the cost frame is known it can be decided which technique will be used to make the light pattern adaptive. There is no feasible concept yet known which allows to realize arbitrary light pattern in a single headlamp. In reality, a few major light pattern states, e.g. curve illumination, together with the corresponding adaptation technique have to be selected to realize a powerful ALP headlamp.

There are several techniques to realize an adaptive beam:

- Changes of the light source(s) only
  e.g. moving the bulb inside the reflector, dimming
- Adaptive reflectors
  e.g. moving the reflector (and bulb), moving or deforming parts of the reflector, inserting new reflective surfaces, blocking parts of the beam...
- Adaptive Lenses
  e.g. moving lenses, inserting new lens parts or other optical elements, blocking parts of the lens
- Changes on the whole bulb-reflector-lens system e.g. moving the system, superposition of single beams
- Combinations of the described methods

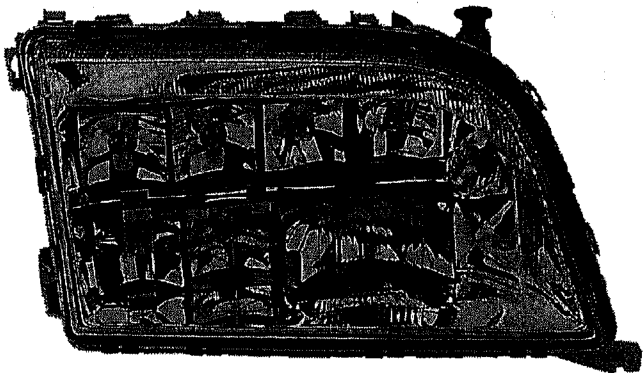
...

A lot of patent applications and patents about all of these different methods can be found and it would go beyond the scope of this paper to comment on all of them.
Generally, motorized moving parts should be avoided in a headlamp or should be as simple as possible because complex motorized motions are expensive, need much space and are potentially unreliable. Often a simple movement of the bulb or a rotation of a reflector is not sufficient to achieve a well-adapted light pattern.
On the other hand continuous movements have the advantage that a beam pattern can be continuously changed to another beam pattern whereas other solutions often do not allow the realization of transition states between light pattern.
It has to be found out whether motorized motions of headlamp parts can be done in cost-effective technically elegant way in order to be attractive for ALP. Also, we find that blocking of parts of the beam pattern may be a reasonable technique to realize adaptive light pattern but we prefer solutions where no light must be blocked.
The technique, we want to describe here and which has been realized in samples, is the superposition of single beams.

Fig. 3 illustrates this method: An ALP headlamp with this technique consists of multiple sub-units each having a special light pattern (basic illumination, hot spot, curve illumination, etc.). Depending on the driving situation one to three or four of these sub-units will be activated for superposition of their individual light pattern to build the adapted total light pattern. One advantage of this method is that it is rather inexpensive and the assembly is not too complex if it is possible to merge the sub-reflectors to one or two plastic parts. Also, the sub-units can be optimized very well for special illumination tasks (e.g. for the hot spot) and this technique is very reliable as well.

The number of adaptation states must be limited with this technique because each of the multiple sub-units needs considerable space. It is very important to determine in the concept phase of an ALP project the most important driving situations that shall be adaptively illuminated by the headlamp. This yields the total number of sub-units. Then the available headlamp area must be divided in a way that all individual light pattern are well balanced to each other. It is advantageous to use free form reflector layout for some of the beams. This technique, which has been described in an earlier paper (Ref. 10), allows the application of clear lenses and hence avoids some problems with profiled lenses when dealing with multiple closely spaced beams. Fig. 4 shows our early prototype sample which has been realized using multiple free form reflectors incorporated into an existing frame.

This sample received very much interest from our customers as well as from the public and it was useful for some of our first ALP tests. Interesting experiences were collected and contributed to the first conclusions mentioned in the previous chapter. It also turned out that the lighting functions, the balancing of the single components and the operation modes still had to be optimized. Therefore, a further prototype sample is under development. Fig. 5 shows schematically the layout of this new system which again will be based on the superposition method using free form reflectors.



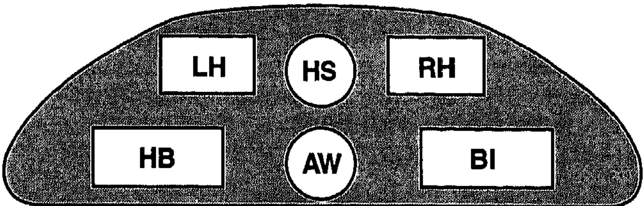


Fig 4: ALP headlamp sample

Single components:

LH Left hand bend
RH Right hand bend
HB High beam
BI Basic illumination
AW Adverse weather illumination
HS Hot spot

Fig. 5: Advanced ALP sample layout

This sample will include the basic low beam illumination which is most often active, it will also include a high beam function, a hot spot illumination, a left and right curve light pattern and an adverse weather beam. Both samples, the early one shown in Fig. 4 and the new one, were designed to fit into existing series production headlamp frames. Nonetheless, it would be also feasible to arrange all reflector components in one horizontal line in order to get a low profile headlamp with not more than 70-80 mm in height.

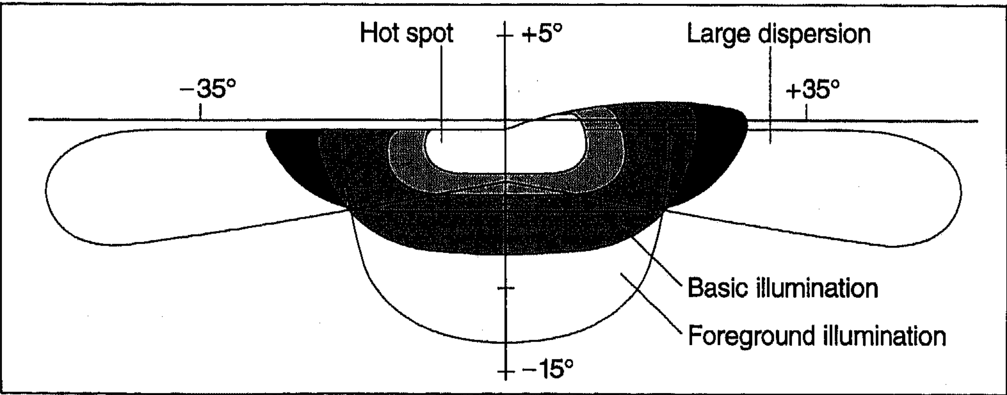

Fig. 3: Light pattern of multiple beam headlamp (Isolux curves in wall projection): The individual light pattern of multiple sub-units sum up to the total adaptive light pattern

The lighting performance of three of the sub-units in terms of isolux plots is demonstrated in Figures 6 and 7. Fig. 6 shows a comparison between the basic illumination and the additional hot spot illumination. The effect of enhanced range on a straight road by additional hot spot lighting is demonstrated.

Similarly, Fig. 7 shows the effect of curve illumination in comparison to the standard or basic low beam. The two figures clearly show the benefit of a well-adapted light pattern and the excellent performance of this prototype headlamp sample. An additional hot spot improves considerably the driver's view when driving on a straight road in an upper speed range.
Likewise, in a narrow bend a special curve illumination makes pedestrians or obstacles visible for the driver which normally will be hidden in the dark.

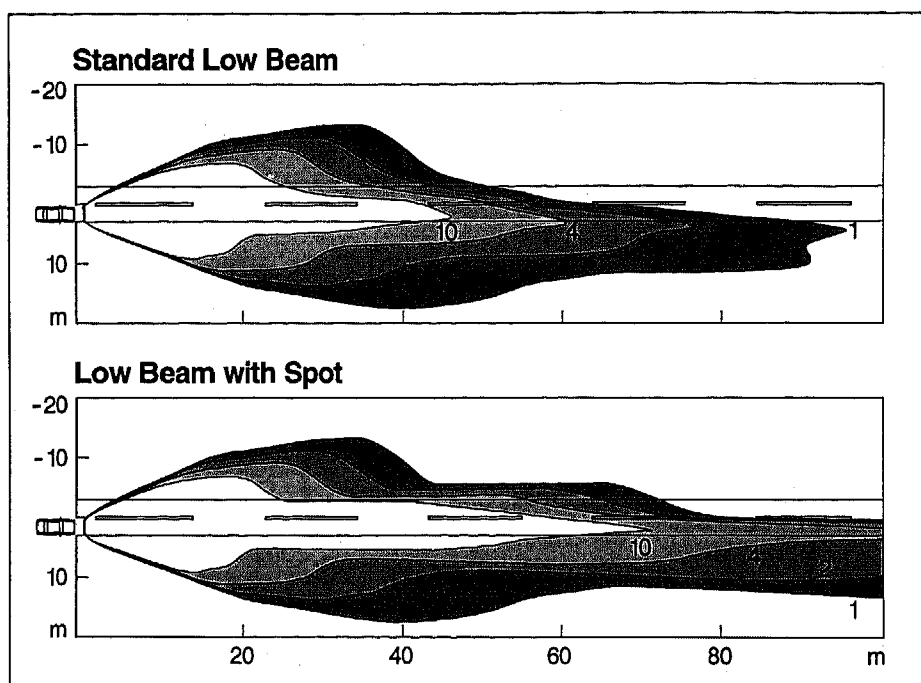

Fig. 6: Comparison between basic low beam and basic low beam with hot spot. Isolux curves from bird eye's view

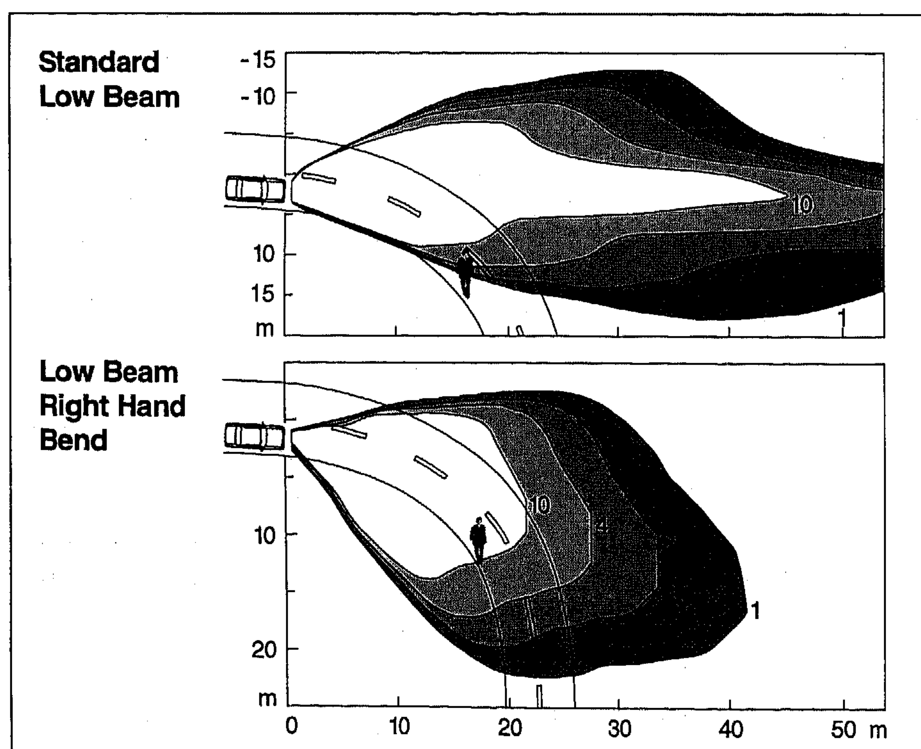

Fig. 7: Comparison between basic low beam and right curve illumination. Isolux curves from bird eye's view

CONTROL OF ADAPTIVE LIGHT PATTERN

The different adaptation states of an ALP headlamp must be switched or controlled in an appropriate manner. Depending on the number of states and their complexity ALP could be operated manually by the driver. But an additional safety system should not impose more tasks on the driver, it should let him concentrate on his main task to drive his car. Therefore an automatically controlled ALP is necessary. This also offers the opportunity to introduce, together with ALP, even more automatic functions, e.g. automatic light on/off or automatic headlamp leveling etc.
For this electronic control the following components are necessary (Fig. 8): Sensors, which capture the relevant driving parameters, an electronic control unit (ECU) including the switching logic, a power unit and a link between these components, preferably an advanced bus system like CAN (Controller Area Network).
The ECU and the power unit should have a rather general layout with a sufficient number of sensor signal input channels and output channels in order to cover a broad variety of ALP application cases. The sensors and sensor signals will be selected according to the specific application.
The sensor signals of speed and the turn signal state may be considered as a basic set of control parameters which almost every ALP headlamp will use. Adding more and more control parameters by supplying the corresponding sensor signals will increase the number of driving situations that can be detected and adapted to (if the headlamp supplies the corresponding light pattern)

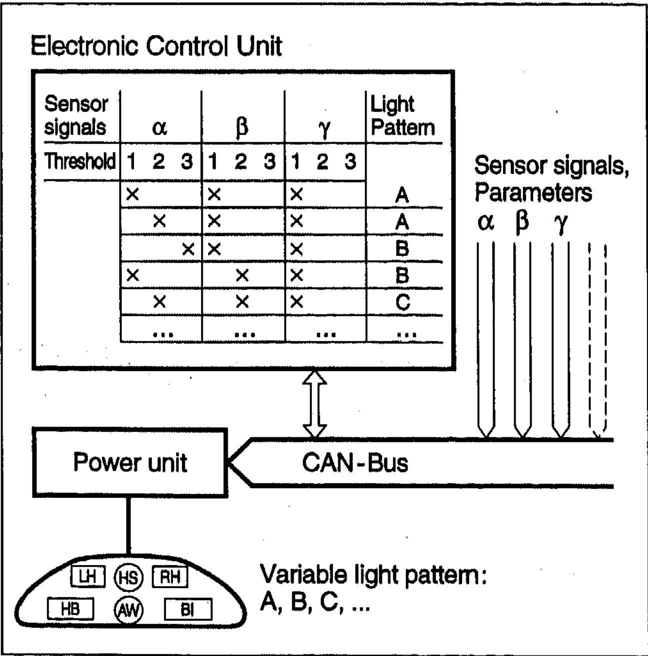

Fig. 8: Basic concept of ALP electronic control.

and it will of course increase the system costs. Hence, a modular control concept can handle ALP applications with a few basic adaptive states and also more complex applications:

	Control Parameter	Light Function
1	Speed, turn signal	Hot spot, improved lateral dispersion intersection illumination
2	+ Steering angle	+ Curve illumination
3	+ Rain sensor	+ Adverse weather condition illumination
4	+ Radar and video sensors	+ Drive in a columne enhanced hot spot in meeting situation
5	+ Navigation	Predictive control to all kind of driving situations

This list , which can be further extended, shows the enormous potential of a well-designed automobile lighting equipment together with an intelligent electronic control concept. To keep the system costs within an acceptable range it is worth while thinking about an integration of the ALP control with other more and more frequently used advanced electronic systems in the car. This may be for example the ABS (Antilock Braking System), VDC (Vehicle Dynamics Control) or ACC (Automatic Cruise Control) which can deliver speed, steering wheel angle, distance and other signals. Also the on board navigation, e.g. the Bosch Travelpilot, which is increasingly often integrated in upper class vehicles, can be combined with the ALP control. Using navigation as a signal source has the advantage that certain signals which are related to the road map (e.g. curve radius) can be delivered in advance. Thus, a curve or an intersection can be adaptively illuminated before reaching actually the point when the steering wheel is turned or the turn indicator is operated. Night time driving tests with the available prototype samples will help to find out the specific properties of predictive and non-predictive control. The ECU

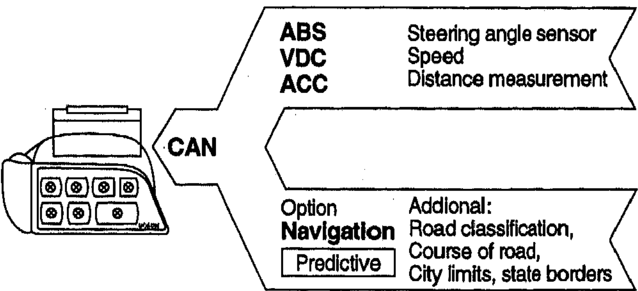

Fig. 9: Possible integration of ALP control with other advanced electronic vehicle control systems

logic will then be programmed correspondingly to apply the adapted light pattern with the right timing.

CONCLUSION

Headlamps with „Adaptive Light Pattern" (ALP) can improve current headlamp illumination through continuous automatic adaptation of the headlamp's street illumination to the actual situation.
Prototype headlamps are now ready for test driving. Advanced electronic control concepts for the complete car are available that can realize either simple direct automatic control or even high class predictive control (Fig. 10).
Additionally, the legislation process is started to formally allow this technique to be applied to series headlamp products in the future.

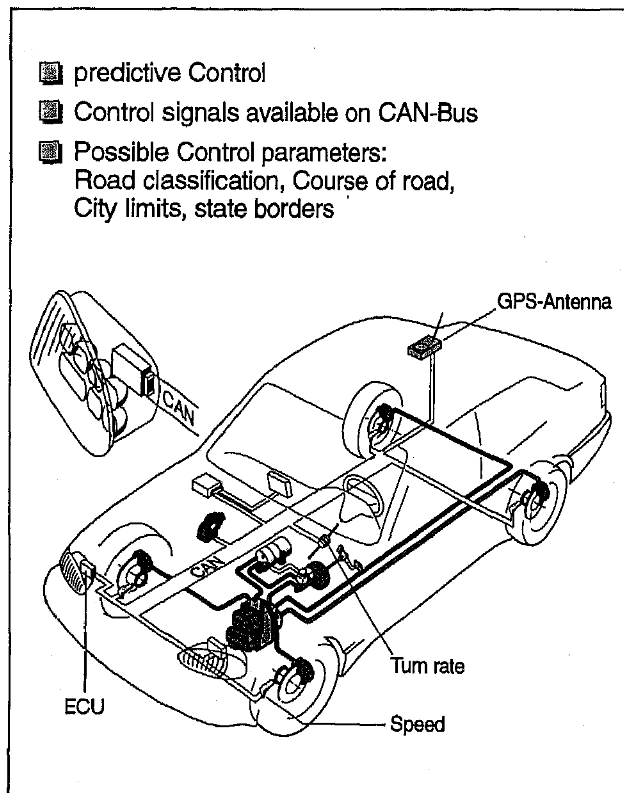

Fig. 10: Car equipped with ALP headlamps including predictive electronic control

Adaptive light pattern headlamps will contribute to more safety in night time traffic. They will help the driver in orientation and will serve as active guidance devices by means of the variations of the light distribution on the road.

ABSTRACT

Lighting and signaling functions are key factors for road safety and driving comfort at night. Night-time traffic represents 20 % of total mileage, but generates more than 50 % of fatalities. This percentage is even higher in adverse weather conditions.

New developments are being proposed to improve safety when driving at night. Systems which take account of environmental factors modify the beam pattern in accordance with driving conditions. Automatic beam modification is one of several projects grouped together in the wider approach known as *Intelligent lighting*. This approach differs from current vehicle lighting techniques which, being based on legal and regulatory requirements, entail design and testing in static conditions.

Intelligent lighting involves electronic data acquisition and processing, with the target of altering the shape, the relative intensity, the aim and the direction of the headlamps in accordance with the prevailing conditions. These external conditions include rain, fog, speed, road geometry and traffic density.

This highly innovative lighting system requires homologation by the existing laws and regulations, which is currently under review.

INTRODUCTION

THE PRESENT SITUATION - The current situation is defined by laws and regulations which consider lighting as a collection of static functions.

The conditions under which these different lighting functions are to be utilized are clearly defined, for example: high beam function when there is no traffic in front of the vehicle, low beam in traffic, parking lights in urban areas if ambient light levels are adequate etc.

These fixed functions correspond only partially, however, to actual traffic conditions. In the event of bad weather, or on a winding road, the driver often finds his lighting inadequate. The utilization of fog lamps in the event of dense fog is an appreciable safety factor in comparison with the simple utilization of the low beam. But in all cases, switching between the functions is the responsibility of the driver. The notion of automatic adaptation of lighting to the external conditions is rarely implemented, and is sometimes prohibited.

An initial analysis should enable us to determine which are the new functions liable to be of interest to drivers by amending deficiencies in present-day lighting systems. The possibilities are wide ranging, although there does seem to be a general desire to see certain specific functions. Of course, not all these new functions will necessarily be accepted by the different regulatory or legal systems.

The main new functions concern bad weather lighting, lighting for winding roads, special lighting for rural or urban zones and lighting for highways or more generally for lighting adapted to speed.

Several investigations into these different themes have been carried out by various equipment manufacturers and automobile constructors with the aim of proposing technical solutions which, on the one hand, would provide increased comfort and safety for drivers, and which on the other, could be accepted by different national regulatory systems.

The first task is to define the type of lighting which can best meet the needs of any particular given situation.

The second task is to define the technical solutions which will allow us to modify the power and the geometry of conventional beams in order to obtain a new function corresponding to the lighting required for this particular situation.

The third task, the development of automatic lighting management, constitutes a particular problem. How far can we allow a part of the lighting to be entrusted to automatic systems? What functions need such automatic responses? What functions can be managed automatically while maintaining correct safety levels? What normal functions can be automated to procure improved safety and responsibility?

PRINCIPLES OF INTELLIGENT LIGHTING

Data is acquired by sensors. This data reflects the parameters which are used to define whether or not the lighting function needs to be activated, and to configure the function appropriately.

The data is processed by systems based on micro-controllers or microprocessors. These systems analyze the situation of the vehicle relative to the lighting function being utilized and, if necessary, command the reaction of the lighting.

This reaction can take different forms:

Automatic activation or deactivation of one or more lighting functions.

Modification of a lighting function.

Warning to the driver that his lighting is unsuitable for the situation.

Warning to other drivers that their own lighting is unsuitable.

The first general principle is shown in Figure 1.

DATA ACQUISITION - An intelligent lighting system can acquire data relative to four types of parameters: (figure 1.b)

- The road environment: the type of road, existence of bends, gradients, passage through urban areas, tunnel, mountainous zone, etc.

- The ambient conditions: weather, luminosity

- Road traffic: density of traffic, oncoming or preceding vehicles

- The state of the vehicle: speed, acceleration, attitude, functional state of the lighting

A part of this data is already utilized by other systems present on the vehicle. For example, the speed of the vehicle is used by the dashboard display, the attitude and the acceleration by intelligent suspension systems, the ambient luminosity by certain air conditioning systems, or the presence of rain by certain wiper systems.

Potentially useful data may be acquired by sensors of all types. However certain information sometimes proves very difficult to acquire in a simple physical form. Defining and analyzing the surrounding traffic is extremely complex with reasonable resources, i.e. with resources compatible with the automobile industry.

DATA PROCESSING - The data acquired must be routed to one or more processors and control blocks. Future automobiles will certainly incorporate can type (controller area network) data transportation buses. This type of bus enables data to be distributed to the entire vehicle over a paired wire physical medium, which will enable the bulk of automobile system wiring harnesses to be significantly reduced. Each processing unit takes the data it needs, while each sensor unit transmits the data it acquires as quickly as possible by means of a communications controller.

The complexity of the processing necessary to such systems is increasing. Present processing systems are sufficiently powerful to respond to these new demands, at costs which remain low. The automobile lighting sector is no exception to this trend.

MODIFICATION OF LIGHTING - Automobile lighting is subject to laws and regulations which are relatively strict. The idea of developing lighting which is responsive to the surrounding conditions is already present in the existence of the four standard functions, parking, low beam, high beam and fog lights. The way to obtain increased safety and comfort is to improve the capability of lighting to respond optimally to surrounding traffic conditions.

This improvement implies both the modification of the four existing functions and the creation of new functions. To achieve this, it is necessary to provide the means to be able to modify the geometry, direction and distribution of the lighting, and finally to vary the power of the beams.

From this viewpoint, a number of different paths are being explored. The first is to increase the number of lamps, i.e. create additional lamps to perform new functions. This solution has the disadvantage of being costly and bulky, but it is by far the most simple; the second path is to investigate systems which can be used to modify an existing function in order to provide another. With this solution, for example, more than one light source may be used, the geometry of the reflector may be modified or the power supply may be increased or decreased.

BENEFICIAL FUNCTIONS

Future lighting systems must be able to adapt to a wider range of situations than at present. Drivers and manufacturers want lighting systems that respond to specific situations. Each country, each individual, has different requirements, but there are a certain number of situations which are generally perceived as dangerous or uncomfortable with present lighting. In other words there is a general desire for innovative new functions corresponding to a certain number of particular points.

Of the situations where current lighting is perceived as inadequate, bad weather is by far the one which poses the most problems. The presence of fog is a particularly critical situation. Present day fog lights are often judged inadequate, or too dazzling. Progress could be made by controlling the light flux in ratio to the density of the fog, for example, or by improving light distribution.

Loss of visibility on winding roads also represents a danger that needs to be eliminated. Glare, particularly as regards oncoming drivers in rain is another a problem of the same type. In both cases, modification of the geometry of the beam would provide a response adapted to the situation.

Automatic control of lighting is a particular challenge. While it is obvious that bending headlamps must be able to modify the beam automatically, the automatic activation or deactivation of the main functions poses a problem of safety. Automatic deactivation can result in a fatal accident very rapidly, so fail-safe controls for such functions are absolutely vital. Automatic control must include a notion of absolute reliability which must be absolute for certain functions. Advanced technical research needs to be carried out to guarantee that this type of automatic control system are fully certified.

SOME EXAMPLES OF DEVELOPMENT

THE BENDING LOW BEAM - Operating principle:

The purpose of this system is to provide the light necessary in the direction of the movement, principally around the bend when the vehicle is turning through a curve.

- Description of the system: (Figure 2)

The data required comes from several sources. The first is the steering wheel angle which enables the vehicle's angle of turn to be calculated. The speed can also be used to determine this target angle more precisely. The acceleration of the vehicle can also be usable data, together with the activation of the turn signals.

The most interesting data would be the direction of driver's eyes, but such a system of detection has not yet been adapted for automobiles.

Light can be provided in the target direction (Figure 2.b) in different ways: by pivoting the normal lamps, by pivoting additional lamps, or by activating other light sources, for example.

Valeo has developed experimental prototypes which sense the steering angle and which use additional lamps (Figure 2.c) whose movement is controlled by a system based on a microprocessor. Figure 2 shows how the system works:

The system provides the driver with illumination of around 20 lux in the target direction. At night, current illumination in a direction 30° to the right or left relative to the vehicle is normally less than 1 lux, which is inadequate for a correct view of the road.

THE MODIFIABLE HIGH BEAM - Operating principle:

The principle of this function is to be able to distribute the light of the high beam differently according to the speed of the vehicle. The beam will tapered to a longer range at high speed and wider at slower speeds.

- Description of the system: (Figure 3)

Speed data is already utilized for the instrument panel. This data can be recovered and transmitted to an electronic processing unit. A variation of the system utilizes acceleration/braking data when the vehicle is already at high speed; significant acceleration gives a more pointed beam, significant braking gives a wider beam. In this case, the acceleration data is acquired through the pedals or by a speed differential measurement.

Valeo modifies the beam by the interposing a lens between the high beam light sources and the reflector. (Figures 3.b and 3.c)

The pointed beam gives a maximum of 185 lux, as against 80 for the wide beam, but this latter provides 5 lux at 10° as against less than 2 lux for the pointed beam. (Figure 3.d)

AUTOMATIC ATTITUDE CORRECTION - Operating principle:

The purpose of attitude correction is to maintain the low beam at the correct height in order to avoid dazzling oncoming or preceding vehicles while at the same time ensuring the driver has optimum lighting.

- Description of the system : (Figure 4)

The most interesting data in this case is the distribution of the light beam. One good way of acquiring this data is by determining the light distribution on the ground. Another way is to determine the attitude of the vehicle relative to the ground immediately in front of the vehicle. This attitude can be calculated by measuring the attitude of the vehicle relative to the ground beneath the vehicle, that is by measuring the clearance of the vehicle's axles.

Valeo proposes attitude correction systems using 2 sensors to measure the height of the axles, a processing unit and lamps fitted with actuators used to change the attitude of the lamps.

Variations can take account of the ground distribution of the lighting, of the speed, and of the vehicle's acceleration. A variation might take account of the vehicle's speed to provide a function known as the highway or high speed function. In this case, the processor raises the low beam. (of less than 1 %rad, depending on speed). Another variation might take account of weather conditions, so that the processor lower the low beam (of about 1 %rad) in bad conditions, particularly in fog conditions.

The results obtained enable glare vis-a-vis other vehicles to be significantly reduced, while at the same time ensuring better lighting. An additional advantage is that the lamps are always correctly adjusted.

CONCLUSION

The current situation of vehicle lighting systems, with regulations principally based on static conditions, is necessarily undergoing change. This change is of interest for drivers for two essential reasons: SAFETY and COMFORT.

Intelligent lighting systems in fact procure improved comfort because they provide the driver with lighting which corresponds more closely with his visual needs in terms of amount, shape and position. By adapting to surrounding traffic conditions, intelligent lighting systems also provide drivers with improved safety, particularly in difficult conditions. The need for better lighting is urgent in certain traffic situations, particularly for elderly or visually impaired persons .

The automatic control of certain lighting functions will also provide further improvements in safety and comfort. For example, automatic deactivation of rear fog lamps when a vehicle approaches from the rear will avoid glare for the following driver, thus providing increased comfort and safety.

The types of function described here indicate a clear way forward. The utilization and combination of the functions described will undoubtedly improve automobile lighting.

The future may even see automobile lighting systems designed for data acquisition by camera, or possibly by multi-wavelength reception. Image processing could be used to acquire the total vehicle situation, and to define the best possible lighting. Other safety systems could benefit from devices to determine such functions as braking when closing on an obstacle or a vehicle. This type of approach reinforces the overall vision suggested by intelligent lighting, not only for the lighting system, but more generally for the complete transportation system that is the automobile.

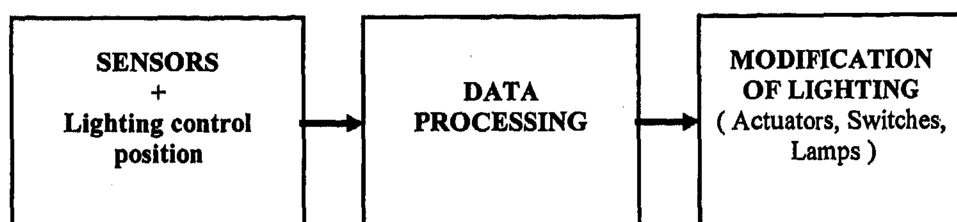

Figure 1

PARAMETERS	STATE OF THE ART	FUTURE SOLUTIONS
Weather conditions	Existence of adequate sensors, special difficulties with regard to fog detection	Possibility of determining these parameters at reasonable cost
State of the vehicle	Existence of adequate sensors	These parameters are easily acquired, existing or easily adaptable solutions
Road environment	Research, development of special sensors (tunnel, street lighting etc.)	Limited to particular points, or complex system with image, infrared, UV or multi-wavelength processing
Road traffic	Complexity of effective systems, development of systems detecting following or oncoming vehicles	Complex system with image, infrared, UV or multi-wavelength processing, or limited to detecting non-complex circumstances

Variable Headlamp Beam Pattern - Lighting Requirements for Different Driving Situations

Joachim Damasky

BMW AG

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Light distributions of headlamps are defined as static values. Neither FMVSS nor ECE allow variable beam pattern for low beam headlamps. New electronic systems and sensors available for car applications facilitate a situative lighting, that prepares an optimum lighting for each driving Situatuion.

This paper shows the necessity of different beam patterns for certain driving situations. Based on an road geometry analysis and an investigation of objects in the street the optimum light distributions are carried out for the single situations.

1. Introduction

New technologies and light sources open new possibilities in headlamp design. On the other hand the infrastructure of the available informations in cars has changed in the last years dramatically. New cars with digital bus systems have all informations available everywhere in the car. Also the efficiency of the microprocessors increased in the past. As a result of all these changes during the last time but also of the changes in passenger car traffic an adaptive variable headlamp beam pattern seem to be possible and necessary.

Paper No. 960920 shows the fundamentals of the investigation. A road geometry analysis, based on an video tape recording of more than 5500 km european roads, seen from a driving car, delivered the necessary data for the different driving situations.

Fig. 1 Evaluation of objects in the road based on video

The video tapes were analysed with the help of a special computer-video system. The analysis took account of the course of the roads, the brows and dips, and the positions of all objects relevant to lighting technology.
The small black lines are adapted to the road markings and describe therewith the course of the road. The radius of the curves, of crests and sags but also the with of the road is therewith exactly determined.
The white lines, adjusted to the base point of an object, give the exact distance between object and video camera.

The white squares mark the position of objects relevant for lighting equipment, such as traffic signs, delineation reflectors or the mirrors of the car ahead.
A result of the video tape analysis the road situations were differenced into the following types:

1. Urban Roads
2. Smaller country roads (straight or bended)
3. Larger Country Roads (straight or bended)
4. Motorways

Parameters were the width of the roads, Radii of curves, public lighting e.g..
In the following the details of the certain roads an the resulting beam pattern are explained.

1. Urban roads

Task of a urban beam pattern is the illumination of the foreground in front of the car, but also the objects in the roads like pedestrians and traffic signs. It has also to ensure the recocnition of cars with a minimum of dazzle to other road users.

Appr. 1100 km roads in european urban situations were analyzed. The position of traffic signs but also of all objects like pedestrians were determined. The following figures show examples of the evaluated data.
Figure 2 shows the distribution of overhead signs in urban roads, Figure 3 the locations of pedestrians.

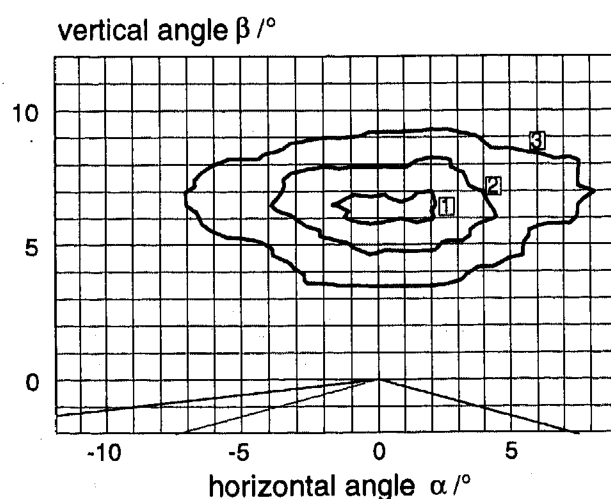

Fig.2 Locations of overhead signs on urban roads
dist. 50 m,
1 = 10%-, 2 = 50%-, 3 = 90%-propability-area

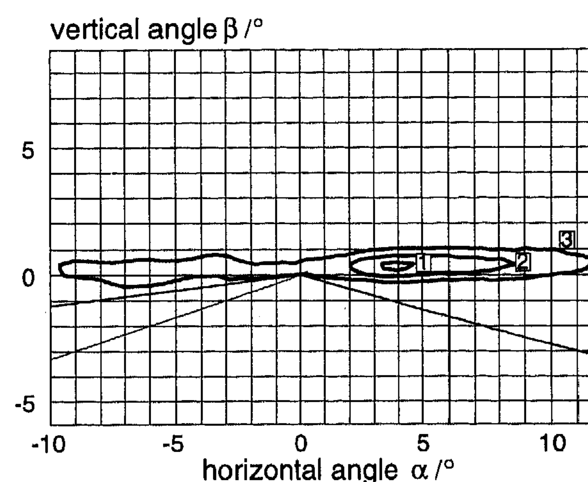

Fig. 3 Distribution of pedestrians on urban roads
dist. 50m
1 = 10%-, 2 = 50%-, 3 = 90%-propability-area

Based on the results of the investgation the following parameters have to be considered:
The foreground illumination has to provide the adaptation level for areas with lower public lighting. For less glare caused by dynamic movement of the body of the car the sharpness of the cut-off line has to be softer than for a country or motorway light.
In the areas of the pedestrians a minimum illumination is recommended. The positions of fig.3 mark the center of the body, the feet positions are appr. 1.14° lower.
In the areas of the traffic signs, overhead, left hand and right hand mounted, a minimum illumination must be ensured.
As the result of the investigation of the urban roads the following beam pattern for an urban light was developed.

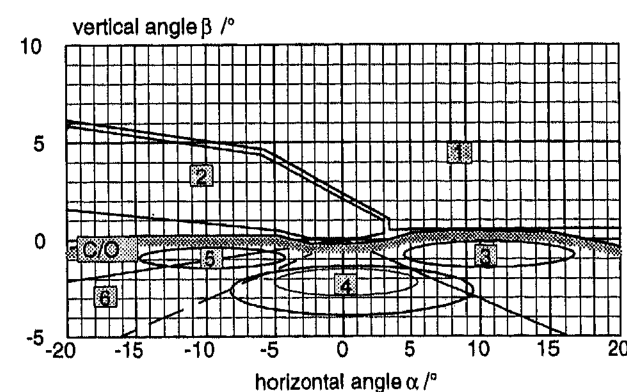

Fig. 4 Beam pattern for urban roads
zone 1 overhead traffic sign E < 2 lx

2 glare E < 1,0 lx
3,5 pedestrian feet area E > 25 lx
4 foreground right hand E >15 lx
6 foreground 5 lx < E < 25 lx, homogeneous luminance on road

It shows the consideration of the oncoming drivers in zone 2, the location of traffic signs in zone 1, but also the position of pedestrians and bicycles. Zone 4 and 6 is the area for the adaptation level and foreground illumination.
A first headlamp realized for urban traffic shows a wide illumination without a sharp cut-off line. Figure 5 shows a scematic birdseye-view of the road isolux diagram.

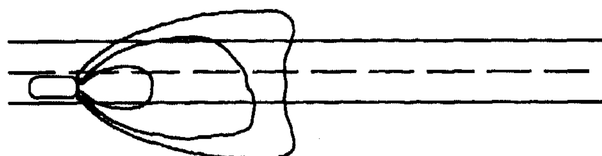

Fig. 5 scematic birdseye-view of the urban traffic light

2. Country Roads

The evaluation of the new country road beam pattern was described in the SAE-Paper Nr. 960920 from 1996. Only a short summary should be given here. For the country road light distribution appr. 2500 km country road have been evaluated. Considered objects were: traffic signs, delineation lines and reflectors, eyes of oncoming traffic, rearview mirrors of ahead traffic, but also parameters like curves and crests/sags.
On country road glare becomes a more important problem. Compared to urban surroundings, where the adaptation level is caused by public illumination higher and the glare sensitivity decreased a lower dazzle illumination is necessary.
The side illumination becomes more important for the driver too , from this area he gets the most important visual information for visual guidance and delineation of the road. The distribution of the objects was shown in Paper Nr. 960920, so figure 6 shows the proposal for the country light distribution.

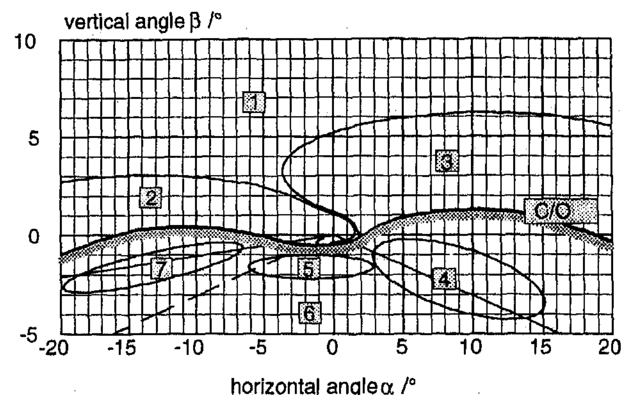

Fig. 6 Country light (fixed mounted part)
zone
1 overhead traffic signs 0,2 < E < 1,5 lx
2 glare area 0,5lx < E <1,0 lx
3 right shoulder traffic signs E < 2,5 lx
4 foreground right E > 15 lx
5 fixation area at Cut Off 50lx > E > 25lx
6 foreground 5lx <E < 15 lx, homogeneous resulting luminance
7 foreground left E >10 lx
on the 25m measuring screen

The realised light distribution. is shown as a scematic birdeye view.

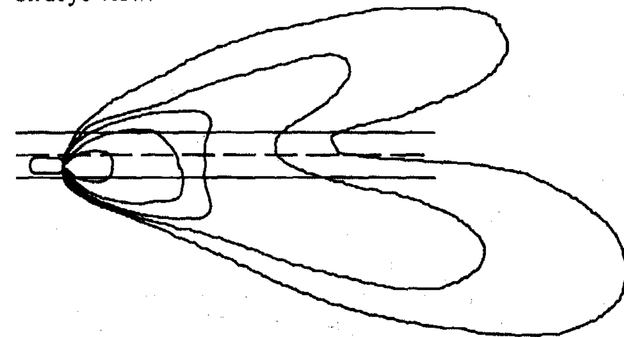

Fig. 7 scematic birdseye view on country road beam pattern

Out of all parameters of the geometry, but also considering lighting parameters like adaptation and glare the beam pattern shown in figure 6 and 7 was developed for country roads. In this light distribution no moving part of the light is included for the smaller, curved roads.

Test drives with this headlamp showed the advantages of this system: much better visual guidance and increased comfort without increased dazzle for other traffic.

But these test drives showed too, that the static light distribution is not an optimum solution for narrow, curved road. In these situation a moving part of the light, that lits into the curve, is necessary and very comfortable.

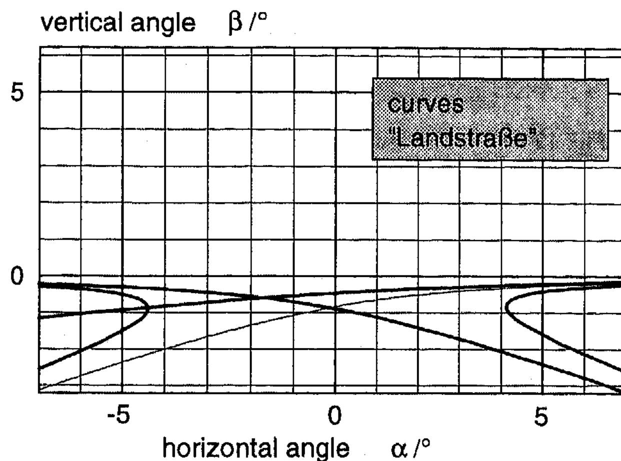

Fig.8 90%-area of curves on smaller country roads ("Landstraße") up to a distance d = 100m

As a result of the statistical evaluation but also from test drives a curve radii of appr. 2500 m is a conveniant threshold for a curve or bend lighting. Above this curve radius no bending lighting seems necessary, but below it provides a save and comfortable steering in curves.
The moving part of the light distribution needs no vertical component in its Cut-Off, the visual range can be shorter than the range of the low beam. The speed in curves with radii under 2500m is usally lower than the maximum speed on country roads. The maximum intensity should be in the range of the illumination of the low beam.

The lines in Fig. 8 show the edges of the road. They have to be illuminated dynamically. This could be realised by an electronic steering unit, that uses a gyro-sensor, a steering angle sensor or a navigation system as the necessary signal input.

3. Motorway lighting

A third driving situation is the Motorway. On motorways the lighting parameters differ from country roads by radii of curves, geometry of object locations, speed of vehicles, dynamic movement of car bodies and oncoming traffic.
On one hand the glare illuminations can be higher than on country roads, the distances between the oncoming cars are much larger. On the other hand the reaview mirror glare, resulting from the illumination above the horizon should be reduced.

The necessary parameters for a motorway lighting are:

- large viewing distance
- optimal optical guidance
- traffic sign illumination
- less dazzle for other road users

For alls these parameters data have been evaluated.

90% of the radii of curves on Motorways are larger than 5000 m .This is one of the results of the statisical evaluation. The number of lanes per driving direction is in Europe mostly 2, less than 5% have more lanes.
The problem of dazzle of overtaken traffic and traffic ahead increases with the possible light intentsities in the direction of the mirrors. Therfore the position of the mirrors was determined.
Fig. 9 shows the location distribution of left rearview mirrors of cars ahead on motorways in a distance of 100 m, Fig.10 the inside rearview mirror.

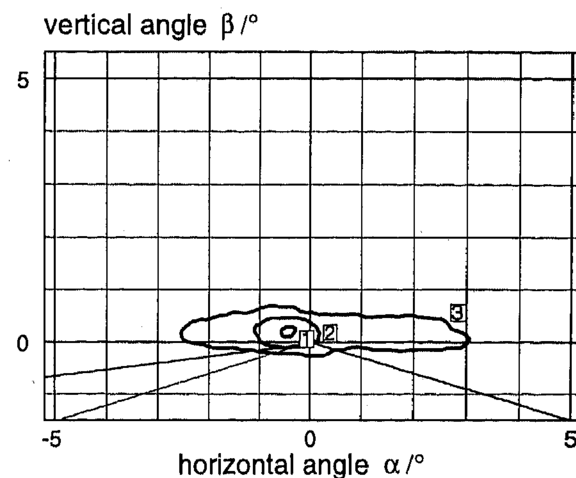

Fig. 9 Position of left rearview mirrors of ahead cars on motorways , distance 100m
1 = 10%-, 2 = 50%-, 3 = 90%-propability-area
related to headlamp, mounting height 0,65m

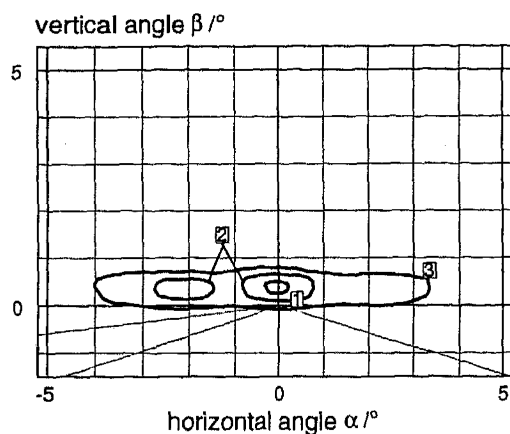

Fig. 10 Position of inside mirrors of ahead cars on motorways , distance 100m
1 = 10%-, 2 = 50%-, 3 = 90%-propability-area related to headlamp, mounting height 0,65m

The different 10 % and 50 % areas are a result of the lanes. It shows, that the observation car mostly drove on the right lane.

The areas shown in picture 9 and 10 show the most important glare areas on motorways. The glare illumination should not exeed a value of 1lx.

For save driving on night time motorways the legibility of traffic signs, right shoulder mounted and overhead, is important. Therfore the position of traffic signs was also evaluated.

The position of overhead signs on motorway is shown in Figure 11.

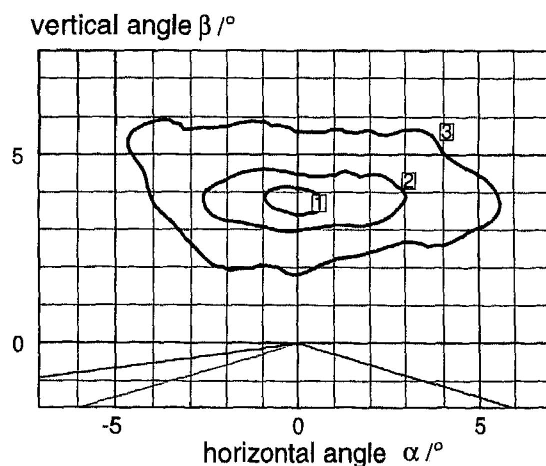

Fig. 11 Location of overhead signs on motorways
1 = 10%-, 2 = 50%-, 3 = 90%-propability-area related to headlamp, mounting height 0,65m

The result of the evaluation of these data, but also of consideration of the dynamic car body movement lines certain parameter out.

1. Sharp Cut-Off-Line with an almost horizontal shape
2. Defined rearview mirror glare of appr. 1lx
3. Illumination of traffic signs in certain zones.

Fig. 12 shows the resulting motorway beam pattern.

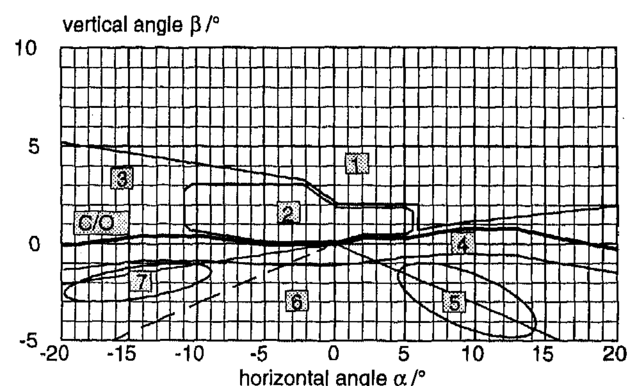

Fig. 12 Motorway light distribution

zone 1 overhead signs E < 2 lx
2 glare area E <1,0 lx
3 shoulder mounted signs E < 1,5 lx
4 fixation area 100lx > E > 25lx
5 foreground right E >15 lx
6 foreground 5lx <E < 25 lx, homogeneous resulting luminance
7 foreground left E >15 lx
on the 25 m measuring screen

Based on this proposal a motorway headlamp was realized. The light distribution of this headlamps is shown in Figure 13.

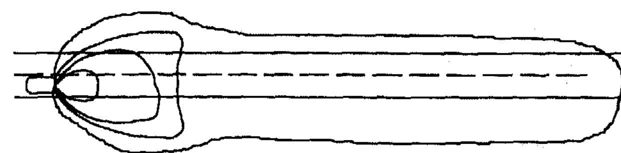

Fig. 13 birdseye view on scematic motorway beam pattern
It shows a long distance lighting for the distances up to 150 m in front of the car and a wide foreground illumination for the optical guidance.

A very comfortable driving on motorways is the result, confirmed by test drives. Test drives showed, that

maximum illumination of more than 100 lx are also possible and very comfortable to drive.
Motorway light in this shapes with high light intensities have to be combined with an dynamic levelling system to avoid glare for ahead and oncoming traffic.

4. Adverse weather lighting

One of the most important light distributions is the adverse weather lighting. Increased glare values and reduced object luminances decrease the avialable visual information for car drivers. Especially older driver feel very unsure and uncomfortable under these conditions.
The main problem is the glare caused by reflection on wet pavements.
As a basic investigation the reflection behaviour of wet pavements was determined. Especially the foreward reflection coefficient is of interest for the glare of oncoming drivers.
For this reason the measurement point 4 D exists in the US-Regulations. Modern free shape form reflectors enable a big amount of light direct in front of the vehicle. Therefore the reflection coefficient for foreward reflection was measured for different distances in front of the test car. The result is shown in Figure 14.

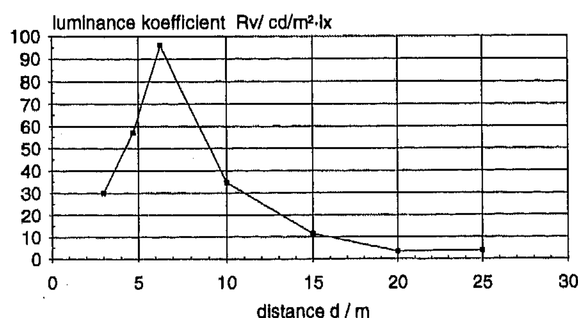

Fig. 14 Foreward reflection on wet pavement, distance between illumination and observer 30m

The Figure shows, that the maximum is not at the distance of 10 m, where it should be for illumination angle = reflection angle. The headlamps were mounted on a height of 65 cm, the observation height was 1,2 m. The maximum value was shifted to the illumination source. A limit for the foreground illumination is necessary.
Also a fog luminance computing software was worked out. With this system the calculation of the self-dazzling luminance in fog situations is possible.

The result of the investigation of adverse weather conditions is the development of the following light distribution, shown in Figure 15.

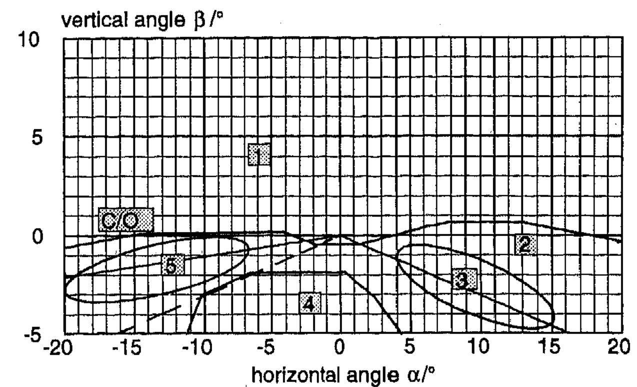

Fig. 15 Adverse weather beam pattern

zone
1 dazzle and self dazzle area E <0,2 lx, homogeneous
2 foreground 5lx <E < 25 lx, homogeneous luminance
3 delineation right E > 30 lx
4 reflex-glare zone E <5 lx
5 delineation left E > 10 lx

The necessary headlamps are in development. Zone 1 is the glare zone, where a low and uniform light level is recommended. Zone 3 + 5 are necessary fo the optical guidance, zone 4 is the reflection glare zone.

5. Eureka Project No. 1403 AFS

European lamp manufacturers, setmaker and carmaker work together for a situative, adaptive lighting in an Eureka-Project AFS. AFS (Advanced frontlighting systems) includes the following companies:
Carmaker: BMW/ Rover, Mercedes Benz, Volkswagen/ Audi, Ford, Volvo, Renault, PSA
Setmaker: Bosch, Hella, Valeo, Magneti-Marelli
Lamp manufacturers: Osram, Philips
The target of this partnership is a new ECE-Regulation, that allows more freedom in Lighting design towards a situative lighting.
The work is carried out in three phases:
Phase 1: feaseability study.
In this phase the target was to carry out if an AFS system is possible. Therfore the different functions:
1. City light
2. Country road light
3. Bending light

4. Motorway light
5. Adverse weather light
6. Overhead light
were tested in static and first dynamic test.
A market study in Germany, France, Italy and Sweden on customer demands sets priorities.
This phase was finished in summer 1996 an the conclusion was the recommondation for proceeding.
In the now running phase 2a test drives to all funktions were carried out in Germany and France under participation of all members.
Variable systems, which allow very different light distributions were build up and used for these test.
The phase with the scientific research work will start in 1997.
Target is a proposal for a new regulation before year 2000.

Development of Active Headlight System

ABSTRACT

The highest fatal traffic accident rate occurs on a curved road at nighttime. The "Active Headlight (AHL)" system developed by Honda R&D and Stanley Electric is the system that the beam pattern of the headlamp changes and more headlamp light is distributed toward a curve direction. The AHL system can direct a light toward a curve before the vehicle enters a curve by using road information from a navigation system. When the AHL system moved in nighttime, visibility on curves and stability of driving were improved and glare to an oncoming vehicle was acceptable.

INTRODUCTION

The number of nighttime traffic accidents has been increased in Japan [1]. Figure 1 shows the number of both daytime and nighttime traffic accidents on a yearly basis, assuming numbers for 1982 are 100 each. For the first 10-year period following 1982, the number of fatal accidents at nighttime rose almost 1.5 times. The fatal rate of nighttime accidents is higher than that of daytime accidents; the ratio is about 3 to 1. Figure 2 shows the fatal rate categorized by the type of road and time (daytime or nighttime). Fatal accidents on a curved road at nighttime are the highest among all traffic conditions.

To decrease these fatal accidents on curved road at nighttime, Honda R&D and Stanley Electric developed the "Active Headlight (AHL)" system. The parts of the development results were presented as the vehicle "Honda ASV-1" at the Japan Ministry of Transport ASV (Advanced Safety Vehicle) project in August 1995, and after that we continued improvement.

ANALYSIS OF ACCIDENTS ON CURVED ROAD

More than 90 percent of driving depends on incoming visual information [2]: insufficient visibility can be a critical factor triggering improper driver response. The visibility and eye-points, taken by an eye-marker camera, were recorded both at daytime and nighttime, and the comparison is shown in figure 3. At nighttime, it is harder, to see what is beyond a curve. Therefore, drivers tend to set their eye-point closer to themselves. Most of the drivers' eye-points at nighttime was distributed in the area illuminated more than 3 lux on the road.

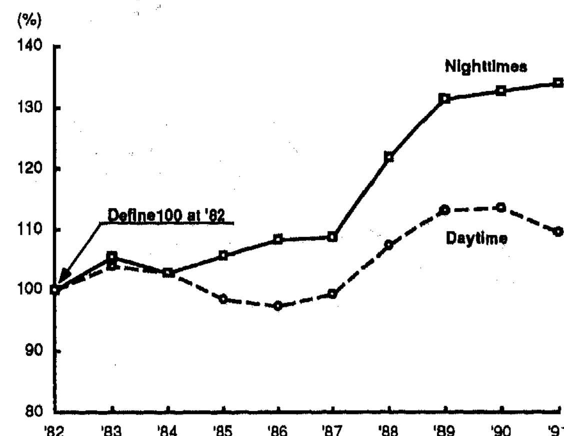

Figure 1. Fatal accidents number (in Japan)

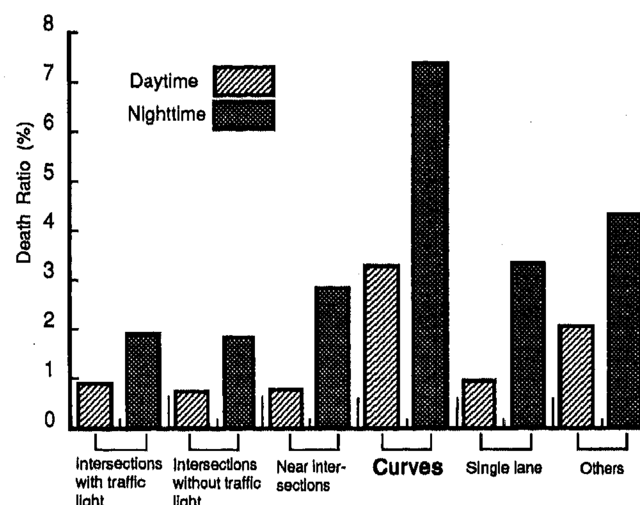

Figure 2. Fatal rate categorized by the road type

The Nagata's report [3] suggested that inexperienced drivers tend to set their eye-points closer to themselves compared with experienced drivers while moving around a corner, and that insufficient driving skill and closer eye-points are interrelated. Hirao defined [4] a margin time "Td" as the time the vehicle reaches to the driver eye-point. He reported driving becomes inconsistent when "Td" value is too small. "Td" tends to decrease particularly at nighttime, that cause inconsistent driving and accident.

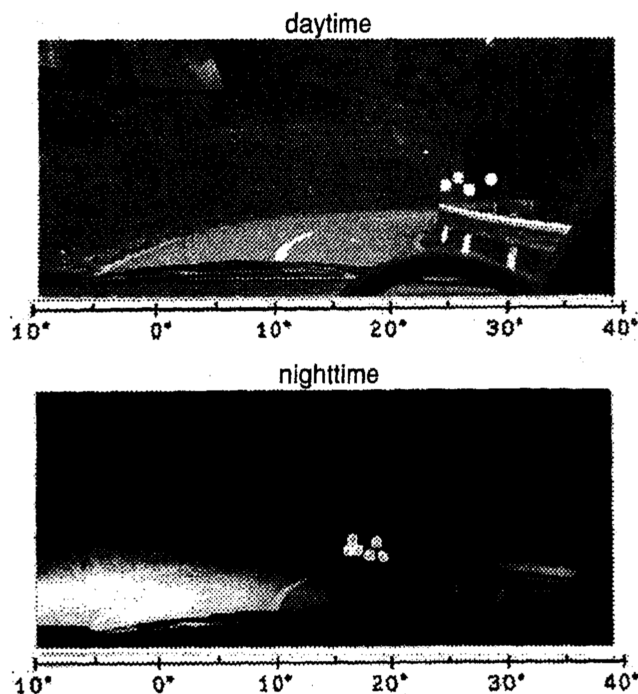

Figure 3. Eye-points distribution on a curve road

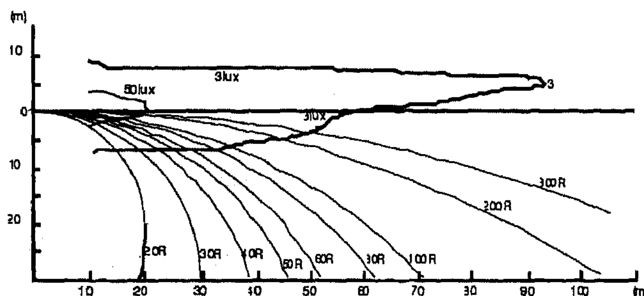

Figure 4. Conventional headlamp beam pattern

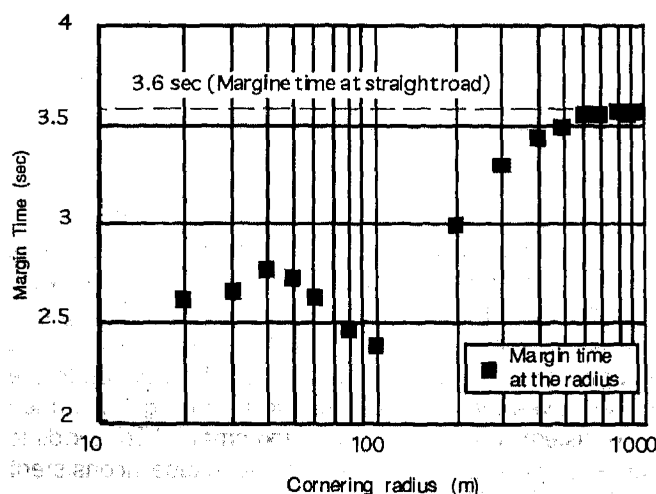

Figure 5. Cornering radius and margin time

Figure 4 shows the beam pattern of a current headlamp with various curved roads. Assuming that the driver's eye-point directs on the 3 lux line and the vehicle runs centrifugal force of 0.3 G, we estimate the margin time of each curves. Figure 5 shows the calculated margin time on curves when the figure 4 headlamp is applied. The margin time on straight road driving at 60 Km/h is about 3.6 sec. The margin time of each curves is evidently small.

The Active Headlight (AHL) system is developed to improve visibility, to increase the margin time and to stabilize the driving.

ACTIVE HEADLIGHT SYSTEM

OUTLINE

The main structure of the AHL system is shown in Figure 6. The system calculates headlamp turning angle using a steering angle, vehicle speed, turn signal and information of curves from a navigation system. In the preliminary experiments, drivers tended to see a turning direction before they operated the steering wheel. The system received a distance to a coming curve and the radius of the curve from a vehicle navigation system so that the system can direct the headlamp beam before the vehicle enters a curve. Curved roads ahead were predicted by the method of corner notice and warning [5] used in the "Honda ASV-1."

HEADLAMP

A HID is used as the light source. The system is used for lower beam only. The reflector of the headlamp is split into two parts, top and bottom. The top half reflector can rotate horizontally. The right-hand lamp can be rotated 50 degrees to the right and 20 degrees to the left. The left-hand lamp can be rotated symmetrically to the right-hand lamp. The top half reflector is designed to reflect the light under the horizon. The bottom half reflector is fixed and this part alone can meet low beam requirement. The total candle of the top reflector and the bottom reflector is meet low beam requirement at any rotational angles.

On a straight road, the movable reflectors are directed beams straight ahead, improving the visibility of an object far ahead. At a curved road or a cross-section, the movable reflector on the turning side is rotated more than the reflector on the other side so that the visibility in the turning direction is improved while overall light distribution is kept smoothly.

CONTROL

There are three ways to control the rotation angle of the reflector.

1) Control by steering angle
   When a vehicle is on a curved road, the AHL system calculates curve radius by the steering angle and the vehicle velocity, and determines the rotation angles of the reflectors.

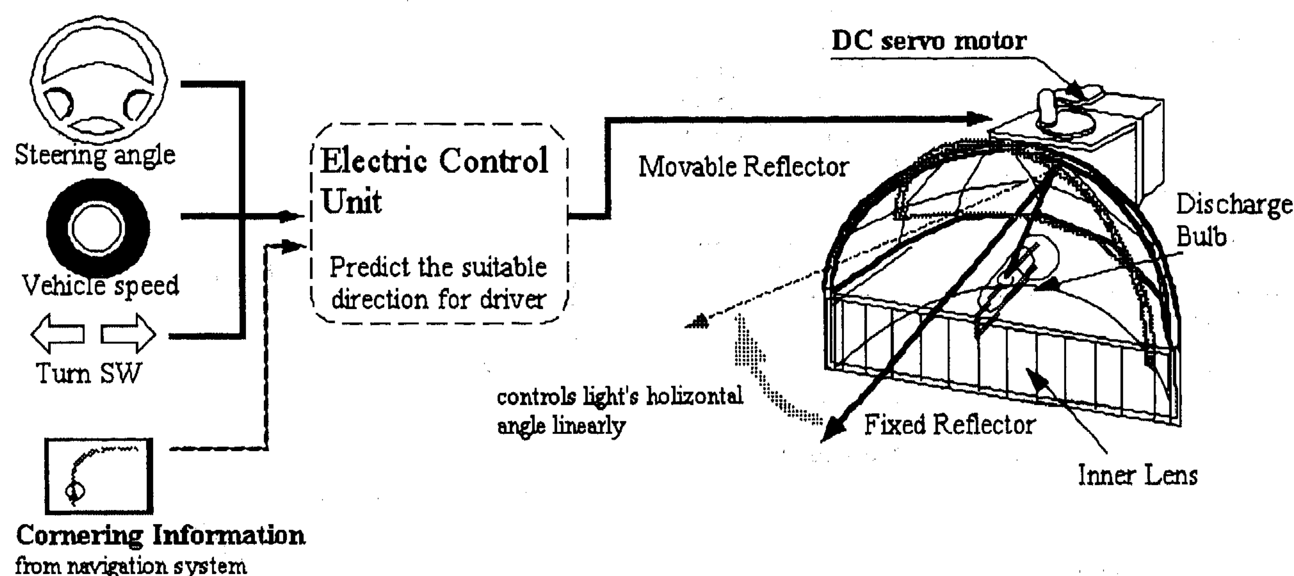

Figure 6. Structure of the AHL System

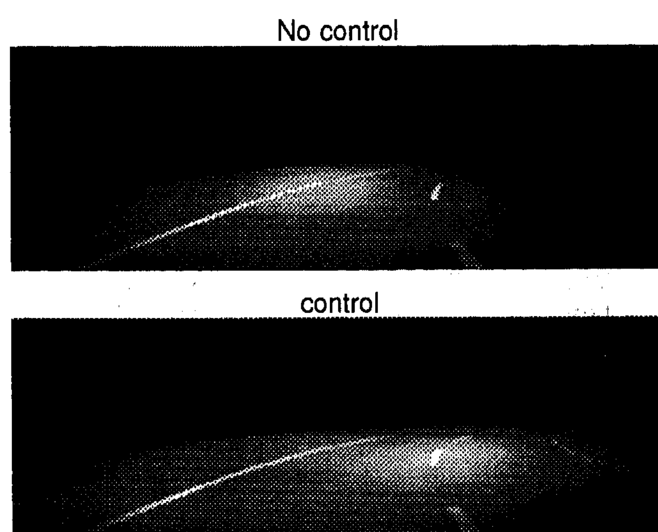

Figure 7. Illuminated area image by computer graphics

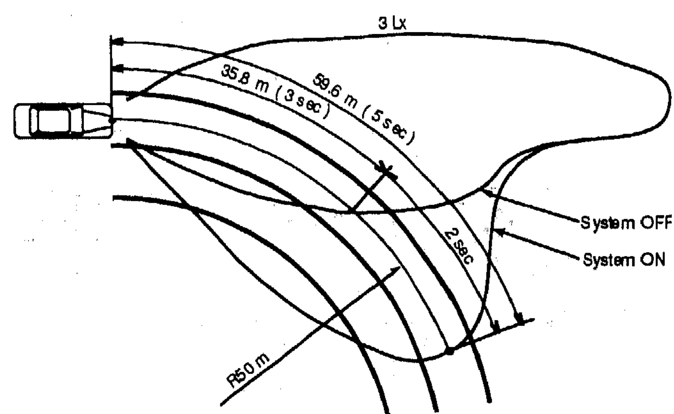

Figure 8. 3 Lux area of the AHL system

2) Control by turn signal
   When the turn signal is on, the system rotates the reflectors with a large angle. In case of the steering angle exceeds a predetermined value, the control will be switched to the "control by steering angle" mode.

3) Control by road information from the navigation system
   When the vehicle approaches a curved road in some distance, the navigation system sends an expected curvature information to the system. The system rotates the beam to adequate direction. In case of the steering angle exceeds a predetermined value, the control will be switched to the "control by steering angle" mode.

VALIDATION

EVALUATION OF VISIBILITY

Visibility on a curved road with a 50m curvature (hereafter called "R50") was evaluated using the AHL system. Three lux ISO-lux lines on a road surface of the AHL system and a conventional headlamp are shown in Figure 8. When the AHL system is on, the illuminated area with 3-lux reaches 60m along the curve. In case of the conventional type, illuminated area with an intensity of 3-lux reaches only 36m. The AHL system improved the visibility of the turning direction. If the vehicle runs at 45 km/h along the "R50" with the AHL system, a driver can detect road conditions two seconds earlier than with conventional one. Illuminated area images by computer graphics with each headlamp system are shown in Figure 7.

EVALUATION OF GLARE

We have also evaluated glare level for an oncoming vehicle. In the test of glare, 8 subjects sat in a stationary vehicle and they graded the glare level of an oncoming vehicle with AHL system and with conventional system. They graded with the de Bore scale. Figure 8 shows the results of the study. The AHL system increases glare, but it was still acceptable level.

	Left curve	Right curve
Conventional	7.0	4.5
AHL	5.8	4.9

Figure 9. The results of discomfort glare

SUBJECTIVE EVALUATION

Subjective evaluation of the AHL system has been done by Honda on the winding course. Six subjects drove the vehicle equipped the AHL system with two modes. The one mode was the AHL system was on, and the other mode was the AHL system was off. Figure 9 shows the results of the evaluation. The most subjects answered that the vehicle with the AHL system was comfortable, confident and better visibility on the curves.

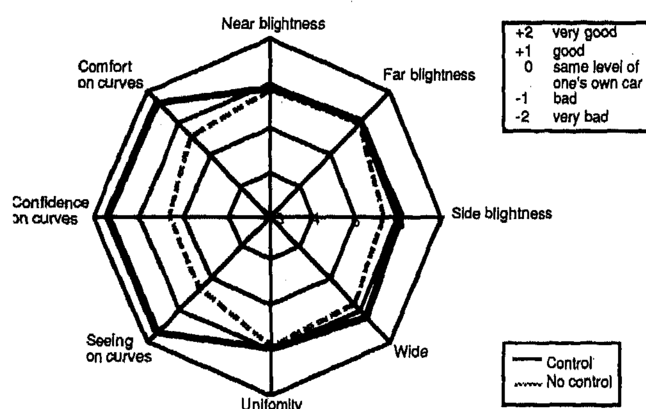

Figure 9: Subjective evaluation

EFFECT FOR EVASIVE OPERATION

The evasive action of a vehicle, driving on a constant radius, was evaluated to assess how the system would affect the driving. A subject drove the test vehicle on a constant 30m radius curvature at 40 km/h speed. Obstacles were placed at random on the course without knowing the driver. The steering angle was recorded by a sensor. The test results are shown in Figure 10. With the AHL system, evasive action became quicker and steering speed was decreased, steering wheel operation became stable. However, with the conventional system, evasive action was less responsive and steering speed tended to increase, resulting in more corrective steering action and unstable driving. Driving with the AHL system was closer to daytime driving than driving with conventional systems.

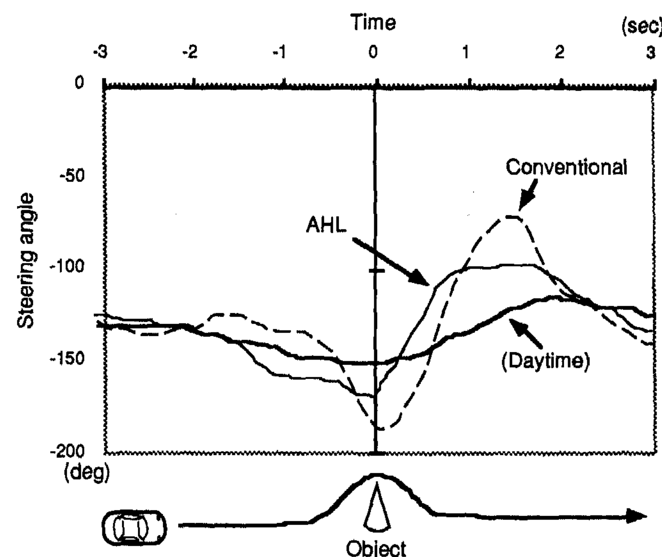

Figure 10: Evasive Operation

CONTROL BY ROAD INFORMATION FROM THE NAVIGATION SYSTEM

The most advanced feature of the AHL system is illuminating curve direction before the vehicle enter a curve by using the road information from the navigation system. The prediction method of a curve is called "Zone Judgment Method" developed by Honda. The detail of the method is described in the reference paper[5]. The AHL system can get the road information 5 seconds before the vehicle enter the curve. Waiting for 4 seconds, the AHL system starts to rotate the reflector to curve direction. The control angle is adjusted at the entrance of the curve.

CONCLUSION

In 1950's, there was a vehicle which third headlamp moved together with the steering wheel. The AHL system achieved accurate headlamp beam direction control and beam control in advance the vehicle enters a curve by using high accurate sensors and an advanced vehicle navigation system. As described validation section, the visibility on curves and the stability of driving task were greatly improved by the AHL system.

Last two years, high performance HID headlamps were introduced in the market. It seems to be still difficult to illuminate adequately in all curve conditions with this HID light source.

The AHL system can't be on the market immediately by the restrictions. Headlamp regulation should be changed along with the technological progress.

Progress and Perspectives of LED-Technology for Automotive Signal Lighting

Detlef Decker

Uwe Thomas
Hewlett Packard

Copyright 1997 Society of Automotive Engineers, Inc.

Abstract

Of all the light sources for automotive applications, only the LED increased its efficiency by a factor of more than 100 within the last quarter of a century. The use of new chip materials and new LED packages raised the emitted flux in the latest "TS-AlInGaP" process to more than two lumens per LED. Offering an extremely high service life, low power consumption, little mounting depth and quick response time the first LED application for signal lights was the Central High Mounted Stop Lamp (CHMSL).

In order to continue this success for other signal functions further technical problems have to be solved: Highly efficient secondary optics have to collect the light and to form it into an adequate beam pattern. - New methods of electrical connection are needed to enable LED's to follow the 3D-shape of the car.

1 Introduction

The latest developments of highly efficient LED technologies in combination with an increasing number of package options enables the LED to compete cost efficiently in the area of automotive exterior signal lamps. Today LED's are already being used in many automotive interior and exterior lighting applications.

With several 10.000 hours life time, an LED exceeds the life time expectancy of a motor vehicle under harsh automotive operating conditions. This means that an LED lamp does not need to be replaced at regular service intervals anymore. Another major safety benefit is the instant turn-on time of an LED lamp. A study by the University of Michigan found out that an LED lamp is seen 170 msec earlier than a bulb. At a speed of 70 mph this translates to a possible reduction of braking distance by up to 15 feet.

LED's come in small package sizes and have little weight. That makes it easy to arrange the LED's in various array formats to serve difficult design requirements. With a new mounting option LED's even can be attached to a three-dimensional metal substrate which follows the curvature of a car body. The low power consumption of the LED technology helps to minimize the vehicle's electrical load, to reduce the diameter of copper-wires and minimize the heat generation of the LED lamp.

The color emitted by an LED depends on the composition of the semi-conductor material being used. The band width of an LED's emitted color spectrum is very narrow. It emitts pure colors and thus tinted filters to generate the required color are not needed. This makes it very easy to design unicolor appearances, e. g. a dark gray look for the entire signal lamp.

2 Chip Technology

2.1 LED Efficiency

In the past the efficiencies of conventional LED technologies such as GaAsP (Gallium Arsenic Phosphate) or GaP (Gallium Phosphate) were not sufficient to generate enough flux for exterior automotive signal lamp applications. These technologies have an efficiency of about 1 to 2 Lumen/Watt.

A breakthrough was made with an LED technology called AlInGaP (Aluminium, Indium, Gallium, Phosphate) about four years ago. This material has an efficiency of about 20 Lumen/Watt which is equal to the efficiency of an unfiltered incandescent bulb (see Fig. 1).

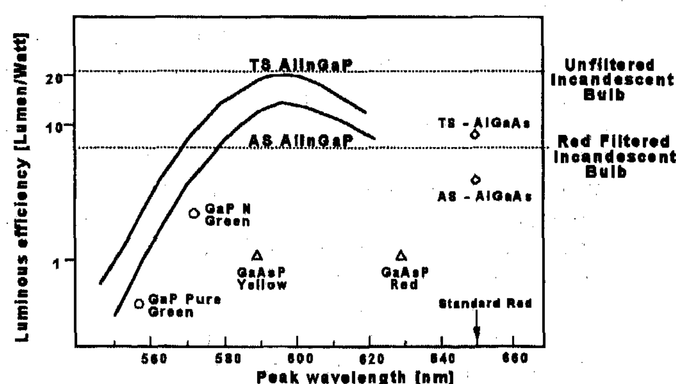

Fig. 1 Performance of LED Technology

With this tenfold increase in efficiency, suddenly the minimum required LED count for a signal lamp decreased by a factor of 10 for the same amount of flux required.

Light emission with AlInGaP is not limited to certain wavelengths. With variation of the doping levels, light green, yellow, orange and red colors are possible. AlInGaP generates its peak efficiency in the orange (~ 600 nm) color range. Improvements in the fabrication of the AlInGaP LED die will increase the efficiency even further.

2.2 AlInGaP Chip Structure

The crystal substrate of Hewlett Packard's AlInGaP LED's is made of a 200 µm thick GaAs (Gallium Arsenic) layer (see Fig. 2).

On top of the substrate there are three differently doped layers, each 1 µm thick, consisting of variations of Al, Ga, In and P. This structure is called a hetero junction structure.

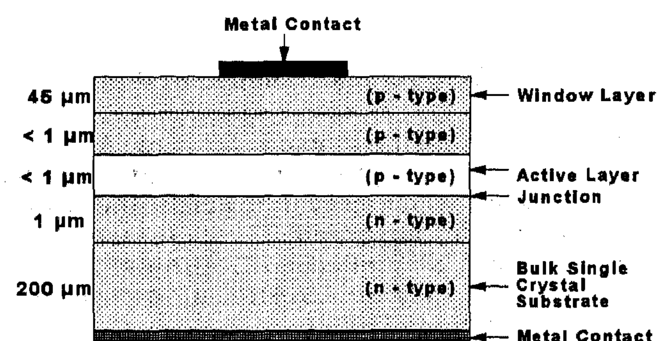

Fig. 2 AlInGaP Heterojunction LED Structure

The middle layer and the bottom layer form the pn-junction. The middle layer is also called the "active layer" because the distinct doping of the three layers forces the electrons mainly to recombine within this active layer. Due to its relative thickness this active layer provides more room for the electrons to recombine. This results in a higher maximum allowed drive current with hetero junction LED structures.

Standard AlInGaP LED's reach their maximum recommended current density within the junction at 50 mA while conventional LED technologies approach this limit at 30 mA. High current densities cause partial overheating which damages the crystalline structure of the LED die. At these areas, so called darkline defects, light ceases to be generated. The LED has degraded. The active layer of a hetero structure can handle higher current densities and thus is less susceptible to degradation.

On top of the three AlInGaP layers there is a 45 µm thick GaP window layer which creates the interface to the metal contact. The majority of the surfaces of an AlInGaP die cube do not expose any materials with metal contents. Only the sides of the very thin 3 µm AlInGaP layers have an aluminium content. Thus there is very little surface which could oxidise in a humid environment. The AlInGaP technology has shown excellent degradation results under the most stringent stress conditions such as high drive current, temperature cycling and humidity.

2.3 Absorbing versus Transparent Substrate

The GaAs substrate used for the AlInGaP LED absorbs light. Photons generated in the active layer which travel towards the GaAs substrate are absorbed. That is why this technology is called AS-AlInGaP. The efficiency of such an AS-AlInGaP structure is about 10 Lumens / Watt.

With a new process called "wafer bonding" the absorbent GaAs substrate can be replaced by the transparent GaP substrate (see Fig. 3).

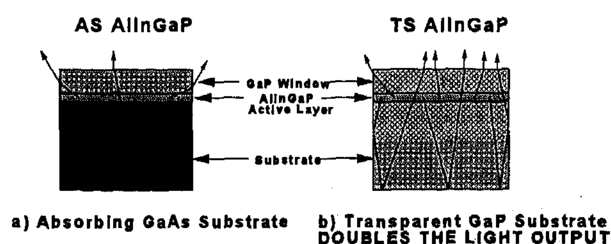

Fig. 3 HP High Performance AlInGaP LED Chip Structures

This technology is called TS-AlInGaP. With the help of a reflective coating on the back of the new GaP substrate all photons are reflected back through the material which increases the efficiency up to 20 Lumen/Watt. This is twice the efficiency of an AS-AlInGaP LED.

Both the AS- or the TS-AlInGaP dies are cubes with an edge length of 0.25 mm and can be built into any existing LED package.

3 LED Design

3.1 Packaging

With the use of silver conductive epoxy, the back of the chip (substrate) is connected to the cathode lead of the leadframe. At the location where the die sits the cathode lead is formed to a little reflector cup to capture the light which emits from the sides of the LED die. The top of the die is metalized and connected to the anode lead of the leadframe via a 25 µm diameter thick golden wire bond. The leadframe is now dipped into a mold cup filled with optical grade epoxy. The shape of the mold, the insertion depth of the leadframe and the reflector cup surrounding the die determine the radiation pattern of the LED. Also the different indices of refraction of the LED die, the epoxy and the ambient air have to be designed into the shape of the cathode reflector cup and the epoxy mold cup.

For a narrow emission angle package more light from the LED die has to be redirected into a narrower solid cone angle. This causes some optical losses. The wider the radiation pattern of the LED package, the more optically efficient it is.

3.2 Design with LEDs

The design objective of an LED signal lamp application is to generate as much flux as possible while taking the maximum operating limits into account. The maximum drive current should not be exceeded because of the current density as described above. The maximum junction temperature of the LED is related to the higher temperature at which the optical grade epoxy starts to expand rapidly and increase the risk of catastrophic failures such as broken wire bonds or lifted LED dies.

The following formula determines the LED junction temperature:

$$T_j = T_a + P_d * R_{th\,(j\text{-}a)}$$

where:

Tj	= junction temperature
Ta	= ambient temperature
Pd	= power dissipation (Vf * If)
Rth(j-a)	= thermal resistance junction to ambient temperature

This formula shows that by reducing the systems thermal resistance the drive current through the LED can be increased while keeping the junction temperature below its maximum. A higher LED drive current does increase the LED light output because the two are proportional to each other.

3.3 High Power Package

With the development of a power LED package the junction-to-LED pin thermal resistance was reduced to 150 °C/W. This power package is flat, which shortens the path for the heat to travel by bringing the LED junction closer to the pcp. The diameter of the leadframe is larger, which gets the heat out of the package more quickly. A new epoxy development has shifted the maximum junction temperature up to 125 °C.

Standard 5 mm LED packages have a junction-to-pin thermal resistance of 250 °C/W and a maximum junction temperature of 110 °C.

Also the power package has been designed for maximum optical performance. The radiation pattern options for this package offer wide viewing angles only to minimize the losses caused by larger angle refractions of the redirected light as described above. Such a power LED can run at 70 mA and with the TS-AlInGaP die it typically generates 2.5 lumens.

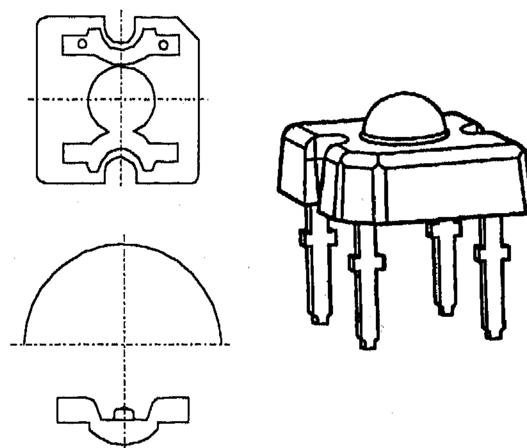

Fig. 4 Outline of Power LED Package

About 12 of these TS-AlInGaP power LEDs generate enough flux to meet the photometric specifications of a Center High Mounted Stop Light. The power consumption of such a unit would be about 5 Watt. under the assumption of typical system thermal properties [Rth(j-a) = 300 °C/W] the temperature rise of the junction above ambient is about 50 °C.

4 Applications

Needing the features "high reliability", "quick response time" and particularly "little mounting depth", the CHMSL was the first application of LED signal lighting.

Naturally this technology is also being investigated for other signal functions. The use of LED's - particularly for complete combination rear lamps - places new requirements on the optical and mechanical layout due to the more complex basic conditions for such lamps:

- The shape of the signal field does not always allow integration of a (rectangular) LED matrix.
- Modern combination-rear-lamp styling frequently requires shapes other than lines and rows; variations in brilliant or high contrast technology are frequently preferred.
- Low-profile versions also have to be curved, because today's combination rear lamps are almost always integrated in freely curved surfaces.

5 Optical Design

Different optical design possibilities result depending on the geometry of the lamps and the desired styling.

5.1 Fresnel Lens Systems

This classic optical system for capturing the light rays emitted in a cone shape from the LEDs and passing them on effectively parallel to one another is always suitable when the luminous surfaces can be composed of a number of individual segments. In addition to square surfaces (see Fig. 5) the overall surface can also be composed of individual hexagonal / trapezoidal or similar surfaces.

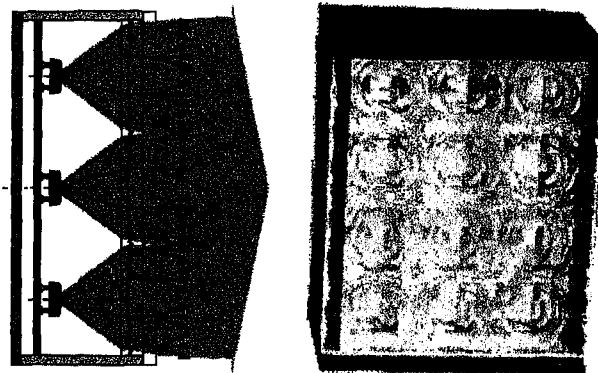

Fig. 5 Fresnel lens optics: Principle and sample

5.2 "Flat Mirror" Optical Systems

Fresnel lens systems require greater overall depths for the illumination of large surfaces. This applies especially to tail lamp functions as the above-mentioned new LED-Technology allows the requested lighting pattern to be generated with only one or two single diodes. The overall depth can be reduced considerably by reflecting the light rays. Turning the combination "LED - Fresnel lens" 90 degrees towards the optical axis of the lamp means that a greater area can be illuminated by the inclined mirror on which the light falls (fitted with prisms-flat mirror) than would be the case if a Fresnel lens surface were used directly. Simultaneously the "spots" of the individual LED's are not as clearly visible. Since the reflecting mirror coating remains visible in the cold state, the system provides a brilliant impression (see Fig. 6).

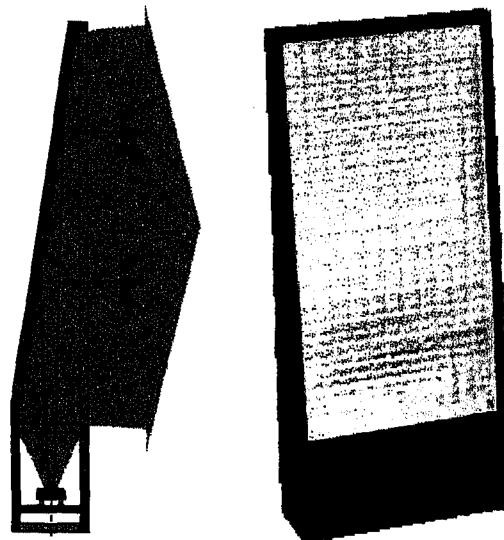

Fig. 6 LED flat mirror system / schematic drawing and example

5.3 Light Guide Technology

Light guide technology can be used for particularly flat versions. The light is carried by total reflection after entering a transparent material. As these light guides can be formed out of thin plastic materials and can be provided with reflecting elements (e. g. prisms) these designs allow the flattest versions of all.

Contrary to incandescent bulbs the "cold" LED's can be installed directly next to the light guide, eliminating increased overall depths and volumes for the light source and input segment. Figure 7 shows an example for a flat taillamp.

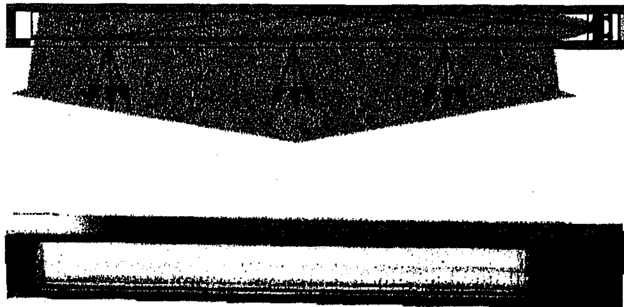

Fig. 7 Light guide taillamp / schematic drawing and example

6 Connection Technologies

Selection of the technology depends considerably on the basic geometry of the lamp. The possibilities are evaluated below:

6.1 Circuit Board Installation

This classic solution for mounting electronic components also provide an excellent solution for the LEDs in the safety brake lights mentioned at the beginning. Since the circuit board is a flat component, curved lamp contours require that the LEDs be arranged in terraces on individual circuit boards connected by wire bridges at equal distances from the lens. These limitations can be eliminated to a certain extent by the use of flexible circuit boards.

6.2 Snap-LED's

This connection technology developed by Hewlett Packard fixes the LEDs with a type of rivet within a stamped grid. Certain sections of the grid can be shaped (see Fig 8) to allow terrace-shaped structures by means of deformation. This connection technology appears to be the least expensive alternative for complex 3D structures.

Another advantage of this principle is that the LEDs are not subjected to any type of thermal load during processing. Conduction of the heat away from the semiconductors can be improved and the danger of cold solder points is eliminated.

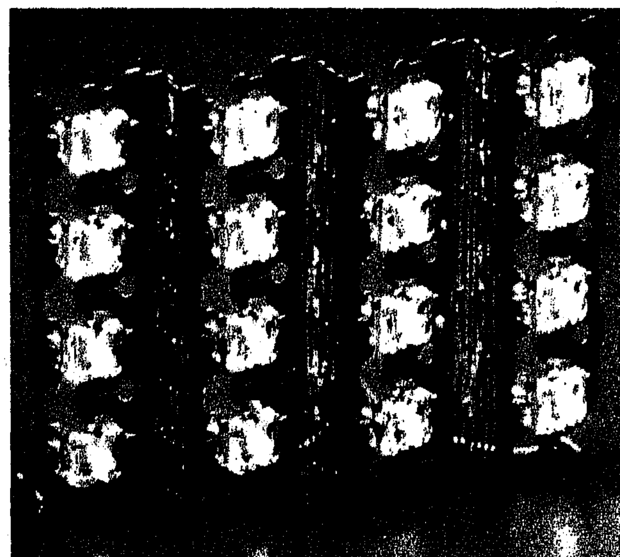

Fig. 8 Application example for SNAP-LEDs on a 3D carrier

6.3 Moulded Interconnected Devices

Moulded Interconnected Device Technology (MID) produces conductive connections by means of galvanized conductors on complex three-dimensional plastic surfaces. The LED's can be connected by soldering. In addition to automation, the many process steps still required for production of the circuit board represent a major obstruction for this technology.

6.4 Alternative Concepts

Dependent on the basic geometry of the lamps and the type of diode used, other alternatives are imaginable. One possibility here is wire connection technologies using industrial robots. The connections could be completed for example by using snap-lock connectors.

7 Prospects

Looking at the LED itself one of the major tasks for the future will remain to increase its light output further. With a reduced number of required elements the competitiveness of LED-lamps will grow even more.

Apartly from this the challenge to achieve the white color for the signal functions "Position", "Reverse" and "Daytime Running Light" will so remain. Attaining better efficiencies for the green and blue color will enable this goal be realized by mixing red, green and blue by color addition to "white".

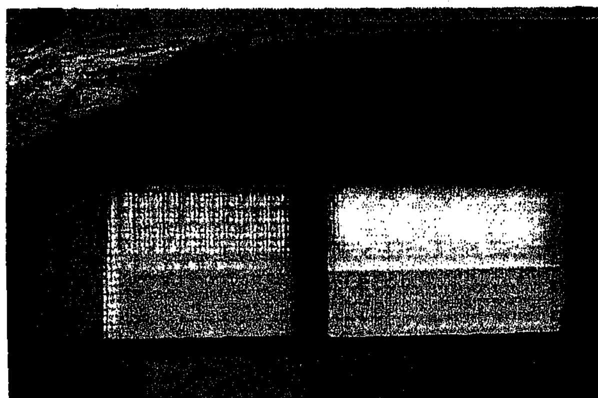

Fig. 9 Prototype of a combination rear lamp

The possibilities for application will increase, too. In addition to the mentioned use for complete combination rear lamps shown as a prototype in figure 9, use in side marker lamps as well as additional side repeater flasher lamps will provide the next applications for LEDs. Since the high reliability of LEDs offers particular advantages in the commercial vehicle sector, the next fields of application for LED signal lamps will be found here.

LED technology can also be used to great advantage for new concepts for the rear signal appearance on motor vehicles, because the size of the signal field as well as the overall brightness can be varied just as easily as can, for example, the light-up frequency using LEDs with one simple electrical control. This ensures that the control or adaptation of future signal appearance patterns on motor vehicles can be implemented simply in terms of optical technology.

LEDs can be used for many signal functions - as shown - even before the registration codes allow implementation of such visions. It will soon be necessary to examine new lamps more carefully to determine whether incandescent bulbs need be used at all.

LED Automotive Rear Combination Lamp (RCL) Dual Level Driver Electronics

Derek S. Mallory
North American Lighting, Inc.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

For the current class of available automotive LEDs (Light Emitting Diodes) used in CHMSLs (Center High Mount Stop Lamps), voltage regulation is required for operation at an optimized output light flux. We have built and measured the performance of resistive, voltage reference, and pulse width modulation DC-DC voltage regulators in order to achieve the required dual level control for RCL (rear combination lamps). These three types of driver electronics for dual level operation of a RCL are compared for performance, and efficiency under various operational conditions.

INTRODUCTION

Current automotive circuitry achieves the required voltage level with passive resistors on the boards located near the LEDs. A typical high output LED is operated at 2.5 V compared to 12.8 V supplied from the battery. With an array of four or three LEDs in series, 22% to 33% of the power is wasted as heat in the voltage divider resistance. The additional heat generated on the circuit board from this voltage divider reduces light output for the LED array.[1] This is of major importance since photometric requirements are tested after having the LED lamp on for 30 minutes. A 30% decrease in light output due to heating of the LED/circuit board is not unusual over this time.

The use of LEDs in a RCL will require dual level operation for stop/tail functions which can be easily achieved by an external driver electronics module. Removing the on board regulation circuitry to an external driver control unit will reduce heat in the lamp package, and improve performance of the LED lamps. Additionally, different DC-DC voltage regulation techniques can be utilized to further increase the operational efficiency of the driver electronics.

MAIN SECTION

PHOTOMETRICS - For dual level control to be considered, it is first useful to understand the motivation behind the need for dual level voltage regulation. SAE J585 and SAE J586 address tail and stop lamp photometric requirements respectively.[2] These typically assume a dual filament bulb to meet the requirements. SAE J586 sets the minimum intensity ratio for stop (high) operation to tail (low) operation at 5:1. Table 1 shows a comparison of maximum and minimum allowed values at H-V for stop and tail operation.

Compartments	1	2	3
Stop max (min)	300 (80)	360 (95)	420 (100)
Tail max (min)	18 (2.0)	20 (3.5)	25 (5.0)

Table 1. Stop and tail requirement comparison at H-V test point with maximum and minimum requirements in candela. A 5:1 minimum intensity difference is required.

The 5:1 intensity difference would correspond to minimum stop lamp intensity and maximum tail lamp intensity at H-V. It is of note that a standard dual filament bulb accomplishes this ratio with a 7:1 intensity difference between stop and tail.[3] Additionally since the tail filament is usually defocused ratios of ~9:1 are achieved in practice. Thus, a more reasonable intensity ratio for an array of LEDs would be in the range of 7:1 or more for design purposes. With LEDs this can be achieved by voltage regulation, or current regulation. For the purposes of this paper, we only consider voltage regulation as a possible means to achieve the dual level light output.

VOLTAGE REGULATION SUBCIRCUITS - The following is an introduction to DC-DC voltage regulation circuitry that would be useable to drive LED arrays for RCL applications. For our design purposes, we considered two different arrays of 48 LEDs. The two parallel arrays

were accomplished by **1)** 16 rows of 3, and **2)** 12 rows of 4 LEDs in series. For the purposes of this comparison, high operation for the individual LEDs was at 2.5 V @ ~70 mA, and low level operation was at 1.9 V @ ~30 mA. Table 2 shows the complete operational conditions required by the LEDs.

Mode	16 rows of 3	12 rows of 4
high (8.40 W)	7.5 V @ 1.12 A	10.0 V @ 0.84 A
low (2.74 W)	5.7 V @ 0.48 A	7.6 V @ 0.36 A

Table 2. Typical operating voltages for one stop/turn/tail LED array with total current.

RESISTIVE CONTROL - Figure 1a) is an example of a resistive network that can be utilized for dual level LED control circuitry. Currently, this is the standard arrangement for single level operation of CHMSLs. It is recommended to operate the LEDs in arrays of three or four in series.[4] Since the LEDs typically cannot handle large reverse voltages or currents, a protection diode is added to the array.

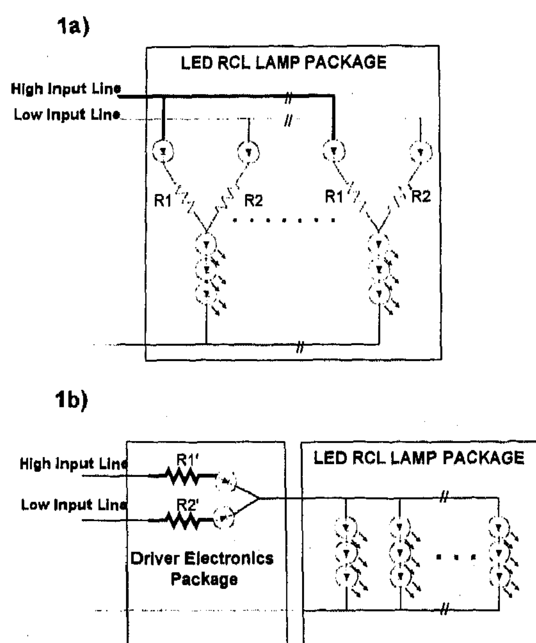

Figure 1. a) An example of a possible on-board resistive network for dual level control of an LED array. b) Shows a schematic of the driver electronics using power resistors R1' and R2' for dual operation.

Another resistive option is to operate the array with a single power resistor voltage divider as in figure 1b). This circuit could be placed in a control module that is attached to the lamp housing. This has the advantage of removing the resistive heating from the local board area near the LEDs. However, the large wattage power resistors, and high current diodes required are not the most power efficient options available as will be seen.

All resistive control methods have potential drawbacks. During operation at higher or lower voltages than design, the LEDs will be run at incorrect voltages and light output levels. Large voltage spikes and EMI will not be filtered from the LEDs. Large wattage power resistors add considerable weight compared to other control methods.

VOLTAGE REFERENCE - Figure 2 is an example of a Darlington voltage feedback circuit for DC-DC operation. This is a standard method widely used in automotive circuitry to provide reference voltages. The output voltage is determined by the voltage divider. This fixes the transistor into saturation and the output V_e is determined by the voltage drop across V_{be} (which is typically 0.6 V). Thus,

1) $$V_e = V_b - 0.6\ \text{V}.$$

The Darlington voltage reference will provide a fixed drive voltage at reasonable efficiency if operated in saturation mode. The efficiency depends upon the current gain of the transistor used. The current gain of a typical medium power output Darlington is low (10-20) when driven in saturation for high output current.[5] Thus to drive an input load of 1.5 A, ~100 mA injection current will be required. The lower the current gain of the transistor, the higher the losses in the voltage divider and Zener diode reference input to the transistor base V_b.

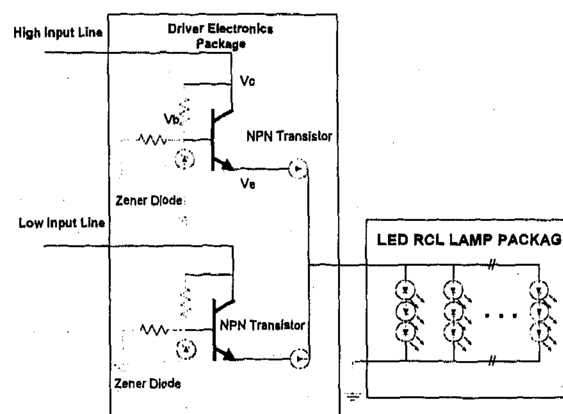

Figure 2. Example of dual level Darlington voltage references for driving a LED RCL lamp.

For operation at higher input voltages than originally designed, the Zener diode will clamp the base voltage to the required output level. However, when operated at lower than design input voltages, the output voltage to the array will fall linearly with the base voltage divider circuit. Efficiency can also be lost at low input voltages due to the transistor dropping out of saturation mode.

This DC-DC voltage regulator will filter some high frequency voltage spikes from the LED array, due to the transistor switching times. But, additional filtering would be required to completely isolate the array from electromagnetic susceptibility on the input line. Tradeoff considerations for output voltage vs. input voltage would also need to be made when selecting the reference Zener diode values.

PULSE WIDTH MODULATION (PWM) - Figure 3 is an example of a pulse width modulation circuit for dual level voltage regulation with voltage feedback. Two options exist for using the PWM circuitry. The first is to use rectification or wave shaping on the output. This will limit the efficiency of the overall circuit depending upon the rectification circuitry. The advantage is it will supply a filtered DC voltage for which the LED light output is fully characterized, which may help meet EMC requirements.

The second method for PWM operation is to drive the LEDs with no rectification. This is the most efficient method power wise to operate a LED array. A major consideration for using unfiltered square wave output is the possibility of EMI problems (Electromagnetic Emissions). Typical drive frequencies are in the range of 60 Hz to 400 Hz.

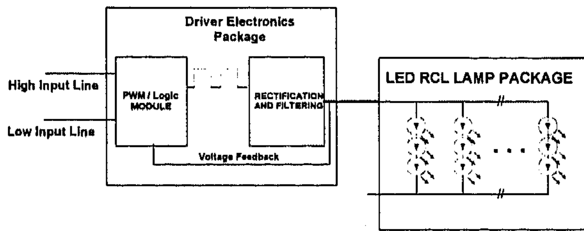

Figure 3. Pulse width modulation with rectification for dual level LED voltage regulation in RCL applications.

An additional advantage of this more complicated system is the operation at over voltage and reduced voltage. Light output (and power supplied) can be feedback controlled by adjusting the duty cycle of the LEDs,[6] effectively allowing constant controlled light output over a large input voltage range from 9 to 18 V.

ELECTRICAL EFFICIENCY - Table 3 shows the relative efficiency comparisons between the three main types of driving circuitry we constructed. The comparisons are for high and low operation of the driver circuitry with the LEDs in rows of three in series. The power dissipated by the LED array in low and high operation was given in table 2.

For the driver circuit modules above, the heat from the losses is separated from the LED array circuit board. It is apparent that the PWM method for voltage regulation is the most efficient. However, PWM is the highest cost system and will have possible EMC problems. The greatest energy savings are achieved during high mode operation, which would be the stop/turn signal functions. This high efficiency translates into weight savings as well, since a smaller heat sink would be required for the control circuit.

Driver Circuit Type	3 LED Array
Resistive Low Mode	3.4 W
Resistive High Mode	5.9 W
Darlington Low Mode	1.5 W
Darlington High Mode	3.5 W
PWM Low Mode	1.2 W
PWM High Mode	2.1 W

Table 3. Comparison of driver circuit wattage required for operation of a 3 LED in series array. Total power dissipated by the RCL lamp is the sum of driver circuitry plus LED array given in table 2.

THERMAL CONSIDERATIONS - When designing LED rear lamps, performance at elevated temperatures must be considered. The junction temperature of an LED needs to be kept below 125° C to insure no failures. These failures are typically caused by the wirebond becoming disconnected from the LED die when the plastic around the die passes through the liquid/solid glass transition at 125° C. Design of the circuit board, location, venting of the lamp, external temperature, and operational voltage all play important roles in determining the final junction to ambient thermal resistance.

For the dual level control methods mentioned in this paper,

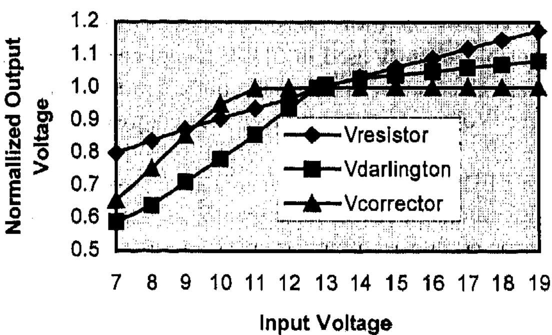

Figure 4. Experimentally measured normalized output voltage for the three types of regulation circuits driving 3 LEDs in series. Operation mode is for "high" output of 7.5 V across 3 LEDs at 12.8 V input.

operational voltage is what can be controlled. Figure 4 shows the normalized measured output voltage for input voltages varying from 7 V to 19 V for the three different dual level control methods. In figure 4, Vresistor is using the power resistors shown in figure 1. Vdarlington is using the Zener diode driven voltage regulator from figure 2. Vcorrector is using a voltage feedback circuit similar to the PWM module in figure 3.

Figure 4 further highlights the problems that can occur if LED lamps are driven above the designed voltage of 12.8 V. If resistors or the Darlington voltage reference circuitry have been used, additional heating will occur in the LEDs from the higher drive current. Only control circuitry with feedback will limit the maximum drive voltage for the LEDs, thus eliminating additional thermal factors. It is not a stretch of the imagination to envision dual level control modules that are temperature compensated to further reduce LED drive voltage at elevated temperatures. Further study of total lamp system thermal and photometric interactions is needed to propose circuitry to effectively handle these concerns.

CONCLUSION

The LED systems that are employed in future automotive applications will need to be designed cost effectively with an understanding for the optical, photometric, thermal, and overall system performance interactions. The demands for better fuel economy and electric cars will continue to motivate that the most efficient electrical voltage regulation and lighting be employed. LEDs are an excellent consideration for this task, and will need dual level drive circuitry to meet these requirements.

A voltage regulation driver circuit can be used to operate a LED array for dual level RCL applications. The lowest power consumption option is accomplished by a PWM DC-DC voltage regulator. However, PWM modules cost more and have possible EMC considerations. Resistive methods of control currently used in CHMSL applications are not as efficient electrically or thermally but are much simpler to design. Voltage limiting by feedback control may be needed for LEDs because of thermal considerations. For future LED RCL lamps, a case by case approach to these considerations needs to be approached when selecting the optimum dual level drive system.

ABSTRACT

The automotive lighting industry has undergone major changes over the past 25 years. The sealed beam lamp, the industry standard for half a century has been replaced by a number of new aerodynamic headlamps. Over this same time period signal lighting has undergone dramatic changes; from a standard hand signaling for brake and turn, to complex multi-cavity systems for running, turn, and stop lighting. In the interior of the vehicle similar changes have also occurred which have dramatically improved driver visibility of the instrument cluster. In all three application areas major changes are continuing to occur particularly in the light source and optics of the illumination system. This paper discusses some of these changes and compares the various light sources and optical systems used to illuminate the space around the automobile and the communication between vehicles. While the forward illumination has been the dominant element in lighting, signaling to improve accident avoidance is becoming of equal importance. The central theme of this paper is to provide information about the various sources with a particular emphasis on the neon discharge light source and its auxiliary system components that can expand our communication ability.

INTRODUCTION

The automotive lighting industry has undergone major changes over the past 25 years. The sealed beam lamp, the industry standard for half a century, has been replaced by a number of new aerodynamic headlamps. The gas-filled tungsten incandescent evolved to the hard glass halogen. Today, High Intensity Discharge (HID) sources are being used on several vehicles both in the United States and Europe. Signal lighting has undergone a dramatic change from the days when hand signaling was standard for brake and turn with a simple red tail marker lamp to multi-cavity systems and now Light Emitting Diode (LED) and Neon Low Pressure Discharge (LPD) lamps are available. In the interior of the vehicle similar changes have also occurred. Simple gas filled incandescent lamps have been replaced with multi-colored edge-light cluster lighting in addition to LED and Sub-Miniature Fluorescent (SMFL) lighting techniques. In all three application areas major changes are continuing to occur particularly in the light source and optics of the illumination system.

While forward illumination has been the dominant element in lighting, signaling to improve accident avoidance is becoming of equal importance. However, it should be noted that the requirements for signaling as well as for forward lighting have historically been developed based on criteria involving human interaction with the performance properties of incandescent source and optics. In general, the evolution of new light sources and optics produce different performance characteristics. These differences must be continuously evaluated during and after the development process to ensure that they provide improvements to the intended safety requirements derived for the incandescent function.

LIGHT SOURCES FOR ROAD ILLUMINATION AND SIGNALING

FORWARD LIGHTING - The simple glass headlamp that served so well for so long in the United States was an incandescent filament mounted in a parabolic reflector with a hermetically flame-sealed lens to ensure an inert atmosphere. The reflector collimated the light from the tungsten wire source and a glass spread lens was used to distribute the light to meet the required beam pattern. In the mid-seventies, hard glass tungsten halogen capsules replaced the incandescent filament source and the bonded beam replaced the flame-sealed glass lamp. Plastic optics replaced the glass leading ultimately to the aerodynamic headlamp with replaceable bulbs (9004, 9005/6 and 9007). More recently, HID sources have found their way into headlamp applications. [1] The blue-white light of the source interacts favorably with road markers, signs and paint. [2] Under wet driving conditions this source enhances illuminated surfaces, providing a visual aid to drivers. The development of improved low glare optics using these sources will allow older people to extend their driving years by keeping them more mobile during evening hours.

SIGNAL LIGHTING - Even though signal lamps have traditionally been incandescent vast improvements in optics and system designs on the rear of the vehicle have occurred. Automotive lighting engineers are providing illuminated areas to outline vehicle shape, and provide direction and braking information. Rear-end collisions have been reduced by the addition of brake/turn/tail lamps and reflex material for passive identification. As a further improvement, the third brake lamp, the Center High Mounted Stop Lamp (CHMSL)

has been added for transmitting vehicle de-acceleration information.

Incandescent signal light sources have changed from a metal based bayonet incandescent to hard glass tungsten halogen wedge base and S-8 style clear and amber bulbs. The latter sources have greatly improved bulb alignment, reduced contact problems and are becoming standard with some automotive manufacturers. During this evolution, optics for these applications have transformed from simple round three- or four-inch diameter parabolic reflector lamps with a plastic pillow colored lens to large red lens systems with multiple incandescent sources. As insert and multi-color molding technology evolved, single piece lens packages with different lighting functions (color filters) have become dominant. High contrast luminaries have been introduced to reduce the glare effects produced by the sun from these lamps. As with forward lighting new sources are beginning to replace the incandescent signaling lamp. For instance, LED's and LPD lamps were introduced into CHMSL's. [3]

HID LIGHT SOURCES - At least in a general way the HID and LPD sources are similar because they both are plasma discharges and they both need ballasting. The operating pressures, electrodes, arc gaps, and lamp chemistry are, however, significantly different. Briefly, the HID source is a high luminance device ideally suited for focusing-type optics that are used for illuminating subjects such as roads and pedestrians. However during a cold start, the initial output radiation is limited to xenon and some mercury. After approximately one second the mercury pressure builds, providing a mercury spectrum which is visually bluish-white. Within five seconds the discharge becomes visually white as the contribution from sodium and scandium metals produce additional emission. The discharge processes that provide emission of light are driven by initial high power levels (75 watt for the steady state 35 watt HID source) applied to the arc tube during the start-up phase. Within approximately ten seconds the heat provided by the applied power provides a gas mix of metal halides such as scandium iodide, and sodium iodide. Thus, the color chromaticity and luminance are varying until the bulb wall steady state temperature is achieved after several minutes.

SMFL LIGHT SOURCES - Low power narrow diameter fluorescent lamps can be used for interior lighting applications. Typically instrument cluster back lighting and general lighting with a dome fixture are good examples. The efficacy of the SMFL lamp is quite good, ranging above 35LPW. The lighting process involves a low pressure discharge through mercury gas which emits strongly in the ultraviolet (UV). A phosphor material, coated on the inside of the bulb, absorbs the UV and converts the energy into longer visible wavelengths. Unfortunately any mercury-based discharge depends on the volatility of mercury. Particularly for fluorescent lamps the pressure of mercury is very important. At temperatures below 0^0Centigrade(C) the fluorescent lamp does not work well because the vapor pressure of the mercury is low. Typically electrical heaters are attached to the outside of the SMFL tube to heat up the mercury. On the other hand, as the temperature increases above approximately 30^0C the increase in the vapor pressure of mercury causes the UV to be self absorbed and results in a reduction in efficacy.

LPD LIGHT SOURCES - The LPD, on the other hand, achieves its spectral characteristics nearly instantaneously. The bulb chemistry is simple in comparison to the HID source. Its electromagnetic spectrum is determined by the excitation of atomic species in the gas phase. For automotive applications neon gas, which emits a reddish spectrum, is the most useful LPD source. However, even for pure neon the emission spectrum will depend upon the applied power characteristics as will be discussed later in this paper.

The LPD sources provide much faster response time than the incandescent filament because the tungsten wire must be heated to incandescence. Wire heating is achieved by passing an electric current through it. As the power is increased the filament's resistance turns the electrical energy into heat, thus raising its temperature. At about 1000°Kelvin(K) the radiation from the wire begins to shift from the infrared into the visible portion of the electromagnetic spectrum. As the filament temperature increases, a higher percentage of radiation is formed in the visible region of the spectrum. The filament size, shape, wire size, applied voltage, and power of the light source are related to its steady state radiating level. The resultant rise and decay time of the light output is on the order of hundreds of milliseconds. On the other hand, the low pressure gas discharge of neon are atomic radiators and can produce light significantly faster.

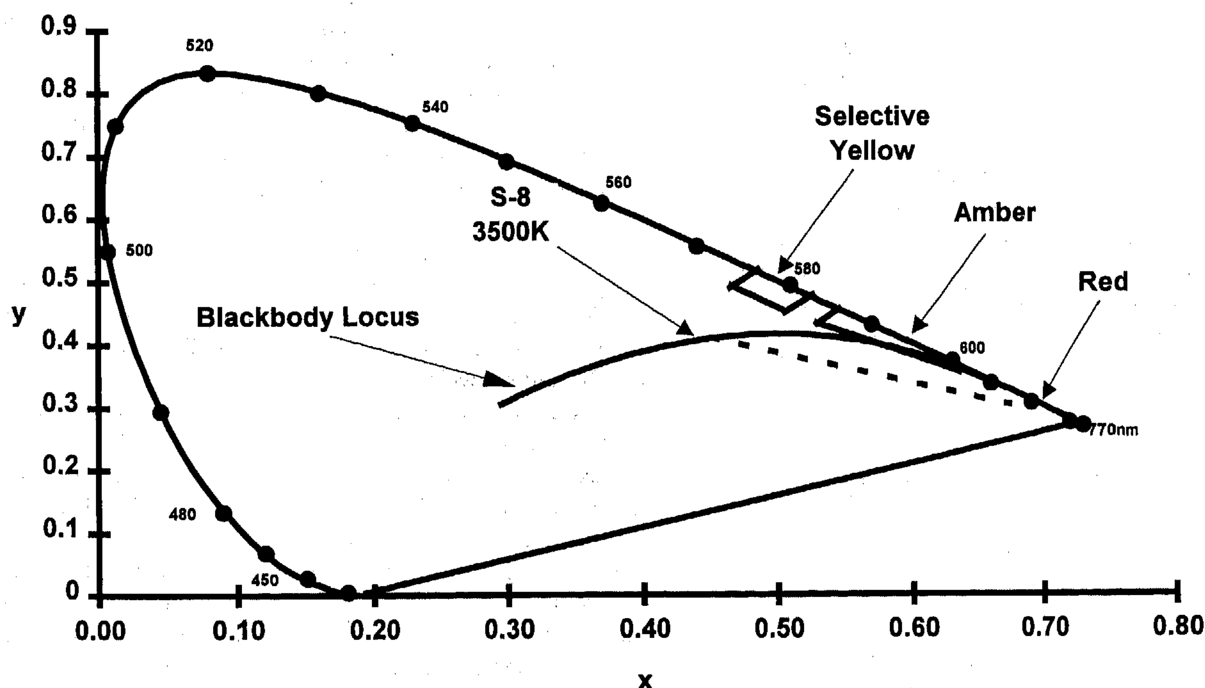
The neon gaseous discharge is less dependent upon the temperature of the environment, and more on its own internal continuous operating temperature. The steady state temperature in typical luminaries is reached in about 20 minutes, with a light output reduction of about 10 to 15 percent comparable to effects found with LED's. It should also be noted that the incandescent source is usually designed to operate at or near its operational limits to provide high luminance and efficacy for a desired life requirement. Therefore, the applied voltage variations to the source affect its output and life expectancy. The current state of voltage regulation found within most vehicles permits significant variation in lamp life and output. HID and LPD sources can be regulated within a few percent over an input voltage range from 8 to 18 volts. This helps maintain a regulated output and protect the source.

LED LIGHT SOURCES - The LED has also found applications in automotive. The red LED is used primarily for CHMSL units. Typically twenty or more individual diodes are clustered or arrayed in order to achieve acceptable light levels. The LED also has a fast rise time since the emission is due to solid state "gap" transition. Barrier junction noise is

dependent on the heat level which contributes to a light output reduction at elevated temperatures.

Because of heat transfer limitations the LED power levels are limited to about 0.1 watt. In spite of today's most advanced fabricating techniques heat sinking is required when large clusters of LED's are used for continuous operation. This sets the appearance characteristic of the LED lighting module as an array of point sources. The high luminance LED source is highly directional because of the fabrication technique of a plastic collection lens over the solid state component. This highly directional feature can present two problems that need to be solved in packaging of these small sources. First, the mounting of the LED needs to be controlled precisely or the array will have an element that appears to have burned out at certain viewing angles. Second, to create enough spread for the signal light pattern, the peak intensity pattern of the individual LED's needs to be spread to achieve off-axis coverage for the lighting function. In order to achieve this condition more LED wattage will be needed. This will require more diodes because the light per LED is limited, about fifty diodes would be required to perform the turn or brake function. This number of diodes with the most advanced technology will produce luminaries with a blotchy lit appearance, unless large optical packages or highly diffuse one are utilized. The latter indicated method will require a larger population of diodes to meet photometric requirements.

INCANDESCENT (TUNGSTEN) LIGHT SOURCES - The tungsten source for rear vehicle lighting is of low wattage and compact size and in general is placed in optical packages with a great deal of light spreading capabilities to form the desired lighting pattern and appearance. The reflectors are generally deep and highly diffuse in comparison to the specular forward headlamps. This is done to reduce the impact of bulb size, position, and tolerance limits, of multi-functional bulbs, etc.. The tungsten source is filtered by the use of the colored lens. Presented in Figure 1a is the CIE Chromaticity Diagram indicating the color shift necessary to transform a 2600°K incandescent source, in this case a tail lamp of the wedge or S-8 design, to the recommended red signal region. About two-thirds of the visible light must be absorbed by a red lens filter material in order to achieve the desired effect. Thus, about 3% of the lamp wattage is converted into useful red light. The remainder goes into heat.



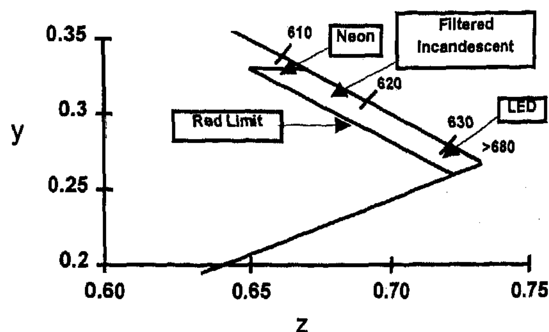


Figure 1a. - CIE Chromaticity Diagram indicating color areas. Dotted line represents color shift of incandescent through a red filter.

An exploded view of the red corner of the CIE is shown in Figure 1b. The positions corrsponding to the various sources are indicated. The red limit box is the specification for red light as defined in the SAE Signal and Lighting Handbook.

Figures 1b - Transformation of white light from S-8 absorption of lenses (approximately 2/3 of visible light energy is lost).

SPECTRAL PROPERTIES OF THE LIGHT SOURCES - The LED generates light in a narrow wavelength band and thus is highly efficient, unlike the continuous broad electromagnetic spectrum of the incandescent source or the multiple line neon spectrum (see Figure 2). A comparison of the typical visual radiating properties of the three sources is shown in Table 1. In the past, it has been difficult to make a hybrid system using LED's and tungsten with good color matching characteristics. The LED source could not be filtered to bring it into the region of the chromaticity diagram where the red filtered incandescent was located. The basic problem is the inherent narrow spectral band of radiation at about 650nanometers(nm). In order to achieve color matching between the two sources the incandescent source, which emits in a continuous broad band, had to be filtered further into the red region. This required higher bulb wattage's to provide sufficient intensities for various lighting functions. More recently new LED sources have been developed that radiate closer to the filtered incandescent chromaticity.

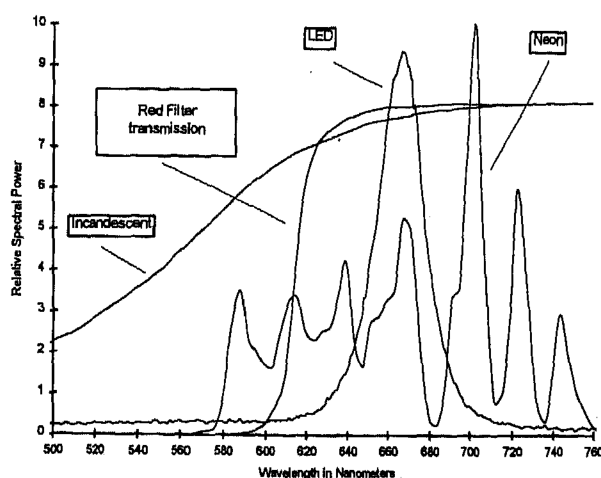

Figure 2. - Spectral power distribution of Incandescent, Filtered Incandescent, Neon and LED sources.

The neon source, while not a continuous spectrum radiator, has a series of atomic emission lines that generate light from the yellow-green to the deep red (between 580 and 750nm). A small amount of filtering between 580 and 620nm can shift the system deeper into the red to match any filtered incandescent source. Any filtering to the red will reduce the lumen value of the neon radiation because the eye responds more to the yellow-green than to the deeper red stimulus. The filtering can reduce the effective light of the neon radiation by about one quarter. Note that the unfiltered red neon spectrum meets the SAE color specification and that a crystal clear colorless lens could be used in this case, minimizing the amount of wasted wattage.

SIGNALING CHARACTERISTICS

Signaling with the gaseous type of sources (also LED's) allows for a number of advantages not available today with the current tungsten or mercury-base sources. Even with the advent of radar, sonar, and other navigation aids, mariners and air craft pilots still depend on visual aids. Communication by means of colored and white lights are readily accepted by humans. Information can be superimposed within the field of view of an observer, and can be easily utilized while monitoring driving conditions and the surroundings. The improved use of signal lamps and reflex materials/or signs and sign illumination has reduced fatalities over the past several years. To date, with the exception of xenon flash lamps, communication between two vehicles has been performed by the use of tungsten sources or horns.

An incandescent source needs a finite amount of time to build up to maximum outputs on the order of two to three hundred milliseconds. The tungsten decay time is less than, but similar to, that of its rise time. This limits the number of on-off lighting cycles per time interval, limiting the frequency of pulses for signaling lights. Thus, tungsten can only provide strobing information at about 1 to 2 hz rate. While the eye is limited by its critical fusion frequency to about 10 hz for a highly distinctive effect, a person can typically detect light modulation to about 50 hz. The voltage applied to the bulb will have a significant effect on this rise time as well as on the maximum steady state output available from the source. After turn-on, the light increases approximately exponentially with time then approaches the steady state value asymptotically. Figure 3 and Table 2 show time to 90% light output as a function of voltage. The light output of an incandescent source and its spectrum are temperature dependent which in turn, depends on the percentage of its rated applied power. A ten percent reduction in voltage reduces maximum output by about 30%, or a 10% increase can cause a 70% percent reduction in life.

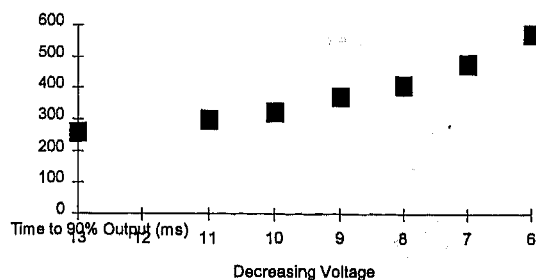

Figure 3 - Delay in Reaching 90% Level of Steady State due to Voltage Reduction in Incandescent Light Sources

The neon source can generate light nearly instantaneously by the ballast once a threshold voltage is applied to the ballast. This instantaneous rise time aids in the recognition of the warning as noted by M. Sivak. [4] The improvement translates into a significant margin of safety in bringing the vehicle to a stop (shown for various speeds in Table 2). The mean reaction time for several sources is shown in Figure 4.

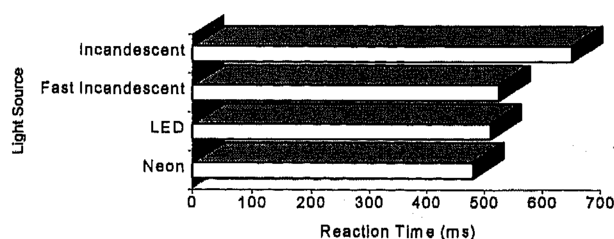

Figure 4. - Mean reaction time by light source

Signal recognition can be enhanced by several methods with the LPD. First, the intensity can be increased. However, limits are quickly reached because of glare issues. Strobing or pulsing will also increase conspicuity but this causes an annoyance after several cycles. Switching between two levels, however, softens the disturbance. Lastly, the rise time of the light source can aid the recognition process. As stated by Sivak:

> "In other words, under the conditions of the present study, the decreases in rise time from that of the standard incandescent lamp to those of either the fast incandescent, LED, or neon lamps had larger effects on reaction time than an eight-fold change in luminous intensity." [5]

Therefore, in order to achieve better recognition of brake signaling the addition of several pulses of light switching from high to low before the constant high level red intensity could be effective. In addition to helping improve braking and turning information, the neon source can conserve energy and improve visual recognition of a disabled vehicle by providing a flashing warning distress signal. The hazard signal lamp function can be achieved with the neon source and ballast very efficiently. A significant amount of the flashing tungsten source energy is used to drive the source through the heating stage. Also, if the vehicle is having battery problems the peak voltage available for the flash mode will be decreasing. By contrast the ballast low operating point could be set at 8-volts or some low voltage before a significant decrease is allowed to occur in lamp wattage. The neon source could provide a significant pulse of light, when the tungsten lamp would be putting out only a small percentage of its rated light.

OPTICS DESIGN CONCEPTS

TROUGH - Both double and single filament incandescent lamps are found in multi-signal functions such as tail, brake and turn applications. The diffuse reflectors and high spread lenses are mainly used to provide a uniform appearance to reduce glare while meeting photometric intensity requirements. Over the past few years both a gem or jeweled and a uniform smooth appearance have been used for vehicle styling identification. At night, these uniformly lit packages are desirable and considered important because they are viewed for long periods of time when vehicles are traveling in the same direction. Because of their light emitting characteristics, the LED and tungsten sources require a significant amount of spread to provide this uniformity at visually accepted levels. Many small point sources in deep optical packages are used to achieve this uniform redistribution of light.

For a given length of tube, the neon source luminance can be increased (or decreased) by adjusting the current density in the discharge column. The current variation and therefore the luminance is limited by the lamp electrodes (also tube bore size, gas pressure) and ballast characteristics. The intensity is uniformly distributed along the tube and the total light output is then directly proportional to its length for a given current density. Optical packages can be fairly simple since the light source can be treated as a line source. As an example, an illuminated reflector seen from various points is depicted in Figure 5. The flashed area is a measure of the intensity at each observation point. On axis at point A, an observer sees the reflector uniformly illuminated or fully flashed. This is the maximum or peak intensity level of the system. When viewing the reflector from other locations in the plane, containing the lamp and the parabolic axes, the projected reflector area is reduced. This foreshortening of the optic system reduces the intensity. The reduction will continue until the combination is viewed end on at location B. The observer at point C sees the specular reflector dark, with light only being provided by the direct view of the linear light source. Light can be redirected to this location by the introduction of a spread lens, spread elements in the reflector surface, or by changing the specularity of the reflector surface. Intensity in this direction also may be increased by increasing the source diameter. Peak intensity values over 100 candelas

are readily achievable with specular reflector surfaces, and the neon LPD lamp.

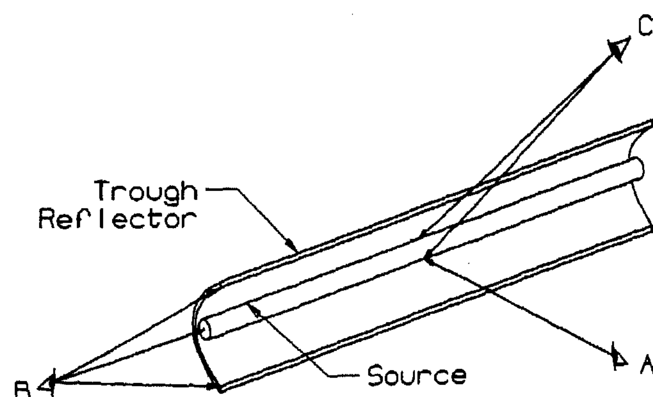

Figure 5. - Primary viewing locations of trough cylindrical reflector with LPD source.

The luminance of a source currently being used in the Ford Explorer CHMSL is about 17,000 cd/m^2 for 28-watts of power and an arc tube length of 0.7m. This signal light system with red lens and EMI protection produces a tail function and a brake function with 150 candela, and a system luminance of over 9,000 cd/m^2. This value is comparable to many lamps utilizing incandescent light sources. The optics to provide the desired photometric performance with the neon LPD also present the lighting designer and stylist with new opportunities. These cylindrical optics with linear sources have lighting distributions that differ from the LED and incandescent systems. A compact source illuminating a parabolic reflector of revolution provides a very symmetrical beam with minor irregularities due to the source shape. On the other hand a cylindrical reflector optic provides good horizontal illumination and conserves the light vertically. With a smooth, highly specular, parabolic reflector the vertical distribution is a function of source diameter and reflector focal length. Further spread in the reflector can be achieved by the use of faceting, spread elements such as grooves, changes in surface finish, or by changing the reflector cross-section shape. The spread function can provide both horizontal and vertical components to the beam pattern. Spread control also can be achieved by lens elements in the cover.

Fresnel reflectors can be used to reduce package depth as shown in Figure 6. The discharge source in this case is located at the top of the lighting fixture. When power is applied to the luminaire, the entire surface becomes flashed in certain directions. The finish of the reflector could be highly specular or partially diffuse. The lens could be red or clear, and may have patterns on it.

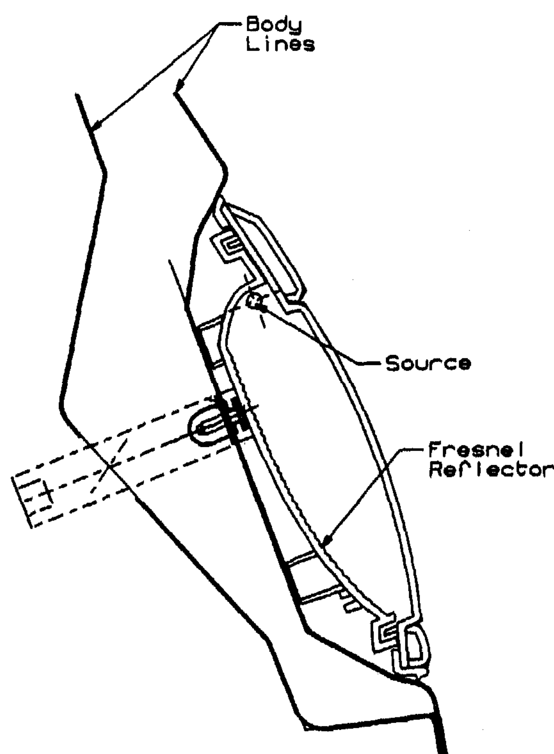

Figure 6. - Compact Fresnel reflector with LPD to reduce packing space and sheet metal deformation.

APERTURE - The luminance of a gas discharge source confined to glass cavities of tubular geometry can be further improved by the addition of a reflective coating (See Figure 7) applied either externally or internally to the arc tube. The coating material can be metallic or high reflectance dielectric. For high gains (five-to-eight times) the reflectance of the coating should be in the mid to upper ninety percent range. The gain in luminance due to the coating will depend directly upon the coating reflectance, inversely upon the angular opening in the coating, and inversely on any self absorption of the light by the gas. An aperture lamp intensity distribution can be approximately represented mathematically by a strip of lambertian material the size of the opening in the lamp coating. Lamps with aluminum coating on the exterior of the tube produce gains in intensity over two, but provide a different luminance profile that is ideal for improving light spreading in optics. The horizontal spread is fairly uniform, but the vertical spread is not the expected Lambertian distribution, which would indicate possible absorption effects within the gas. [6] A typical intensity distribution is shown in Figure 8 for a 2mm aperture opening. The total integrated light output decreases as the angle of view is increased reducing the effective area opening of the aperture. However the peak value actually increases slightly for angles off from the center. While a gain is achieved in the forward direction the increase off axis appears to be associated with reflection and absorption effects in the discharge. This distribution poses no real problem to the optics and in some cases can be helpful to the optics designer to achieve better vertical spread.

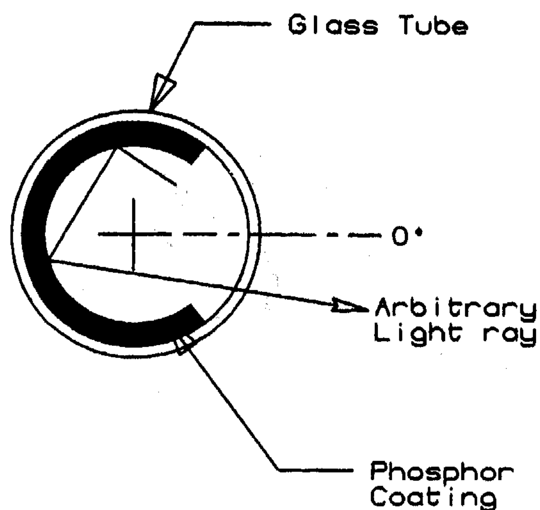

Figure 7. - Crossectional view of aperture lamp with example light ray.

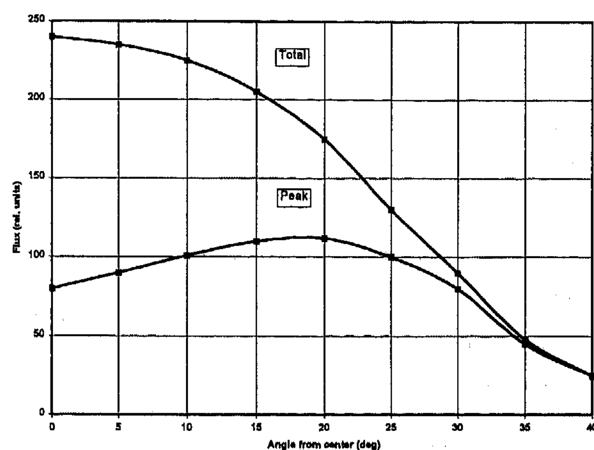

Figure 8. - Luminous distribution fo a 2mm aperture for viewing angles transverse to the lamp axis.

Aperture lamps are very useful for designing small package size luminaires. A thick condenser lens can be placed directly in front of the aperture to redirect the intensity distribution pattern as is shown in Figure 9a. A typical intensity distribution for angles perpendicular to the axis of the optic is shown in Figure 9b. The system was comprised of a three-by-five millimeter diameter aperture arc tube of opening 3mm, and a glass lens of 10mm diameter. The optical system generates a 30° included angle beam of light. An optic of about 10mm in height and length between 300 and 450mm will comply with the 25.8cm^2 area requirement for CHMSL's. The intensity produced by an LPD operating at 26 watts with this design is about 150 cd. Such optics can be located in the automobile at the top of the rear window in the headliner. The small package size and higher luminance can penetrate moderate solar glass windows, and the headliner location provides better viewing for reverse and forward driving.

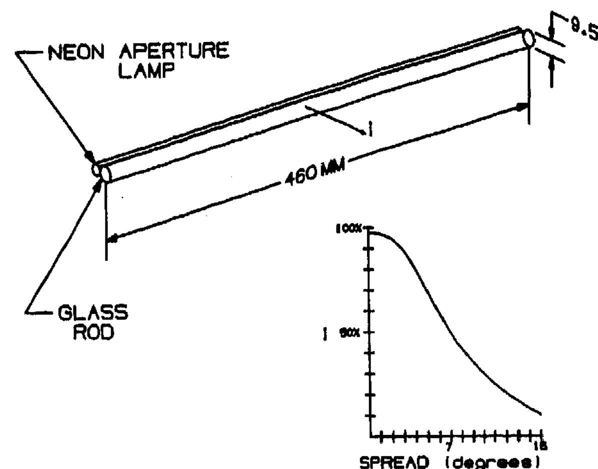

Figure 9a and 9b - Thick lens aluminized aperture lamp. The spread angle is transverse to the lamp axis.

A second similar device is depicted in Figure 10. In this case, the aperture lamp is providing light for a thick sheet optic. The rays from the light source progress through the optics as shown. This device has an added degree of design freedom, the reflective surface, which can provide package depths of 10-15mm and heights of between 25-50mm.

TRUNK SPACE AND SHEET METAL SAVINGS- Thinner lighting packages can be highly beneficial in the reduction of vehicle sheet metal surface complexities. Sheet metal fabrication techniques can be used to deform the metal into a concave section as depicted in Figure 10. A rather complex shaped tail lamp could be mounted into the depression. Thus, thin neon signal packages 25-60mm in height extending from the central part of the car to and including the corner of vehicle appear possible. (See Figure 11).

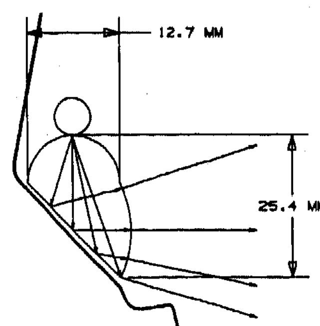

Figure 10. - Aperture source thick lens optic provides thinner "Hang-On" lighting packages for surface mounting.

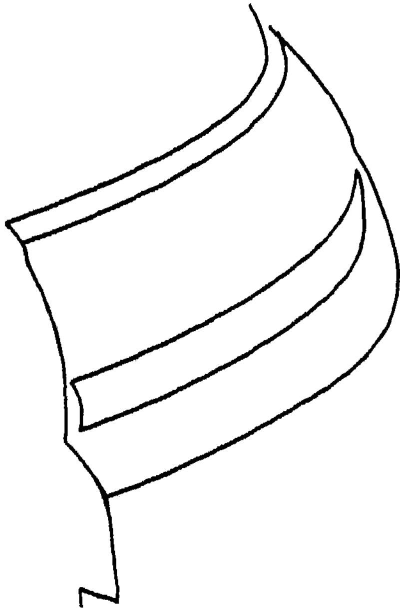

Figure 11. - Neon extended light source provides side markings as well as brake or presence lighting.

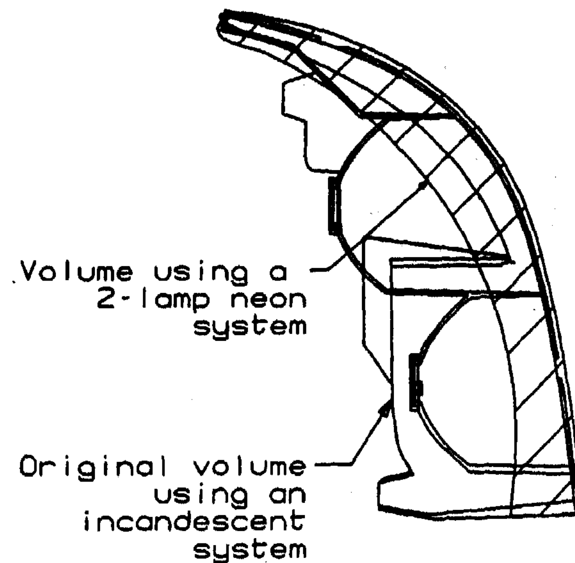

Figure 12. - Improved utilization of the trunk space for transporting large packages.

A lamp with such a thin cross section minimizes cutting and welding of sheet metal compartments on the rear section (See Figure 12). These deformations can be designed into the sheet metal to strengthen the body. While some cutting in the deformed area may be needed for electronics, wiring, and mounting, the largest hole sizes will still be small in comparison with current techniques. This should reduce or eliminate many of the water leaking problems encountered today. Since the lamp is designed to last the life of the vehicle, base-socket systems are not required. Thus, the entire package or section can be attached to the body surface and bolted into place. This packaging would reduce space requirements, adding a cubic foot or more to the truck space in some vehicles. Additionally, the lighting fixture will greatly increase the trunk utilization for storing large packages especially in small vehicles. This is due to the fact that currently the lighting fixtures project into the trunk space causing, in some cases, a high percentage of reduction in capacity for large containers.

LPD SOURCE IN HIGH AMBIENT CONDITIONS - The neon light source luminance is lower than that of either the filtered incandescent or the LED. At first, this might be considered a problem when driving in the presence of the high ambient solar radiation during the beginning and end of the daylight hours. However, as has been shown by M. Sivak, the intensity of the total luminaires plays a more dominate role than the peak source luminance. [7] It should be noted that the light intensity distribution behind the car is dependent upon the source luminance, the optical cross-sectional area and the degree of light spread by the system. Both source luminance and efficiency must be taken into account when designing optical illumination systems for daylight as well as night time driving conditions. High luminance values during night time can cause glare for trailing motorist. While a high luminance is important to achieving high peak intensities, the source must supply enough lumens to provide the desired lighting pattern. Spread lens elements and reflector diffusion effectively reduce the average luminance of the lamp. Thus, while the luminance levels of the LPD lamps are different, the efficiency values (for commonly found vehicle cross-sectional lamp areas) do provide proper rear neon signal illumination functions for turn, brake and presence lighting. This can be achieved at wattage levels from about 15-30 watts for a brake and turn, and about 5 watts for a presence lamp. Strobing or higher levels during daylight are available if desired. The optics in one case studied was about 76cm long by about 5cm in height and depth. This package provided a more uniform wider beam pattern than could be achieve by an incandescent or LED source in the given package depth.

ELECTRONICS

POWER MODES - The neon LPD source and ballast generate both radiative and conductive electromagnetic interference(EMI) when operated in an Alternating Current (AC) mode, and both lamp and ballast need to be shielded and isolated. Common shielding methods involve either a screen or a conductive coating applied to the interior of the fixture or to the lamp surface to reduce the radiated EMI to acceptable levels. The lamps can be designed to be powered in several ways.

The first method is direct current (DC), but this does not convert electricity to light energy efficiently, unless the discharge is operated at low current density levels. For most lamp geometries the power limit is less than 10 watts. However, this approach can be used in some low wattage applications such as appliqués where heat is not a problem because of the low wattage. In this case it may cost less to use DC because filters, screens, etc., are not necessary. The second method is a pure alternating current (AC) sine wave type that provides a better energy conversion for power levels as high as 50 watts. Triangular wave shapes have also been evaluated with an improved efficiency, but this method requires proper electrode design.

Investigations carried out at OSRAM SYLVANIA have shown that the highest output can be achieved by short transient pulses. This method produces a gain of about 1.7 or 1.8 times the AC approach. Briefly, the pulse mode method of driving a lamp can best be explained or summarized as follows: If a discharge tube of rare gas such as neon has a sufficiently large voltage maintained across it's electrodes, it will break down and emit light. This light is formed by the electrons within the neon atom returning to lower states after being excited by the current from the power source. If the supply of current is limited to a few microseconds, an additional gain from the neon emission can be achieved. Allowing the stimulation to decay back to nearly a complete neutral ground state (see Figure 13) provides an efficient light generating method. This decay phenomenon occurs every time the discharge is turned off. During the continuous application of power, the light source dynamics redistribute the energy in the visible, and infrared which produces heat. The upper driving limit is set by the current limitations of component dielectric and of the electrodes while the lower limit is set by the decay characteristics of the gas discharge and/or phosphor excitation as discussed below. A sequential series of pulses are used to produce continuous light. Generally, the rate is above 1,000 pulses per second.

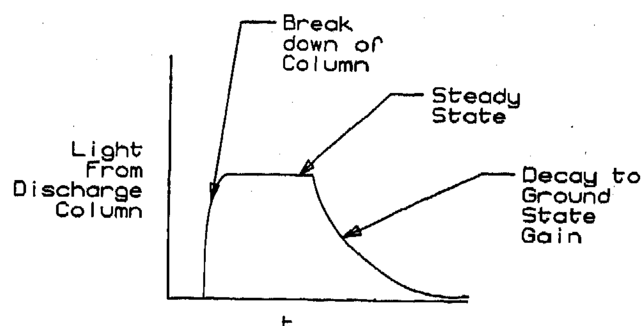

Figure 13. - Advantage of Decay Time (the Impact of Pulse Mode)

The conversion efficiency of electrical power into light will be reduced, however, if the frequency of the pulses is too high. Also, the break down voltage across the electrodes will vary depending upon the time between pulses due to residual charge density within the tube. Typical pulse widths of 1 microsecond with 2-to-3% duty cycle, depending upon gas pressure, bulb wall properties, etc., provide optimum driving conditions for lamps of reasonable lengths and at fill pressures about 100 torr of neon gas. The electron population decay characteristics provide some reduction in break down voltage after the initial pulse. The EMI produced by the pulses of current can be minimized by keeping the leads carrying the high voltage to the lamp as short as possible and by other spatial and time filtering techniques. One aspect of EMI control is to minimize the high voltage lead length by putting a step-up transformer and other electrical impedance matching components as close to the lamp end as possible. These components can serve to isolate the discharge break down from the surroundings of the fixture. For long lamps a second transformer adapter that is driven out of phase with that of the first may be needed at the second end. Figure 14 shows an example of such a configuration. The ballast could be placed remote from the lamp, but this is not advisable for long lengths of lead wire. If the ballast is mounted externally to the lamp module, the ballast needs to provide voltage pulses of less than 50 volts to the transformers (if higher voltage levels are needed, special shielding is required to comply with automotive safety requirements). Such circuits can then run any lamp length with the proper matching of the transformers characteristics. The configuration of transformers at the ends of the lamp and a driving circuit can be designed to operate with any voltage wave shape (non-DC), i.e., pulses, triangular, sine wave, etc.. Thus, a given ballast or driver circuit can be used in all applications by using a matching circuit (adapter). Also, the lamp output can be modified by changing the number of pulses and the wave shape delivered to the arc tube. This may require heavier electrodes for the high current levels, but it yields multi-level lighting mode. This mode can be used to provide a tail and brake function or a tail, brake, and turn function more easily than by amplitude modulation of the source. Modulation of the LPD source by amplitude, digital or frequency is possible. The use of such a drive circuit with the transformer-arc tube combination enables

operation of a lamp of any length in any timing or signaling mode. In addition, two or more transformer/lamp combinations can be shared by the driver circuit, as schematically depicted in Figure 15. Such approaches are necessary to optimize system performance and costs. In multi-discharge lamp systems the regulation, filtering, etc., functions are shared to achieve these goals.

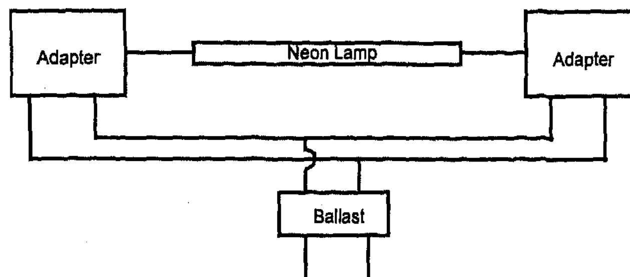

Figure 14. - Neon Pulse Ballast Wiring Diagram with Adapter Interface Circuit for Interchangeable Ballast

During daylight hours and high ambient lighting conditions more signal light can be provided using these techniques than provided during evening hours by changing the number of current pulses applied to one of the arc tubes or by changing the duration of the gating signal depicted in the timing sequence shown in Figure 15. In addition, variable lengths of pulsing of the source can be introduced as a driving aid. For example the current method of signaling a braking command could be changed by introducing the red light level with several initial, visually detectable, red pulses. Pulses of light might be used in some driving conditions to improve recognition of the brake intention.

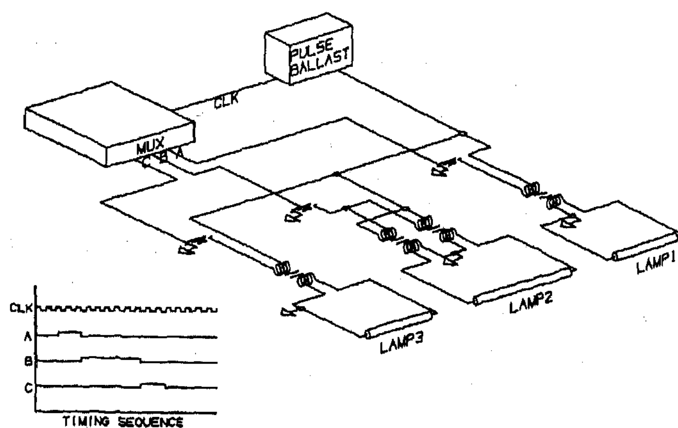

Figure 15a and 15b - Multiple light sources sharing common power source with adapters to interface various lamp loads.

SYSTEM ISSUES

HEAT LOAD AND ENERGY CONSERVATION - The total system power and efficiency needs to be considered when introducing electronic devices and other heat generators such as lamps within a closed, sealed tail lighting package. High ambient temperatures due to geographic and solar environmental considerations along with the absorption of colored lenses and the electrical to light energy conversion efficiency affect system performance. The effects of temperature rise on tungsten and neon sources are not as critical as for the ballast circuit components of a discharge source or for LED light sources themselves. As mentioned earlier, stimulating a LPD lamp with fast transient pulses provides the highest conversion of electrical energy to visible electromagnetic energy. This is a preferred method for reducing heat loads and controlling temperature rise. Concurrently, the pulse mode operation increases intensity in the red region of the spectrum and increases average source luminance for a given diameter, neon filled tube. This option provides a trade-off between a given arc tube wall temperature and arc tube output (over 60 percent gain of light for the same input wattage comparing pulse to AC). In other words, at a lower operating wattage (30% power reduction) a lower wall temperature can be achieved while maintaining luminance and lumen output. Alternatively, a higher luminance will further improve the optical efficiency (the maximum intensity achievable is obtained by the product of the luminance times the cross section of the optical area). Therefore, the pulsed discharge method provides the best optical and energy conservation performance. Balancing these factors, the operating power for the neon source and ballast can be minimized.

Optimization of the power is not only important because of the vehicle requirements, it also reduces the amount of heat energy that must be transfer from the ballast. Heat energy trapped in the ballast can increase individual electrical component temperatures to unacceptable levels before equilibrium occurs. Thus, to limit the temperature rise of the ballast, the design must be as efficient as possible (85% or above), be heat sunk, be convectively cooled, and/or be allowed to radiate the undesired heat energy (The ambient temperature, depending upon placement of the power supply within the vehicle, can reach a value between 85° and 105°C or higher). For example, even an efficient ballast when operating a lamp at 30 watts will need to dissipate about 5 watts of heat. The lamp will produce about one watt of visible light energy, generate about 9 or 10 watts of heat at the electrodes and the remaining heat energy in the gas and leads. Ballast electrical components can be obtained to operate at elevated temperatures before ballast life degradation occurs. However, if not designed properly an individual component in the circuit may be operating at a low efficiency thus generating excess heat, and it may absorb energy from adjacent components. If the ballast is required to operate in an environment of 85° or even 105°C, individual components need to have the rated temperature specification. Some

components may require enhanced energy transfer methods or higher operating temperature specifications to ensure long life and proper operating performance. Added cost, reliability issues, and system complexity, will result.

In summary, as the temperature difference between ballast and the ambient approaches zero, it becomes more difficult and costly to transfer energy to the surroundings, whether by conduction, convection, and/or radiation. The discharge device (HID ,SMFL, or LPD) and ballast must be designed to operate at the lowest power value and highest efficiency possible or it will add cost, consume space, and generate undesirable heat that must be dissipated, or the electronic elements will have a shortened life.

NEON SYSTEM APPLICATIONS

APERTURE LAMP AND VARIABLE COLOR SIGNAL AIDS - The neon LPD source luminance can be increased by the use of a reflecting coat placed on the arc tube bulb wall forming an aperture lamp. Coatings of metal or diffuse dielectric materials can be used to increase the effective luminance of the light source over a limited range of directions at a cost of the total lumen output.

Phosphor materials added to the interior of the arc tube can be used to transform the electromagnetic energy from one portion of the spectrum to another when the transient pulses of current pass through the gas column.[8] The pulse discharge currents in the neon gas stimulate the phosphor producing a light output. The resultant lamp color is determined by emitting materials and the fill gas. As one increases or decreases the number of pulses per second and the pulse duration and wave shape, the ratio of stimulated phosphor light to red light from neon can be adjusted. The light generated from the phosphor is in addition to the red light from the neon column of gas. Some of the red light passes into or through the phosphor, the remaining exiting through the aperture either directly or after multiple reflections from the phosphor. The spectral power distribution of the neon phosphor combination are shown in Figure 16. When the vehicle is moving forward, the rear of the car can display a red presence light for a tail function by applying a continuous sine wave from the ballast to each aperture lamp. When the turn signal is required, an amber color can be generated from the same lamps by changing the wave shape to that of a pulse form (i.e., one micro-second, 2-3% duty cycle). The brake function intensity can be achieved by a higher level sine wave application of power to achieve approximately ten times the intensity of the presence or tail functions. The phosphor material could be used in aperture lamps to blend better with red or other colored gas discharge characteristics. Shown in Table 3 are the possibilities of color with power wave form applications for an aperture lamp.

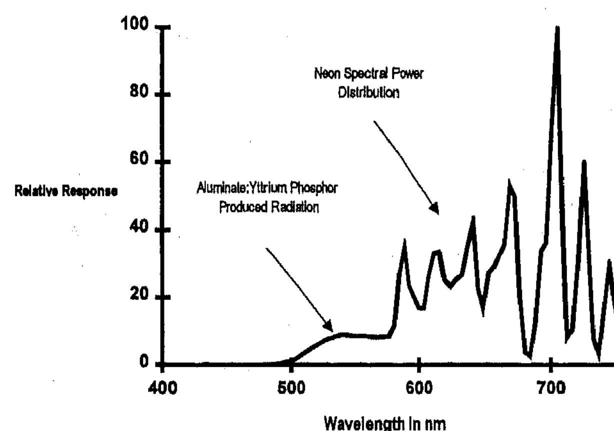

Figure 16 - Spectral intensity for a neon discharge tube coated with agreen phosphor.

ADDITIONAL SIGNAL CONSIDERATIONS - In addition to human visual communications, the LPD source with its fast response time can be used to send information from one vehicle to another, while appearing to be a visually continuous light source. Information can be transmitted optically in the visible or the infrared portion of the spectrum. The frequency is set by the maximum stimulation rate of the gas and ballast. The frequency used to date for the best visual efficiency is about 20Khz. Sending digital codes of information in the visible portion of the electro-magnetic spectrum reduces the amount of radiation being produced in other bands, assuming proper EMI shielding of the source. This is a "line-of-sight" transmission that may prove to be useful, in minimizing noise in the communications channel.

The use of a green emitting phosphor coat in the aperture lamp and a controllable power system allows for a novel signaling opportunity. The radiation is generated by driving current spikes of pulse width of less than one micro-second. The green phosphor coating when stimulated radiates at about 556nm. The stimulus produced by the use of the pulse mode provides two colors green and orange-red. The addition of these two colors provides amber light (see matrix on Table 3). A sine wave produces only orange-red light. Thus this approach can create a visual signal device that can generate a temporal color signal. The color can be switched between amber and red, or other possible colors, by means of adjusting the amount of pulsed to continuous power. It can be done continuously causing a visual "drifting" effect from one color to the other, switching discretely, or a combination of the two (see Figure 17). This also provides an option of using a standard or reference and a variable (continuous or in discrete steps) to communicate a degree of compliance.

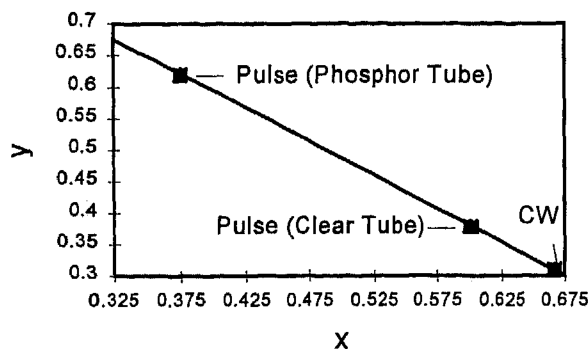

Figure 17 - Shift in the x,y chromaticities during pulse operation.

The red color can serve as the standard to indicate a stop signal or a presence lamp output. By dividing the path between amber and red into several steps one could communicate the degree of slowing of the vehicle. Schematically shown in Figure 18 is a rear lighting assembly to demonstrate the color combinations between a standard red color and a continuously varying red-to-amber source. The lower portion of the figure depicts a temporal signal switching between two color levels. Table 4 provides a list of possible combinations achievable to transmit information. The use of these novel devices must be evaluated before their significance in coding can be attained.

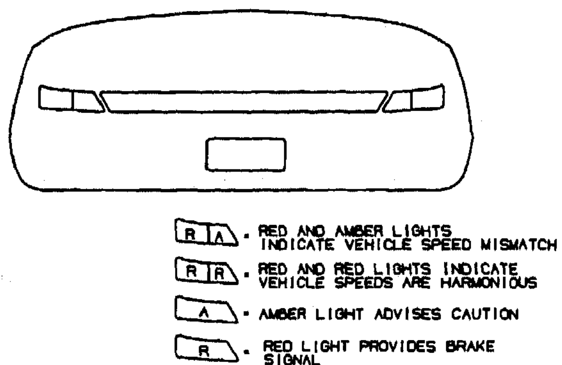

Figure 18 - Schematic of rear lighting. The color combinations for the individual lighting sections are indicated as R=red, A=amber.

VARIABLE LENGTH NEON (WALKING NEON) - By electronically adjusting the pulse height and frequency it is possible to control the discharge length within the lamp tube. While this technique is not new, it does have a good application in automotive. A neon lamp can be made to "sweep" from one side of the lamp to the other at any desired rate. For most applications the sweeping would be at the rate of a turn signal, providing an additional acknowledgment of the drivers intent to turn.

The ability to control the position of the discharge within the tube also provides a wide range of effects that can be both design aesthetic and functional.

A schematical diagram for the walking neon system is presented in Figure 19. The use of an indium tin oxide (ITO) coating as a ground plane is essential for proper operation, but also has the added advantage of reducing the required EMI shielding.

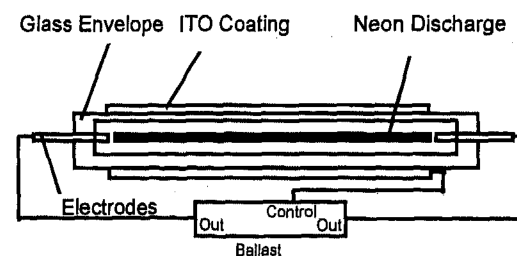

Figure 19 - Schematic drawing of the variable length "walking" neon.

CONCLUSION

The increasing demand for long life light sources to reduce replacement cost is aiding in the transition from incandescent to discharge lighting devices. Both High Intensity Discharge (HID) and Low Pressure Discharge (LPD) sources are becoming available for automotive lighting applications. The HID sources are for forward road illumination and the LPD are for signal lighting. Both sources have excellent resistance to hot-shock breakage - a formidable problem encountered by the incandescent source in the automotive environment. The LPD source has a very long life because of its low wall loading (watts per cm^2) and lamp chemistry. Thus the source and ballast can be sealed into a luminaire with a 12-volt input. This package design can last the life of the vehicle without replacement. Currently, this feature removes the need for legislative jurisdiction and yields the opportunity of harmonization of signal lamps world-wide. The long linear source provides uniformly illuminated areas that can be easily seen from much wider angles than incandescent or LED sources. The uniform illumination will reduce eye fatigue. The faster rise time of the LPD source improves recognition and, therefore, reduces the braking reaction time. The ability to switch colors (red/amber, etc...) enables new coding techniques to be developed to improve communications between drivers and vehicles. By electrically switching power levels, the intensity can be adjusted for different ambient conditions, such as night and day time driving. LPD also conserves power when used as an emergency signal aid on parked vehicles because of its strobing feature. Sheet metal savings in weight, in the component fabrication processes, and structural integrity appears to be favorable. Better utilization

of the trunk compartment is also achieved by the flatter, thinner illumination optics. The smooth continuous flow of the illuminated areas provide the stylist with new exciting tools to provide more appealing and useful vehicle designs.

The accident avoidance capability of LPD affords an additional opportunity to reduce accidents thus saving human life and eliminating suffering. It is difficult to assign a value to an accident but judicial rulings of late are monumental. It is therefore reasonable to consider the cost of new safety devices over the vehicle life cycle similar to ABS brakes and air bags. The ability to reduce or avoid an accident by the use of newly conceived lighting systems is much more economically desirable than building the structure of the car to absorb high speed impacts.

	LED	LPD (Neon)	Incandescent with red filter
Efficacy (Lumens per Watt) for Red	2 - 20*	8 - 16**	3

* Diode wattage range from a typical value of 0.05 watts per diode to a maximum of 0.15 watts. The maximum output is about 2 lumens per diode with present state-of-the-art.

Neon Signal Lighting - An Integrated Approach

Philip Rimmer
Tunewell Technology Ltd.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Neon discharge lamps contribute four main benefits in automotive rear signalling applications, longevity, efficacy, speed of response and most importantly styling versatility. In systems demonstrated to date, the styling advantages have failed to materialize whilst the cost of implementation has been discouragingly high. Together, Corning and Tunewell seek to solve these problems through the use of sophisticated glass processing and novel power distribution technologies, and the adoption of a systems approach to design to minimise cost.

A glass molding process will be detailed permitting the integration of optimal topology discharge channels with compact optics and connection systems into any curved, laminar form required by the lamp designer. Clear aesthetic advantages over incandescent and LED technologies can be shown due to the extended, uniform light source and the precise placement of its associate optics.

A power distribution system will be demonstrated that provides a substantial cost reduction in the provision of power for multiple lamps, additionally eliminating high voltage wires and bulky, individual ballasts. The system will be shown to facilitate multiplexed control and fault reporting. Extension to encompass additional power supply tasks within the vehicle will further reduce costs.

A systems approach will be outlined demonstrating the cost benefit of reducing the power supply burden in favor of an enhanced lamp performance. It will be shown that substantial cost advantages accrue if power requirements, lamp strike requirements and radiated and conducted emission problems are dealt with at appropriate locations in the system.

1. INTRODUCTION.

Often discussed in this forum has been the issue of vehicle power supply systems. The problem of coping with the ever growing demand on the vehicle's power supply has led people to moot higher and multiple power supply rails in the pursuit of efficiency. At 48 volts it has been argued that alternator and motor efficiencies are increased by 4 and 6 percent respectively. The cost and complexity of such a supply change are, however, intimidating for these small returns.

Equally, people have been discussing the implementation of higher efficiency components, not least amongst these lighting components. Discharge lamps like HID, Cold Cathode (Neon) and Hot Cathode (Fluorescent) and LEDs all offer substantial efficiency improvements along with many functional enhancements. Again, component cost has appeared discouraging.

Fortunately, a number of interesting technologies are appearing that have a degree of synergy. To better appreciate why this may be so, it is revealing to analyse the kinds of power supply automotive components would use preferentially.

TABLE 1.1 OPTIMUM POWER SUPPLY FOR AUTOMOTIVE COMPONENTS

COMPONENT	VOLTAGE	CONSTANT CURRENT	CONSTANT VOLTAGE	REASON FOR CHOICE
Incandescent lamp (fast response)	low <12v		YES	Robust filament
Incandescent lamp (slow response)	low <12v	YES		Robust filament and soft start
NEON (cold cathode)	v.high >>12v	YES		Lamp requirement
HID	high >12v v.high >>12v	YES		Lamp requirements
Fluorescent (hot cath.)	high >12v	YES		Lamp requirement
LED	high >12v	YES		More efficient power use
ICE (stereo)	high >12v		YES	Eliminates internal PSU
IGNITION	high >12v	?	YES	Reduces IGBT loss. Increases power available for lean burn.
MOTORS	high >12v		YES	Increases efficiency
LOGIC (microcontrollers) low	<12v		YES	Circuitry requirement
COMMS.	low / 12v		YES	Circuitry requirement
HEATERS etc.	various			

Though the above is an incomplete list, very few items have as their optimum a 12 volt, constant voltage supply system. There is also a lack of bias towards any one type of supply. Moving to higher voltages may partially address our concern for improved efficiency, but it certainly raises other problems.

The unusual power supply demands of discharge lighting are, in fact, for a standard 12v power supply, the major cost element in the use of these components.

A debate is now emerging that power savings brought about by novel and improved electrical components can be set against cost savings in the vehicle power supply system. Inevitably the component supplier's view tends to be at variance with the vehicle manufacturer's. Some component suppliers anticipate a 50 cent per watt saving, manufacturers merely 5 cents. The truth,as ever, will lie somewhere between those two points. The maximum theoretical saving will only come about when the power supply system components are fully optimised for the reduced power demand, and as most supply components only come in discrete sizes, a lot of accumulated power saving may be necessary to trigger a real economy.

The car manufacturers dilemma is that he cannot specify a more efficient electrical component if it is more expensive, and does not immediately pay for itself in savings elsewhere. Incorporating many such devices might unlock the power system savings that would pay for their inclusion, but this is a scenario with considerable risks. There is clearly something of a log jam here, locking out improvements such as discharge lighting.

The question must be asked - Is there a universal power supply system that allows us to optimise all or most functions? Is there a power supply system that is more accommodating to change, reducing the cost of implementing components with novel power demands?

2.0 WHAT IS THE POWER SUPPLY SYSTEM?

Current thinking has it that the "power supply" system consists of all those components and wires carrying the battery voltage. The complement of this is that the "powered components" are those that receive this battery voltage and produce a useful function in response. A growing number of components, however, contain their own power supply sub systems. Ignition has always needed to reprocess the battery voltage to derive the very high voltages needed at the spark plugs. In-Car Entertainment now makes such power demands that it contains a voltage boosting power supply of its own. Similarly, logic and micro-processor control units managing disparate auto functions require their own voltage-converting sub-systems. HID headlamps have massively sophisticated voltage boosting and regulating power supplies.

Every one of these distributed power supply sub systems individually require further complex and expensive protection circuitry, because, not only is the battery voltage inappropriate for the job but it is highly variable and noisy. It would seem that any new electrical component with a degree of electronics involved will bring with it another expensive bit of power supply system, discouraging its implementation. Neon signalling lamps are a case in point.

3.0 NEON DISCHARGE LIGHTING.

3.1 Discharge lighting has a great many attractions amongst them, efficacy, longevity and robustness. For the lamp designer two of the greatest opportunities are the ability to work with a light source that is uniform and compact facilitating very effective optics (HID and Neon) and highly conformable (Neon) facilitating styling.

A Neon lamp, consisting as it does of, glass, iron (typically) and a small amount of gas has negligable material cost. Such significant cost as do exist reside in the processes that form the lamp into useful shapes. For this reason the first Neon lamps used on cars were CHMSLs exploiting the simplest straight tube style lamp.

Turning such tubes into complex shapes is entirely possible. Compact multi-tube fluorescents are cheap but limited in the varieties of shapes that are possible, none particularly useful. The neon sign industry produces most complex shaped lamps, but even with semi-automated bending equipment the unit cost is very high.

3.2 CORNING'S MOLDING PROCESS- The need for a low cost forming process was siezed upon by Corning who adapted an existing vacuum and pressure forming process to create two plates simultaneously, bearing the complementary shapes of the lamp channel. The process continues with the fusing together of the two, still softened, halves of the lamp. A sophistication of the process allows the automated introduction of the electrodes whilst the lamp is still hot. The whole operation is complete in a short space of time yielding a complete lamp, needing only to be cleaned and gassed.

Whilst the cost advantages of such an operation are obvious, the full technical implications which can lead to further cost savings are not obvious. For many reasons the pursuit of efficacy (i.e. the lumens per watt) is highly desirable. Reduced power demand may have its rewards, but so to does the resultant reduced temperature rise. Lower temperatures translate to improved reliability, but also, if sufficient gains are made, a lowering of enclosure costs. The molding process makes two contributions to reduced power consumption.

First, it can facilitate an optimum efficacy tube by permitting highly constricted discharge channels at relatively low gas fill pressures without compromising tube life. Tube life is limited by the amount of gas in the tube, the electrode area and the electrode current. Low volume, small electrode lamps have short lives. The molding process can easily accomodate the inclusion of gas reservoirs providing the necessary life span. By using a constricted channel at low pressure an optimum, discharge-region efficacy can be achieved at the same time as producing a high voltage gradient in the column. This in its turn permits the use of relatively low electrode currents to achieve the desired power input into the discharge region. This low current is desirable as it minimises electrode losses, losses that make no contribution to the lumen output.

TABLE 3.1 10 WATT NEON LAMP WITH DIFFERENT ELECTRODE CURRENTS

TUBE POWER	TUBE CURRENT	ELECTRODE POWER	DISCHARGE POWER	LIGHT (REL.)
10 watts	30mA	4.5 watts	5.5 watts	65%
10 watts	10ma	1.5 watts	8.5 watts	100%

The second advantage, stems from the narrowness of the channel and a further potential of the molding process. Stop, tail and turn lamps have small vertical dispersion angle requirements. A narrow line of light is easy to focus to this small dispersion angle without requiring a very deep reflector. Such a reflector (unsilvered) can be fabricated that is integral to the lamp. This reflector will always be perfectly sited with respect to the tube and therefore can utilise greater degrees of focussing without risking the misalignment of a discrete lamp and reflector.

The design of an integral reflector is quite an interesting task as it involves the combination of reflector optics and light guide optics. The extent and coverage of a silvered coat is subject to factors too numerous to explore here, but suffice it to say that much optical and electrical advantage can be gained from this simple step.

Many other lamp structures can be produced in similar fashion. Front refractor optics can provide advantage as can glass tinting. In summary, very efficient light sources can be created by this process at low unit cost with the singular advantages of covering large, compound-surfaced areas, yet remain very low profile.

4.0 THE COST OF USING NEON LAMPS.

4.1 Lamps produced by the above molding process are low cost compared with bent tube equivalents, but in integrating other functions and minimising package height even greater cost savings are realisable. Thin, high efficacy lamps will also possess lower enclosure costs due to the reduced amount of material required as well as the lower temperature rating mentioned earlier. Indeed, in future, it can be envisaged that complete rear lamp assemblies can be fabricated in a thin, ready-wired package that can be attached to the outer surface of the vehicle bodywork. Such pre-tested packages could well incorporate in a single component all rear signalling and include such components as fenders, spoilers and license plate and will have a major impact on vehicle assembly costs. Such superficial lamps will in addition maximise vehicle internal space, simplify body panel press tools and increase body panel strength.

Now we must address the major cost penalty of using any discharge lamp. This is the cost of converting power at the battery voltage to the high voltage, high impedance type required to safely drive the lamp. Typically a ballast to do this task will cost some 5 to ten times the cost of the lamp itself. Ballast costs are unlikely to drop below $7 even for the lowest power lamps, and current designs are in the region of $10. In consequence a typical five lamp rear-end arrangement with four Stop/Turn/Tail lamps and one CHMSL,would cost $50 for the ballasts alone.

4.2 "COMPLEXITY COST"- One of the reasons for this floor to the cost of a ballast, is the necessary screening, filtering and protection circuitry required by each. There is, if you like, a fixed "complexity cost"associated with each ballast whatever its rating. This complexity is related to the variety of disparate functions in the ballast, by which is meant the number of different sorts of things it has to do. This is reflected not only in the number of components required but also the number of functions to be tested at manufacture. The great majority of these functions are included for safety reasons, protecting the unit from outside abuse and vice versa.

5.0 A NOVEL POWER DISTRIBUTION SYSTEM.

5.1 AC POWER DISTRIBUTION SYSTEMS- One of the lesser known power distribution systems proposed for vehicles is the use of a High Frequency Alternating Current (HFAC) power bus. The major advantage of this system is the ease of changing between different voltage levels. Indeed, one hundred years on from the commercial tussle between Tesla and Edison the arguments for AC over DC are identical. The arguments can be summarised as follows-

1) Power is transmitted more efficiently at higher voltages because ohmic losses are lower.
2) Unfortunately, high voltages do not suit all / many loads.
3) Fortunately, AC can be transformed easily to differnt voltages.

To Edison, the champion of DC power distribution systems, Tesla's AC system, generating and distributing AC at high voltages, then transforming it to lower voltages locally, seemed complex and potentially expensive. What he overlooked was-

- The cost of power from a single large power plant was less than from many smaller ones. (There is a complexity cost associated with each power plant.)
- Many electrical appliances worked advantageously with AC and most didn't care.

Indeed Tesla offered not just a competing system of AC transmission, but also designs for reliable AC powered machines including induction motors. The flexibility of AC as a power source facilitated the introduction of discharge lighting of all kinds, by providing appropriate running voltages and lossless current regulation using inductors.

5.2 THE HIGH FREQUENCY ADVANTAGE- The debate for HFAC is almost identical with one major addition- the high frequency.

For the most part the range of frequencies being considered is in the range 20 - 200kHz, in other words, the first decade of frequencies above the range of hearing. Whilst not being very high it is still high enough to bring about a huge reduction in the size and cost of the transformers required to implement a working system.

Basically, magnetic flux density in transformer cores is inversely proportional to frequency, so we might expect that we could reduce the volume of a 60kHz transformer to one thousandth that of a 60Hz transformer. In fact, the scale of difference is ten times less due to the maximum flux desity allowed in high frequency transformer materials.

TABLE 5.1 TRANSFORMER VOLUMES AGAINST FREQUENCY

Frequency	Transformer Power	Transformer Volume	Cost
60Hz	100W	100 cu in	$5
60kHz	100W	1 cu in	$1-50

A fairly good assessment of the cost of a 60kHz transformer can be made using the following expression-

Total Cost = Complexity Cost + Material Cost

where Complexity Cost = 50 cents
and Material Cost = 1 cent per watt

Given the small physical volume of the transformers likely to be needed for each function in a vehicle it is clear that they would not be dissimilar in size to the conventional connector used in a 12V DC system.

Indeed, building such a transformer into a connector could be the lowest cost way of housing such a component.

Whilst, these costs are significant, I believe they are less than some might expect. Certainly, when viewed against other system savings they are not discouraging.

The argument regarding power production costs carries over very well into HFAC. If we look at the problem of powering 5 Neon lamps, for instance, running at 10watts each-

TABLE 5.2 COST OF POWERING FIVE, 10 WATT NEON LAMPS

Lamps	Ballasts	Ballast Cost	Transformers	Transformer Cost	Total Cost
5 X 10W	5 X 10W	$50	0	0	$50
5 X 10W	1 X 50W	$30	5	$3	$33

Ballast costs are computed with the same expression as for 60kHz transformers, but with the following values-

Complexity Cost = $5
Material Cost = 50 cents per watt

(The Material Cost figure holds good 10W to 100W but becomes depressed above this range.)

As mentioned earlier Edison's final oversight was not realising some electrical tasks worked better with AC. Reviewing our list of loads we can see that all those component / functions preferring voltages other than 12 volts or preferring current mode delivery would use AC with advantage. Clearly transformers can supply the most appropriate voltages but where current mode delivery is preferrable, this can now be achieved by lossless ballasting with inductors or capacitors. LEDs are a case in point.

From the foregoing arguments, regarding the cost of powering discharge lamps, it would seem that these might serve the same facilitating function that Tesla's induction motors did.

6.0 THE PROBLEMS OF HFAC

To date an HFAC power distribution system has not been implemented due to a number of problems. These

are, electromagnetic interference, HFAC switching issues and the daunting number of affected components.

6.1 EMI- Broadcast interference from the distribution cable, mainly in the form of a high frequency magnetic field (H-field), can cause serious interference to other electrical apparatus. It can also lead to serious power loss into adjacent metal surfaces. The total amount of magnetic flux generated is dependent on the magnitude of the current and on the area of the loop around which the current flows. Apart from altering the current, two approaches are taken to minimise the H-field. First, the loop area is made as small as possible and second the conductors are screened. Some distribution cable types are listed below. The peak H-field flux levels are noted in the region close to the cable (0.5mm to 5mm) and are assessed at a nominal 1 amp current. In appendix B the flux plots in this close region are shown.

6.1.1 Wire Pair.

Construction:	Wires kept adjacent to each other by their insulation. This proximity minimises loop area and helps reduce H field.
Cost:	Very cheap.
Distant H-field:	Medium
Local H-field:	Very High. 0.19 milliTeslas.Fig. B1
Flexibility:	Good

6.1.2 Twisted Wire Pair.

Construction:	Wires kept adjacent by twisting together. Rotating field cancels at a distance.
Cost:	Very cheap.
Distant H-field:	Low
Local H-field:	Very high. 0.19milliTeslas. Fig. B2 (Flux plot shows adjacent twists side by side not in line)
Flexibility:	Good

6.1.3 Screened Wires

Construction:	Wires, probably twisted, with a braid outer screen.
Cost:	Medium
Distant field:	Low
Local H-field:	Med./ low. 0.02 milliTeslas
Flexibility:	Poor

6.1.4 Coaxial Cable.

Construction:	Inner conductor with return path conductor as outer sheath.
Cost:	Expensive
Distant H-field:	Very low
Local H-field:	Very low 0.09 microTeslas. Fig. B3
Flexibility:	Poor. Very difficult to break in to and difficult to terminate.

6.1.5 In an automotive application we need to be particularly concerned over the issue of H-field in the local region (i.e. next to the cable). Such a cable will undoubtedly share some of its path with other cables, perhaps sensor and control cables. Also it will lie against the body of the vehicle at some point. It can be seen from the above that only coaxial cable provides the very low field that we desire to assure ourselves of satisfactory results.

6.1.6 DOUBLE SIDED FLEX CABLE- Another cable structure exists that may prove particularly appropriate for automotive use. Following are three different structures, the latter two incorporating amorphous or nano-crystalline metal screens.

6.1.7 Two layer "Flex"

Construction:	Two flat strip conductors separated by a very thin insulator. (Cu, I, Cu)
Cost:	Cheap
Distant H-field:	Low
Local H-field:	Low. 2 microTeslas. Fig. B4
Flexibility:	V.good flexibility.Easy to break in to and terminate.

6.1.8 Two layer "Flex" plus back screen.

Construction:	Two flat strip conductors separated by a very thin insulator plus a back screen of high permeability (Hi-u) foil. (Cu, I, Cu, (I), Hi-u)
Cost:	Med/low.
Distant H-field:	Low/very low.
Local H-field:	Low/very low. 0.24 microTeslas Fig. B5
Flexibility:	V.good. Easy to break in to and terminate

6.1.9 Two layer "Flex" plus back and front screen.

Construction:	Two flat strip conductors separated by a very thin screen of high permeability foil. (Hi-u, (I) Cu, I, Cu (I), Hi-u)
Cost:	Medium
Distant H-field:	Very low.
Local H-field:	Very low. 0.002microTeslas. Fig B6
Flexibility:	V. good flexibility. Easy to break in to and terminate.

Comparing unscreened twisted pair (6.1.2) with unscreened flex (6.1.7) there is a 100 fold flux reduction for the flex, the reason being the dramatically reduced loop area. Remarkably the flex can be screened by placing high permeability foil on one side only (6.1.8). The result is a further ten fold reduction in flux on the non-foil side and a one hundred fold reduction on the foil side. The flux reduction on the non-foil side is due entirely to the close positioning of the flux generator to the low reluctance path of the foil.

Placing screening on both sides of the flex (6.1.9) reduces flux levels to one hudred thousandth of the unscreened twisted pair, substantially better even than the coaxial cable. The screening foil can be electrically connected to the conductor on each side, allowing power removal from the surface of the cable without disturbing its very low H-field structure.

Much development work has been done on this low H-field cable minimising various small loss mechanisms. The end result is a distribution cable whose reduced copper content, when used at 84 volts rms at 60kHz, will more than compensate for the added cost of its novel structure.

6.2 CONTROL ISSUES- HFAC systems are advantageously implemeted with remote switching. Such switching may be carried out in a number of ways.

6.2.1 HFAC constant voltage systems can use semiconductors to interrupt the power on both the primary and secondary sides of any coupling transformer. Because the power is processed and regulated these semiconductors can be considerably lower rated in their voltage specs as transients are prevented entry by the central power supply. Further, by employing zero-crossing switching techniques, generation of any further transients will be avoided. Semiconductor switching costs will be substantially reduced.

6.2.2 Much work has been done on constant current systems. In these the power is provided either by using a constant current output power supply or by inserting a current regulator in series with a feed from an HFAC constant voltage bus. The former would be used where a current loop was required on its own, the latter where a mixed voltage and current system was required.

See Appendix A Fig.A1

A constant current power supply utilising the same flex structure would permit a very cost effective power delivery and control method for discharge lighting. The regulated current in the loop would be transformed down to the current level required by the lamp. The lamp current would be defined by the loop current and the turns ratio of the transformer. Control of each discharge lamp is simply and cheaply achieved by causing the transformer itself to saturate and thereby extinguishing the lamp. Such saturation can be achieved with the application of approximately 100mW of DC power to a control winding.

These saturable coupling transformers constitute massively robust switches that have a very useful analog control region and can be used to moderate the voltage peaks present in the turn-on cycle of cold cathode discharge lamps. The degree of control can eliminate transients in the current loop when switching a wide variety of loads and can also switch sufficiently fast to permit power level control through pulse width modulation.

Special techniques have been developed to power HID lamps, and some work has been done to use a current loop power supply for ignition systems.

6.3 IMPLEMENTATION- Implementing an HFAC bus system throughout a vehicle is a daunting task, not least because it would affect so many components and systems, all of which would require modification. Fortunately, the task can be broken down into smaller parts. It is envisaged, for instance, that a stand alone constant current loop system could ideally power a complete Neon, rear-end signalling arrangement. Provided a reasonable number of lamps need powering, the constant current loop approach will confer a considerable cost benefit over discrete ballasts.

Once the step to put some HFAC on a vehicle has been taken any further tasks for it will simply drive down the effective cost of the system and its components. HID added to a neon equipped car will effectively drop power supply costs for both Neon and HID as a further ballast "complexity cost" is omitted. A progressive growth incorporating interior fluorescent lighting, car stereo, ignition systems etc. will come to displace further amounts of noisy, unregulated battery voltage wiring.

Another driver for such a system will be the desire to implement multiplexed control of the vehicle's electrical functions. At the moment, much effort to achieve such a system is partially thwarted by the problems of dealing with the 12 volt bus that supplies the power to the remote functions. Such a bus carries very high currents to many switched loads. It is unwieldy and is subject to unprecedented levels of transient noise and voltage variation. A regulated HFAC bus is entirely complementary to multiplexed control. Indeed it offers the high reliability, "soft" switching needed as part of the system.

As a final note on this, techniques have been devised to provided back signalling to the central power supply for fault diagnosis. These are rapid poling techniques that require little extra hardware and permit a multiplicity of functions to be controlled via a single signal bus (e.g. CANBUS) node at the power supply or regulator.

7.0 CURRENT LOOP POWERING OF DISCHARGE LAMPS

7.1 The constant current loop approach to powering discharge lamps confers control benefits to the lamps as well as reducing total system cost. These benefits, however can only be exploited if the power supply provider works closely with the lamp maker. With an understanding that the cost of the discharge lighting system resides mainly in the power supply itself, the two groups need to solve problems at a system level if lowest overall costs are to be achieved.

7.1.1 Power supply requirements are by far and away the greatest cost incurring parameter. At 50 cents per watt, the saving of 4 watts could well pay for the lamp.

An efficient optical system is the first priority. A light source that is readily focussed, using a high quality reflector helps here. Also recognising that a neon light source needs only very slight filtering to meet colour specification. Using standard lenses is throwing power away.

Achieving maximum positive column efficacy can be problematic, but if the lampmaker can extend tube life by artificial means (e.g. gas reservoirs) then optimum gas pressures can be chosen without worry.

7.1.2 Cost resides in the dealing with the high voltages that occur in Neon tubes, particularly during the tube ignition period when voltages may climb as high as five times above the running voltage. These peaks require considerable upgrading of the transformer and connector insulation and may even force expensive manufacturing and testing techniques. Here, the lamp maker can aid the situation by aiding a process known as "flow-on". This phenomenon occurs when high frequencies are used to power a Neon tube.

If a high frequency voltage, applied to a tube, is ramped up over a period (several milliseconds) the tube will partially ignite at the electrodes even when the voltage is quite low. Numerous factors are involved in this, but essentially what is happening is that the discharge is capacitively coupling into the environment. As the voltage rises the glow extends out from the electrodes until until they meet in the middle of the tube. Because the tube has been partially alight all the time the voltage never goes far above its normal running value.

The lamp maker can help by utilising the reflector metalisation to enhance the capacitive coupling. This technique can specifically use these external conductive areas to shunt current from the end regions of the tube towards the centre. With care the result is, not only the stimulation of "flow-on", but also a lower peak voltage due to earlier full-tube conduction. A further benefit accrues in a balancing-up of tube brightness.
This same capacitive coupling can bleed current away from the discharge, particularly at the higher voltage ends. The result is the loss of current and therefore brightness in the central region. Low current, high voltage tubes can be noticably non-uniform in brightness. The reflector metalisation, with appropriate electrical discontinuities can restore discharge current uniformity.

Such techniques can only be utilised cost effectively where the reflector and lamp channel are of unitary construction. Molded glass technology is particularly appropriate here.

7.1.3 RADIATED EMISSIONS 1.- It is not often appreciated but the biggest generator of interfering harmonics is usually the discharge tube itself, and it is these harmonics that are the major nuisance. It is comparatively easy to make a power supply produce a low distortion sinusoidal current. Such a current at 60kHz would produce little concern fed to a resistive load. Discharge tubes, however, can be far from resistive in their electrical characteristics.

At 60 Hz a Neon tube will extinguish and re-ignite every 8 milliseconds. Each ignition constitutes a step, a sharp corner, appearing in the tube voltage even though it is fed from a sinusoidal current generator. A considerable high frequency component exists in this step and it is not unusual to find line powered neon signs interfering with AM radio, security tag systems and the like. Increasing the frequency of supply to the tube will result in a softening of this step as some of the neon remains ionised through to the next half cycle. By about 20 kHz most will remain ionised and the step may be no longer visible as such. There is, however, a broad region of operation, depending on the lamp pressure,

diameter etc., when noticable "conductivity modulation" occurs, That is, the conductivity (and therefore resistance) of the lamp varies throughout the sinusoidal current cycle. In short, the voltage waveform will not itself be sinusoidal, but will contain harmonics. By about 200kHz these harmonics have normally disappeared, and the radiated emissions will be comparatively simple to deal with, but at the lower frequencies we want to use, to control capacitive loss from the discharge, we may generate a plethora of much higher frequency components.

The lamp maker can do most to control radiated emissions. Indeed, implementing the start -voltage-limitation-strategy outlined above will help considerably. Channel widths and gas pressures are the main parameters to vary. The power factor of the tube is directly related to harmonic generation, and higher power factors (less harmonic generation) correlate to lower pressures. Some lamp makers have been forced to adopt very high pressures to meet lifespan requirements with consequently poor radiated emissions performance.

The physical layout of the channel has a profound effect on broadcast interference. Because, the voltages are high and the currents low, the major problem is one of E-field generation. The connecting wires and the tube ends, where the voltages are highest, constitute the antenna system broadcasting the interference. The lamp maker can reduce radiated emissions by reducing the efficiency of this antenna. This is achieved be reducing the extent and physical separation of the highest voltage parts of the circuit. For, example a U-tube is greatly to be prefered over a single straight tube. Long high voltage leads are eliminated and throughout the antenna system points of equal and opposite voltage are in close proximity.

The molded lamp can achieve the most desirable structures without incurring any additional fabrication cost. Electrodes can be presented in close proximity, and interference cancelling layouts adopted. The compact nature of the coupling transformers used by the current loop system permit very close siting to the electrodes obviating the need for high voltage cable.

Some have reasonably attempted to use DC to power neon lamps to reduce radiated interference. The results are fairly good, but limit maximum tube length due to ignition problems deriving from the great reduction of flow-on effect. The constant current loop system can help here, also. By using one transformer to supply the highly filtered DC (via rectifiers etc.) and another to provide an AC trigger stimulus, any reasonable length of tube can be powered by DC cost effectively.

7.1.4 RADIATED EMISSIONS 2.-The emission mechanism of conductivity modulation can be described as differential in that the interfering signal is manifest as a voltage difference between the ends of the tube. Another mechanism exists that is best described as "common-mode". The signal produced by this mechanism is essentially a voltage of between zero and 150 volts consisting of even harmonics of the tube current and generated between the whole tube and its power supply. The source of this signal is the steep cathode voltage drop region changing ends every half cycle. Any asymmetry in the capacitive coupling to these regions results in the generation of a common mode signal.

Discrete tubes and reflectors suffer capacitive assymetry due to dimensional tolerances and so need extra circuitry to filter out the resultant common mode noise. Molded glass lamps can be manufactured with much tighter tolerances and so that the amplitude of the signal can be reduced. As a single component it offers the possibility of being "trimmed" to null the effect completely.

8.0 CONCLUSION

The growth of electronics installed on a vehicle is one of the few things we can be sure of in future car design. The demand for power is growing in both quantity and varieties of supply. Useful new technologies like discharge lighting, that save substantial amounts of power have cost penalties related to power supply. Viewing the totality of a vehicle electrical system, i.e. switches, looms and loads we can see that the more "electronic" loads, like HID, ignition systems and car stereos have a substantial "complexity cost".

A system of power distribution has been proposed that offers the possibility of absorbing much of this complexity into a single unit and thereby significantly reducing overall vehicle costs. The stable power delivery and noise-free switching will simplify the performance requirements for all loads. The option of delivering power at any voltage or current will permit the eventual optimisation of all existing loads, and remove substantial barriers to the incorporation of new ones.

Such a comprehensive system could never be introduced onto a vehicle in a single step as every electrical component would need redesign. It is envisaged, however, that sub-systems can be introduced with immediate cost benefit. Specifically, neon rear signal lighting, where a new low cost lamp manufacturing process can supply designers with the shapes and appearance they need, is just such a sub-system opportunity. Other light sources, HID, LED, hot cathode and incandescent provide other sub-system opportunities, likewise ignition, car stereo and motor control. Multiple sub-systems on one car may, one day, lead to the adoption of a pan-vehicle HFAC power delivery system, the ultimate complexity reduction.

Slipping Torque Converter Clutch Interface Temperature, Pressure and Torque Measurements Using Inductively Powered Radiotelemetry

M. J. Throop and D. G. McWatt
Ford Motor Co.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Torque converter clutch friction interface and automatic transmission fluid (ATF) temperatures, pressure difference across the clutch piston, flow through the friction material grooves, and engine crankshaft dynamic torque were measured for typical operating conditions on a running transmission. The friction coefficient, clutch unit pressure, fraction of heat rejected to ATF flowing through the grooves, and time dependent thermal response were determined. Simplified heat transfer calculations were compared with thermal data. Clutch interface temperatures were assessed as they relate to the process of friction material and ATF degradation. The inductively powered radiotelemetry system was found to be a robust and powerful tool for investigating continuously slipping clutch system performance.

INTRODUCTION

In order to gain improved fuel economy, automatic transmission torque converter clutches are designed to bypass the torque path through the fluid coupled impeller-turbine system in favor of a parallel path from the engine directly to the gearbox. When the clutch is employed in an on-off mode of operation, significant improvements in fuel economy can be realized and issues of clutch durability and performance are not much different from those encountered with shifting clutches. On the other hand, even greater overall fuel economy improvements as well as better engine torsional vibration isolation can be realized with a continuously slipping torque converter clutch. Unfortunately, experience has shown that as operating hours are accumulated, continuously slipping clutch systems present a durability challenge because the clutch friction material-ATF pair can acquire a negative friction coefficient slope with respect to slip speed. Once the friction coefficient slope becomes sufficiently negative, the powertrain is likely to exhibit undesirable surge and/or shudder phenomena [1]. The exact means by which a particular friction material-ATF pair degrades (i.e. acquires a negative coefficient of friction slope with respect to slip speed) over time is unknown, but there is evidence that friction material interface temperature plays an important role. Attention has been focused on friction material [2] and ATF compositions [3,4]. The effectiveness of some friction material groove designs has been assessed [5]. It is evident that the slipping speed strategy and clutch system thermal design must have some bearing on the degradation process as well, since these determine the rate of heat release and strongly influence the temperature at the clutch friction material interface.

This paper presents a set of clutch interface temperature and related measurements for a continuously slipping torque converter clutch operating in a realistic powertrain environment. Simplified heat transfer calculations were compared with the results. Friction coefficient slopes with respect to slip speed were examined. Friction interface temperature data for a set of typical operating conditions were used to assess the relative potential for friction material degradation. No attempt was made to degrade the clutch as the measurement process progressed.

This paper also describes the inductively powered radiotelemetry system and its associated instrumentation. The system was a powerful tool for making reliable measurements in a running torque converter without compromising normal powertrain functionality. Its use can be extended to vehicle measurements as well.

EXPERIMENTAL LAYOUT

THE POWERTRAIN consisted of a production 3.8L V-6 engine and four speed automatic overdrive transaxle (Figure 1). The transaxle was modified for dynamometer cell use by eliminating the final drive and

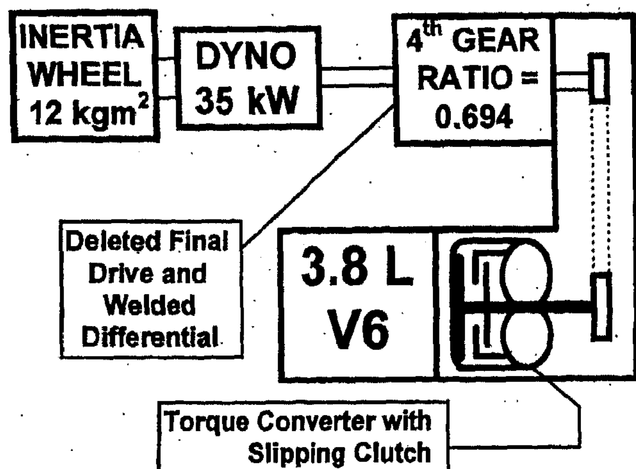

Figure 1 Powertrain layout

locking the output shaft to the final drive input. Following this modification, restoration of the vehicle-equivalent driveline dynamics and the capability of observing shudder required the installation of a special driveshaft with appropriate compliance. Since the work described here was not directed towards observing shudder, a much stiffer conventional driveshaft was used. The driveshaft was connected to an in-line torque transducer (300 Hz bandwidth) which in turn was connected to a 35 kW dynamometer capable of sustained torque absorption at 136 Nm. A 12.4 $kg{\cdot}m^2$ inertia wheel was connected to the other side of the dynamometer by a torsionally stiff coupling. The combined effect of all these modifications made it possible to reasonably simulate the equivalent vehicle speed, load, and inertia.

THE TORQUE CONVERTER ASSEMBLY was a take-apart converter design which was necessary to accommodate pressure and temperature sensor installations (Figure 2). The continuously slipping clutch

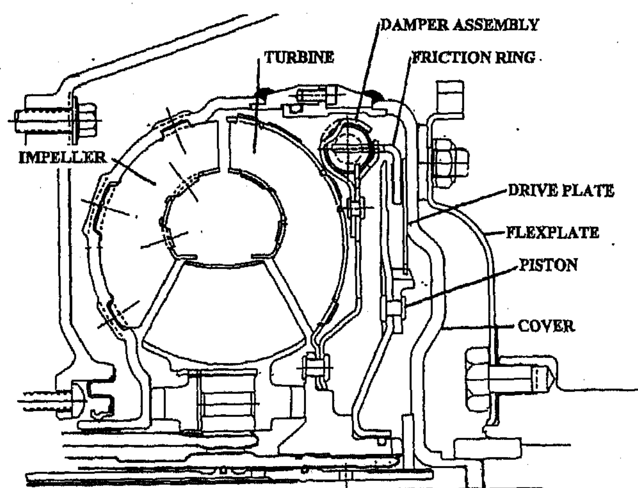

Figure 2 Torque converter cross section

system consisted of a spring damper assembly connected to the turbine hub, which improved engine torsional attenuation during clutch lockup, a friction material ring with grooved friction material on both sides and four tabs that inserted into the spring damper assembly, and a piston assembly piloted on the turbine hub and splined to a drive ring fastened to the converter cover. When the piston pressed on the rear side of the friction material ring which in turn was pressed against the drive ring, the turbine was mechanically coupled to the converter cover. The clutch was operated for locked, unlocked, or modulated slip speed mode by controlling the pressure on the piston release side. The clutch, cover and damper assemblies used in the experiments described here were experimental parts and although similar do not correspond to any production converter clutch system.

THE INDUCTIVELY POWERED TELEMETRY SYSTEM was a joint design and installation with Wireless Data Corp. [6]. It consisted of both stationary and rotating elements (Figure 3). The stationary portion of the system

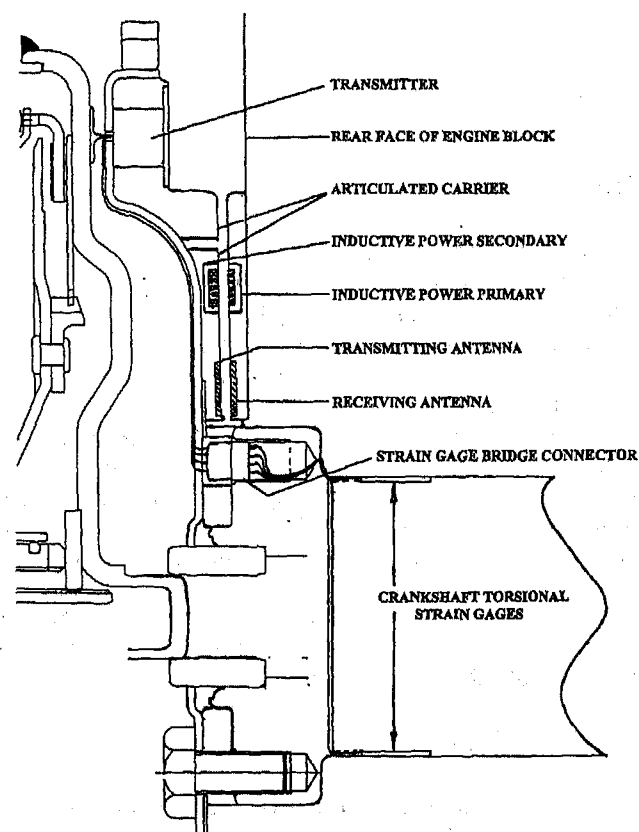

Figure 3 Inductive power and telemetry sensor cross sectional layout

was secured to the rear face of the engine block and included the primary inductive power coil driven at 160 kHz and the radio frequency receiving antenna. The rotating portion of the system was mounted on the torque converter flexplate and consisted of a two piece articulated carrier assembly designed to leave the axial stiffness of the flexplate unaltered. Near its outer perimeter, the rotating carrier assembly contained two pairs of pockets for housing transmitter modules, each 180 degrees opposed to maintain balance. Three pockets contained FM transmitters, two static strain gage type for converter clutch Δ pressure and engine crankshaft torque and one six-channel type for ATF and converter clutch interface

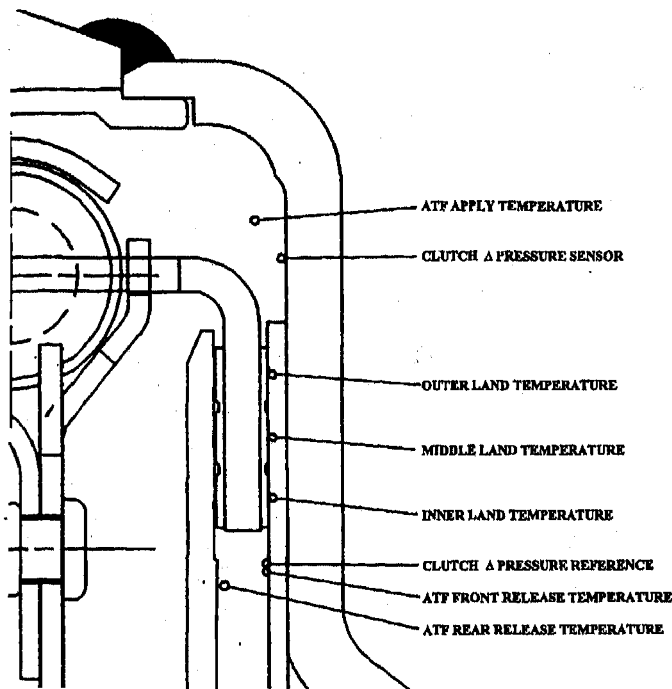

Figure 4 Torque converter cover and drive plate telemetry instrumentation - axial and radial layout

temperature measurements. A counterweight was installed in the fourth pocket. Included on the rotating carrier assembly was the inductive power secondary coil, energized across a small air gap by the inductive power primary coil and in turn powering the transmitter modules and strain gage sensors, and a four piece transmitting antenna (one for each transmitter) relaying sensor information to the stationary receivers via the receiving antenna.

ENGINE CRANKSHAFT TORQUE WAS MEASURED by instrumenting the engine crankshaft rear main bearing journal (Figure 3). Two EDM (Electro Discharge Machined) flats were machined on the rear main bearing journal. The flats were located 180 degrees opposed with the rear main bearing journal oil hole located 90 degrees midway between them. Each flat was connected to the crankshaft rear flange by an EDM groove along the journal surface. One of the grooves continued as a hole through the crankshaft flange to an embedded torque sensor wiring connector. A four active arm torsional strain gage bridge configuration, consisting of two-element high temperature 45° torsional strain gages bonded to each flat with a high temperature epoxy, was employed. Teflon insulated 36 AWG wire was attached to each strain gage set and laid in the journal grooves. From there, the wiring from one gage set was fastened with Nichrome spot welded tabs along the outer edge of the bearing journal to the hole in the rear flange at the end of the other journal groove. At this point all crankshaft torque strain gage sensor wiring continued to the embedded connector in the rear flange. A mating connector continued this wiring on to the flexplate mounted telemetry system carrier assembly and torque sensor transmitter. The strain gage sets, journal grooves, and rear flange wiring hole were coated with a high temperature oil resistant epoxy to assure retention during rotation, restore original oil flow pattern as much as possible, and prevent oil leakage through the rear flange hole.

CONVERTER CLUTCH INTERFACE AND ATF TEMPERATURES were obtained by installing six Type K thermocouples inside the torque converter at appropriate locations in and around the torque converter clutch (Figures 4 and 5). The thermocouple assemblies were 0.75 mm

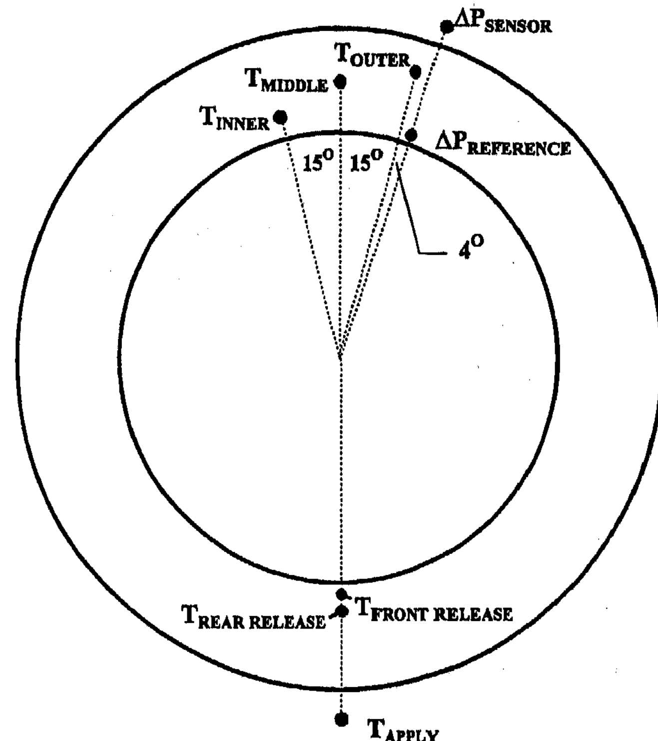

Figure 5 Torque converter clutch and drive plate telemetry instrumentation - circumferential layout viewed from the cover side

diameter stainless steel tubes containing thermocouple wires surrounded by MgO insulating material. The clutch ATF apply temperature thermocouple was mounted in the converter cover and extended into the ATF flow, just before it entered the clutch groove system on the apply side. The converter clutch ATF front and rear release temperature thermocouples extended into the ATF flow above the surface of the drive ring on the release side of the clutch, each sampling ATF temperature as it exited the front and rear friction material groove systems, respectively. The three ATF temperature thermocouple shells were insulated from the drive plate and cover for a distance of at least 10 shell diameters. The friction material-drive plate interface or land thermocouples were routed through EDM grooves in the rear face of the drive plate, entering from the outer edge, and continuing to locations approximately 0.075 mm below the drive plate surface directly underneath the center line of the annular area contacted by each land. After the land thermocouples were fixed in place, the groove volume not taken up by the thermocouple assemblies was filled by welding small sections of fine wire to the thermocouple shell and groove walls. The rear surface of the drive plate

was then restored to its original flatness, the thermocouples were routed through cover penetrations and sealed with epoxy, and the drive plate was bolted to the cover. The three land thermocouple locations were 15 degrees apart (Figure 5).

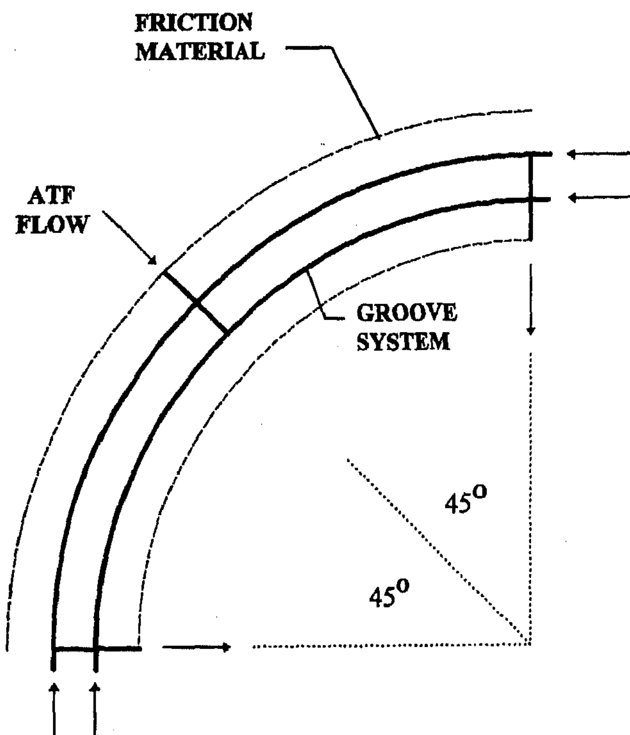

Figure 6 Friction material groove pattern (90° sector)

All thermocouple wiring was bundled and secured to the outside of the torque converter cover with Nichrome spot welded tabs and then guided through the flexplate to the six-channel multiplexed thermocouple transmitter mounted on the flexplate carrier assembly. How much do observed drive plate thermocouple temperatures differ from true drive plate surface temperatures? Since the land thermocouples were located below the drive plate surface, the observed temperatures must be somewhat low. Given that each thermocouple sensing element was located 0.37 mm below the surface of the 1.75 mm thick drive plate, for a worst case power dissipation of 1.8 kW, a friction material contact area of 81 cm^2, and all heat flowing perpendicular to the drive plate surface, the thermocouple was expected to indicate a temperature 1 °C lower than the actual drive plate surface temperature. This is not significant compared to other sources of error.

THE CONVERTER CLUTCH Δ PRESSURE MEASUREMENT was obtained by installing a miniature Kulite strain gage differential pressure transducer in the converter cover radially outward from the ATF apply side entry point into the clutch groove system (Figures 4,5,6). The transducer pressure reference tube was secured along the outside of the converter cover and routed to a location corresponding to the release side of the clutch. A hole was drilled through the cover and drive ring and the reference tube was installed and sealed. The pressure sensor wiring was secured to the outside of the torque converter cover with Nichrome spot welded tabs and then guided through the flexplate to the strain gage pressure sensor transmitter mounted on the telemetry system carrier assembly. The measurement obtained was the pressure difference between the apply and release sides of the torque converter clutch system.

THE CONVERTER CLUTCH BYPASS FLOW MEASUREMENT was obtained by installing a specially modified transaxle valve body that isolated bypass ATF flow after it exited the friction material groove system, directed it to an external Micro Motion flow meter for measurement and then returned it to the transaxle sump. With the modified valve body, clutch slip speed was controllable by manual valve adjustments only and it was not possible to perform transient experiments.

THE DATA ACQUISITION AND CONTROL SYSTEM was utilized to acquire, display, and record all pertinent parameter information and control the engine, transaxle, and dynamometer functions. Steady state data were acquired at 200 Hz, averaged and displayed at 1 Hz, and collected into time averaged data sets for 60 second intervals. A total of 17 temperature, 4 RPM, 3 torque, 15 pressure, 3 flow, and 3 position data channels were monitored, recorded, and displayed. In the dynamic experiments, 16 channels of data were collected at a 5 kHz rate for 60 seconds.

EXPERIMENTS

Time averaged steady-state data were taken at 1200 and 1700 RPM turbine speed and 70 Nm output shaft torque, and at 1500 RPM turbine speed and 40, 70 and 90 Nm output shaft torque. These operating points spanned a representative range of operation for the slipping clutch system. At each operating point, the time averaged torque converter slip speed was varied from zero to 100 RPM in discrete steps, constant output shaft torque was maintained by adjusting the engine throttle, and turbine speed was kept constant by operating the dynamometer in speed control. For constant output shaft torque, the slipping clutch torque decreased with increasing slip speed because the turbine took an increasing portion of the torque split between the clutch and turbine. The clutch torque was derived from output shaft torque taking into account the gear and turbine chain ratios, the gear and chain losses, and then subtracting the turbine torque determined from torque converter performance data. Temperatures were allowed to settle to their steady-state values over a period of several minutes before any data were taken. The transaxle ATF sump temperature was controlled at 70 or 93 °C. At selected operating points, high speed data were acquired for engine and turbine speeds and crankshaft and output shaft torque in order to assess the engine torsional attenuation performance of the slipping clutch

system. The torsional attenuation results are not reported here.

In a second set of measurements, dynamic thermal performance data were taken at one operating point - 1500 turbine RPM and 70 Nm output shaft torque. A step command was input to the pulse width modulated solenoid that controlled the continuously slipping clutch release pressure. Two sets of measurements were made, the first during a step command that corresponded to a zero to 100 RPM slip speed change, and the second during a 100 RPM to zero slip speed change. Data were logged at a 5 kHz rate and included land, apply and release temperatures, engine and turbine speeds, crankshaft and output shaft torque, and Δ pressure across the slipping clutch. The sump temperature was maintained at 93 °C.

In a third set of measurements, time averaged converter clutch release side flow data were taken at all the operating conditions of the first set of measurements. Data were taken for the full range of differential pressures across the clutch, corresponding to both continuously slipping and locked conditions.

RESULTS

A TYPICAL SET OF TIME-AVERAGED LAND TEMPERATURE data is shown in Figure 7 for 1700 RPM turbine speed, 67 Nm output shaft torque, and 93 °C sump temperature. All the clutch land and ATF temperatures were within ± 2 °C of the sump temperature at zero slip speed, then increased as slip speed was increased. The minimum slip speed at which best torsional attenuation was obtained was 20 RPM. ATF exiting the clutch grooves had a higher temperature than that entering the grooves, consistent with a process of heat removal from the drive plate. Assuming equal heat transfer to the ATF from each land, the land temperatures were expected to increase from outer (lowest) to middle (intermediate) to inner (highest), as ATF flowed through the clutch groove system (Figure 6), removing heat and increasing in temperature from one land to the next. However, Figure 7 shows that the outer land temperature was the highest and the inner land the lowest. This result was duplicated at all operating conditions except one high torque condition where the outer and middle land temperatures were the same. Figure 7 also shows the inner land temperature was nearly the same as the ATF front release temperature, indicating heat rejection from this land to the ATF was minimal.

The most likely explanation for the observed land temperature distribution is unequal friction element contact pressures on each land, with the pressure highest at the outer land and lowest at the inner land. No data were available for running land-to-land contact pressure differences in the system reported on here. It is

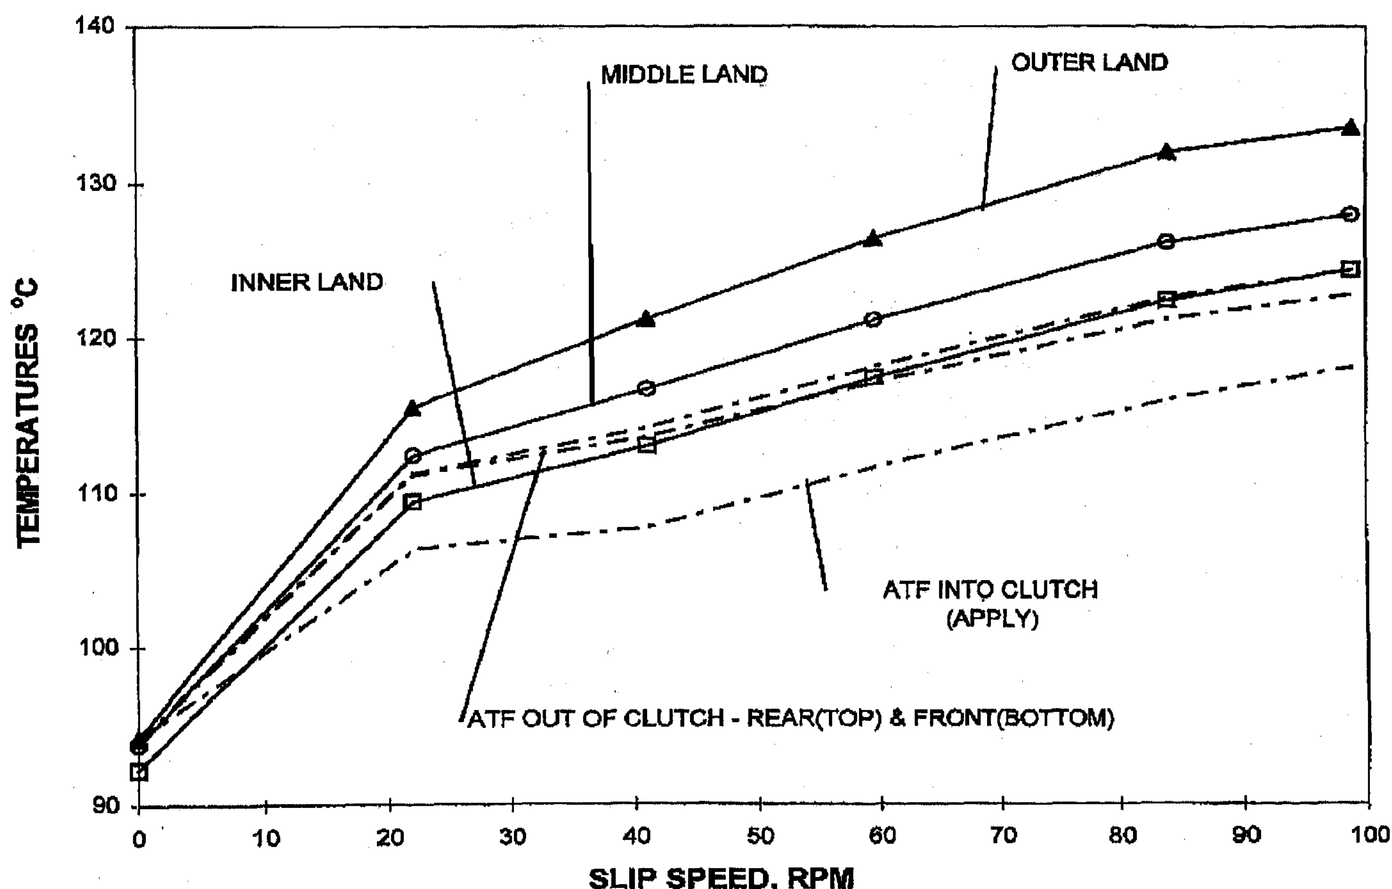

Figure 7 Land and ATF temperatures vs. slip speed

known that the converter housing changes shape as RPM and other operating conditions change, so the drive plate, bolted to the front cover, must change shape as well. Similarly, the piston deforms as a function of the pressure difference across it. These two effects can create a geometry in which the piston and drive surfaces opposite the facing friction surfaces are not coplanar, leading to uneven contact pressures at some operating conditions. Uneven contact pressures at each land imply the heat generated will not be the same, and assuming a constant friction coefficient at each land, it follows that the land temperatures will not be equal. Slipping clutch designs can attempt to remedy this situation by tapering the drive plate and piston surfaces such that they will be coplanar, but only at a chosen operating condition, for example where maximum clutch torque capacity is desired. Inspection of the drive plate and piston surfaces after 125 hours of operation revealed a progression (on both piston and drive plate) from least wear at the inner land to greatest wear at the outer land. This radial wear pattern suggested that average clutch operation must have occurred at conditions where the friction material contact pressure increased from inner to outer land, and the land-to-land temperature differences observed, as in Figure 7 for example, are consistent with this. The inspection also showed that the 12 bolts attaching the drive plate to the cover slightly distorted it such that the drive plate had a vertical variation of about ± 20 microns at 30 degree intervals on all three lands. A circumferential wear pattern, consistent with the drive plate vertical variation, was also observed, although it was not as strong as the radial wear pattern. It is possible that some portion of the land-to-land temperature differences were due to thermocouple locations at drive plate peaks or valleys. As installed, the outer land thermocouple was located near a 20 micron high spot, the inner land near a -20 micron low spot, and the middle land near a spot of average height.

INCREASED APPLY ATF TEMPERATURE was another feature of Figure 7 that was observed at all operating conditions as the slip speed increased from 0 to 100 RPM. Was ATF heated in the impeller-turbine part of the torque converter before some of it migrated to the slipping clutch and entered the groove system? This question can be answered by measuring the rise in converter-out temperature, defined as the ATF temperature exiting the impeller/turbine system referenced to the sump temperature, as a function of slip speed. At 1500 RPM and 70 Nm output shaft torque, Figure 8 shows that the converter-out minus sump temperature rise was constant within ± 2.5 °C over a 0 to 100 RPM slip speed range, compared to the observed apply minus sump ATF rise of 24 °C (Figure 7). The converter-out temperature rise was also calculated, using known converter torque performance and flow data, to be 1.1 °C. Thus an explanation for the ATF rise with slip speed must be sought elsewhere.

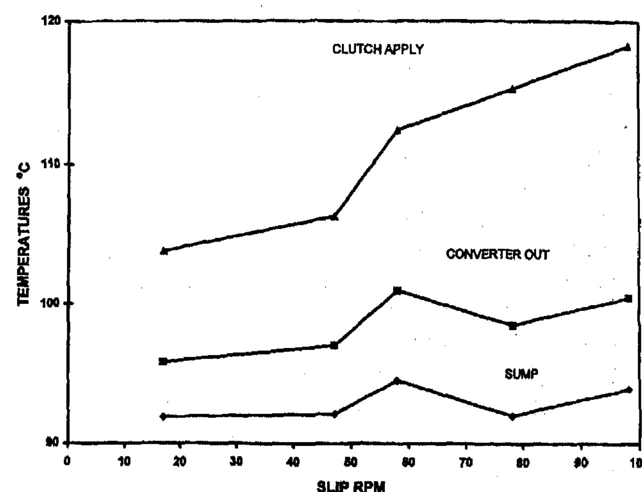

Figure 8 Apply, converter out and sump ATF temperatures vs. slip speed

Another possible cause of apply ATF temperature rise is heat transfer from the torque converter cover and the piston rear face. Apply ATF originated from the primary converter flow circuit via leakage past the impeller - turbine gap and leakage through gaps in the blade retention slots in the turbine shell (Figure 2). The geometry involved in possible apply ATF heating is shown in Figure 9, which indicates how heating could occur as apply ATF flowed past the inside surface of the cover toward the entrance of the front friction material groove system. A similar ATF flow past the rear face of the piston prior to entry into the rear friction material groove system could also take place. Land temperatures were not measured at the interface of the piston and friction material rear face. The actual apply ATF flow paths were not known. The piston and cover contributions to apply ATF heating may differ due to geometry and flow path differences.

An estimate of apply ATF heating by the cover and piston can be made for the case of Figure 7, assuming some reasonable areas, flow rates and flat plate heat transfer coefficients. The estimated apply ATF heat removal rate from the cover and piston was

$$Q = F \rho C_P (T_{APPLY} - T_{SUMP}) \quad \text{Watts}$$

where

F = ATF flow rate through friction material groove system (0.5 l/min.)

ρ = ATF density (8 g/cm^3)

C_P = ATF specific heat capacity (2160 J/kg/K)

to solve for $T_{APPLY} - T_{SUMP}$ required a heat transfer calculation for

$$Q = \alpha A (T_{COVER} - (T_{APPLY} - T_{RELEASE}) / 2) \quad \text{Watts}$$

where

$\alpha = 2 K (0.332 Pr^{0.33} Re^{0.5}) / L$

K = ATF thermal conductivity, 0.14 W/m/K

Pr = the Prandtl number, 93 for ATF at 93 °C

Re = the Reynolds number, 1.86E4 for ATF at 93 °C, estimating the ATF velocity to be

the cover heating area speed with respect to the turbine outside diameter at 100 RPM slip

L = characteristic length, chosen to be 4 cm

A = area which heated apply ATF (a 26 cm diameter, 4 cm wide ring on the cover, plus a piston area of 415 cm^2 or 742cm^2 total area)

T_{COVER} was taken to be the average land temperature

$T_{RELEASE}$ was taken to be the average ATF release temperature

For α = 571 W/m^2/K, the calculated temperature rise ΔT (apply minus sump) was 44 °C compared to the measured temperature rise of 23 °C, which is acceptable agreement considering the difficulty in estimating the Reynolds number and heating area. The heat transfer calculation lends support to the idea that the front cover and rear surface of the clutch piston were responsible for heating the ATF prior to its entry into the friction interface groove system. This heating process had the undesirable effect of raising the land temperatures and the potential for accelerating friction material-ATF pair degradation.

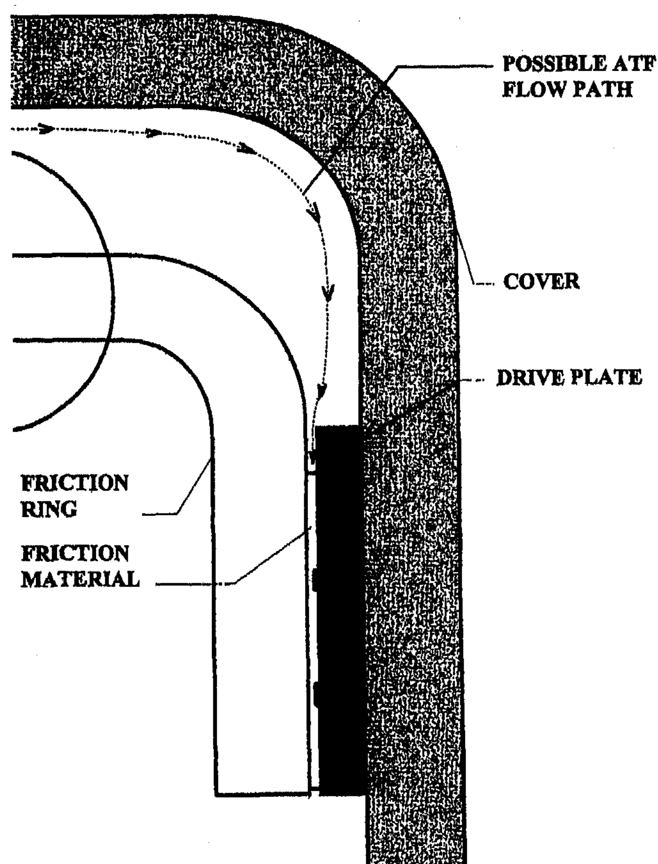

Figure 9 Geometry for apply ATF heating

HEAT TRANSFER TO ATF FLOWING IN THE GROOVES was qualitatively estimated and compared with experiment. At the conditions of Figure 7, the total ATF flow rate was 0.5 l/min. The mean ATF speed in a single groove sector (in Figure 6, a 45° sector of a circle with 215 mm mean radius) was 0.9 m/s. The flow was laminar (Re = 51), but it was not fully developed (in addition to entrance, exit and bend/tee effects, the drive plate wall was moving, the groove was curved, and centrifugal forces acted on the ATF). For fully developed laminar flow, the heat transfer coefficient α depends only on the ATF thermal conductivity K and the mean hydraulic diameter D

$$\alpha = 4.12\, K / D \qquad W/m^2/K$$

Using the groove dimensions given in a following section on groove flow, α was 1377 W/m^2/K. The calculated ATF heat removal rate was

$$Q = \alpha A\, (T_{LAND} - (T_{APPLY} + T_{RELEASE}) / 2) \quad Watts$$

where

A = heat transfer area, taken to be that area of the drive plate and piston exposed to groove ATF fluid flow (27.5 cm^2)

T_{LAND} was taken to be the average land temperature

In the case of the Figure 7 data at 100 RPM slip, the calculated ATF heat removal rate was 30 W, compared to the experimental heat removal rate

$$Q = F \rho C_P\, (T_{RELEASE} - T_{APPLY}) \qquad Watts$$

which was 74 W. It appears that the fully developed laminar flow assumption leads to a significant underestimate of groove ATF heat removal.

HEAT REMOVAL AS A FUNCTION OF CLUTCH POWER for groove ATF flow is plotted in Figure 10 as a percentage of total clutch power dissipation as slip RPM was swept for three output shaft torques at 1500 RPM. The percent power carried away by the grooves decreased significantly as slip speed increased, so the groove system became less effective in cooling at high slip speeds. In contrast, as the clutch torque increased at a fixed slip speed, the percent power carried away by the grooves also increased, so the groove system became more effective in cooling at high torques. Directionally, decreasing slip speed and increasing torque are both associated with increased ΔP across the clutch and therefore increased flow though the clutch grooves and improved heat transfer. The proportion of heat rejected to the ATF before it entered the groove system (apply ATF heating) generally followed the groove ATF trends. These two heat removal processes combined removed less than half the clutch power at 100 RPM slip. Heat removal by cover conduction is a likely explanation for the remainder. Since cover conduction increases with increasing land temperature and slip speed, it removes a larger proportion of clutch power at the conditions where groove flow and cover heating of ATF are less effective.

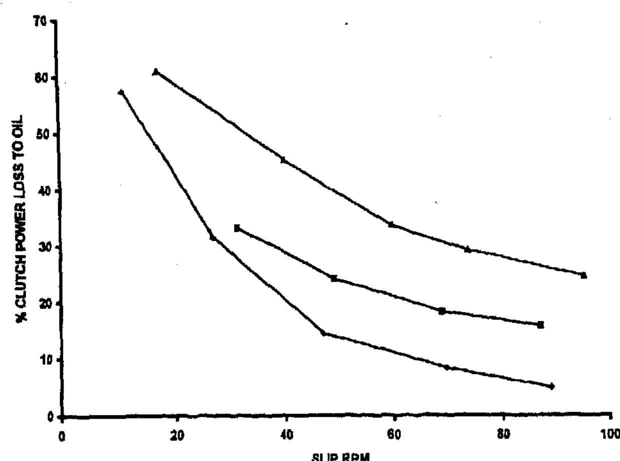

Figure 10 Heat rejected to ATF flowing through the grooves vs. power dissipated in clutch at 1500 RPM, 55 Nm output shaft torque (diamonds), 95 Nm (squares), 125 Nm (triangles)

Outer land temperatures as a function of clutch power (slip RPM times clutch torque) for all 93 °C sump temperature operating conditions are shown in Figure 11. The outer land temperature was always the highest land temperature. The highest temperature observed in the experiments reported here was 163 °C at a clutch power of 1.63 kW. The outer land temperature data showed a trend of increasing temperature with increasing clutch power. Figure 11 is a useful way to assess the susceptibility of a particular clutch design and friction material to temperature degradation. Assuming the land temperature is determined by three heat removal processes - ATF flowing through the grooves, conduction through the cover to other cooler parts of the transaxle, and convective heat loss from the cover and piston rear face to the apply ATF, a generic relationship for land minus sump temperature ΔT can be written

$$\Delta T = Q / (\alpha_G A_G + k A_C / t + \alpha_{CV} A_{CV})$$

The first two terms in the denominator are groove flow and cover conduction terms which are fixed by the ATF properties and the geometry. If only these terms were important, a linear relationship between land temperature and clutch power Q would be expected. The third term is a convective term which has a Reynolds number dependence, implying a correlation with slip speed. Since higher levels of clutch power dissipation are also correlated with slip speed, the presence of a significant convective term in the denominator would reveal itself as a less than linear dependence of land temperature on clutch power.

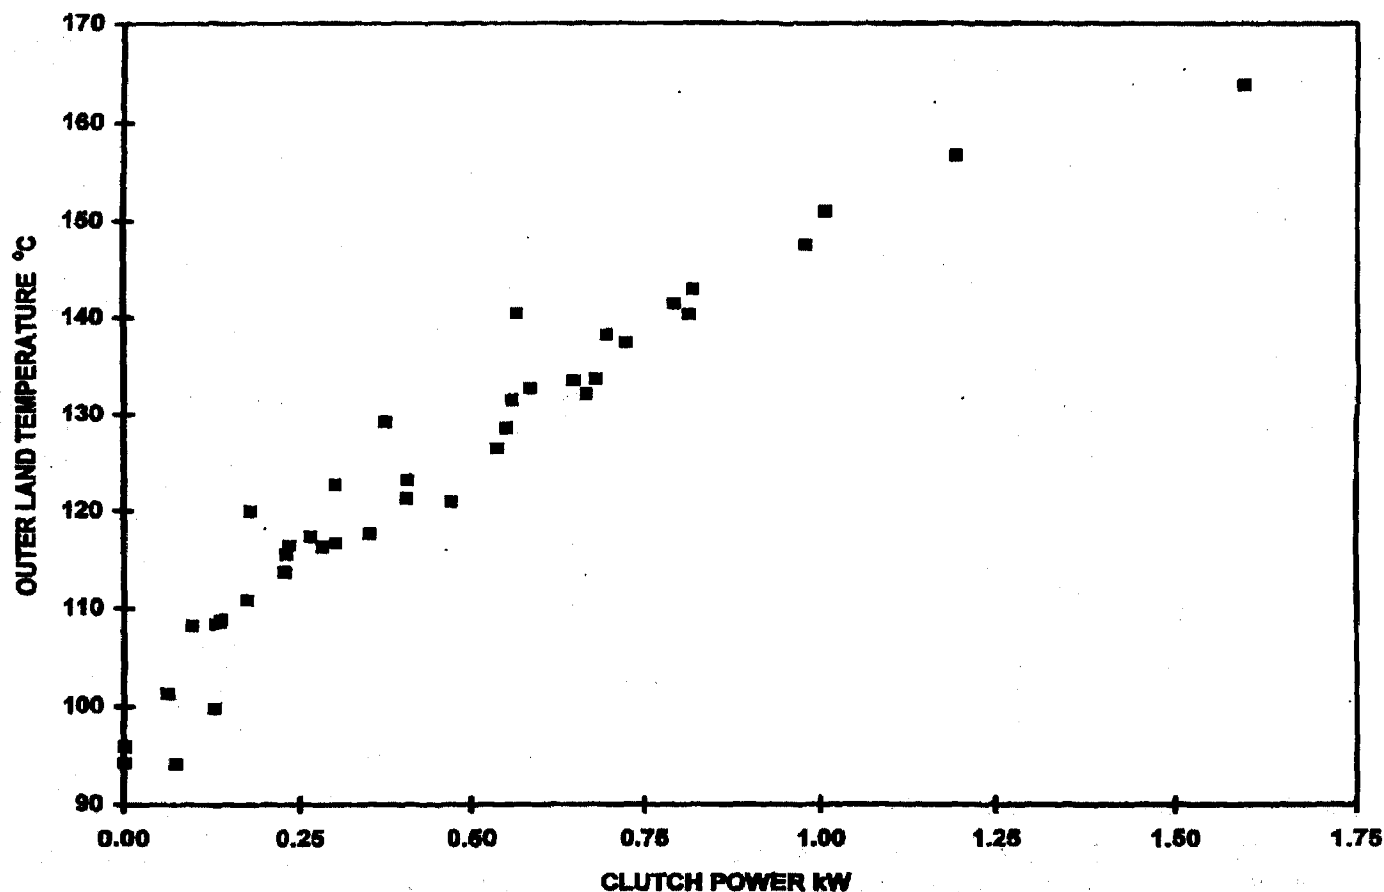

Figure 11 Outer land temperature vs. clutch power, 93 °C sump

Figure 11 does indicate a less than linear trend, consistent with the expected influence of convective heat removal processes. The effect of heat removal by ATF flowing through the grooves alone can be isolated as shown in Figure 12, where the outer land temperature less ATF apply temperature is plotted as a function of clutch power; data for 73 and 93 °C sump temperatures are included. As with Figure 11, there is some evidence for convective heat removal processes, but sump temperature does not seem to have an effect.

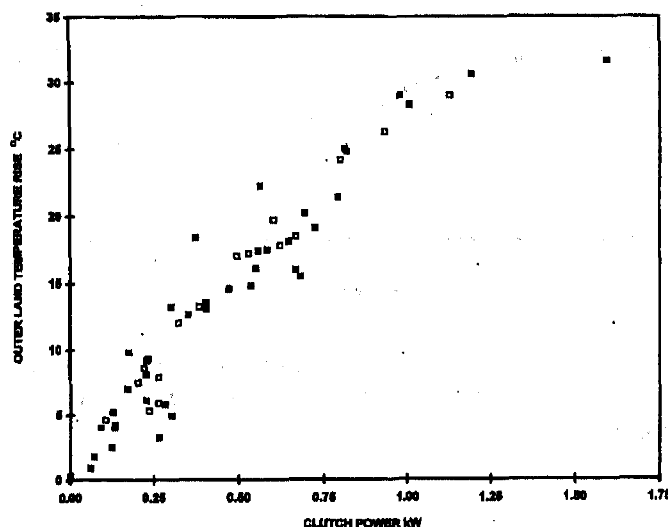

Figure 12 Outer land less apply temperature vs. clutch power, dark squares 93 °C sump, open squares 73 °C sump

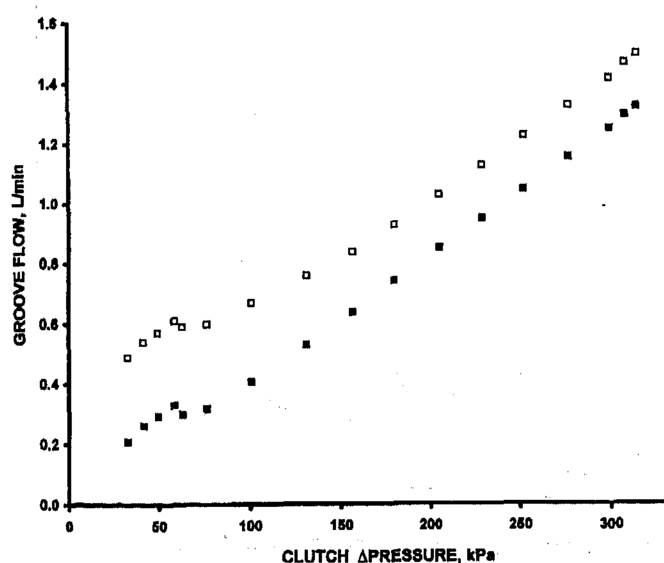

Figure 13 Clutch groove flow vs. clutch Δpressure. Open squares are observed flow, filled squares are calculated flow.

FLOW MEASUREMENTS - Time averaged groove system ATF flow data taken at 1500 RPM for 70 Nm output shaft torque at 93 °C sump temperature are shown in Figure 13. The ATF flow rate through the friction material grooves was estimated using several simplifying assumptions - fully developed laminar flow, neglect of minor losses such as entrance and exit effects, and ignoring the small effect of bends and short radial sections. The groove flow system (Figure 6) was thus reduced to 8 quadrants (4 on the forward friction material surface and 4 on the rear facing surface) containing 4 grooves, two in which ATF flowed in the same direction as the slipping drive plate and two in which ATF flowed in the opposite direction. Each groove was approximated as a straight passage of length equal to one eighth of the average groove circumference. The calculated [9] flow rate F was

$$F = [\, wh^3 / (12\mu L) \{ 1 - 192h / (\pi^5 w) \tanh(\pi w/2h) \} \Delta P \pm whV/2 \,] N_G$$

where

- w = groove width
- h = groove depth
- μ = ATF viscosity
- L = groove length
- ΔP = clutch apply - release pressure
- V = average drive plate velocity with respect to groove flow
- N_G = number of grooves with flow in the same direction

and the ± sign indicates whether the drive plate velocity is in the same or the opposite direction to the flow driven by ΔP. The groove pattern of Figure 6 had equal numbers of grooves for the +V and -V cases, so the V dependent flow contributions canceled, leaving no net contribution to groove flow. Therefore, using the approximations described here, the groove flow depends, apart from geometrical factors, only on the ATF viscosity (a function of temperature) and the apply minus release pressure ΔP.

The groove width was 1 mm, the depth was 0.265 mm, the viscosity varied from 7 cP at 90 °C to 4.6 cP at 114 °C, the average groove length was 84.4 mm, the ΔP ranged from 20 to 375 kPa, and the total number of grooves was 32. The calculated result for a 93 °C sump temperature is shown in Figure 13 along with the measured flow data. At ΔP > 75 kPa the land temperatures were the same as the sump temperature because the slip speed was zero, and for ΔP < 75 kPa, where the clutch was slipping and the ATF was heated as it flowed through the grooves, the flow rate increased due to a reduction in viscosity. The calculated and observed flows are in qualitative agreement for ΔP > 75 kPa. A good flow prediction capability is desirable when the clutch is slipping, but Figure 13 shows the calculated and observed flows differed by about a factor of 2 at ΔP < 75 kPa. Qualitatively, however, there is a clear trend of flow proportional to ΔP and flow increase due to reduced viscosity when the clutch was slipping.

FRICTION COEFFICIENTS - Friction coefficients for various slip speed and clutch torque conditions were calculated according to the relation defined in [7]. The results are shown in two ways, friction coefficient as a function of average load pressure on the friction material (Figure14) and as a function of slip speed (Figure 15). However, as discussed above, wear evidence and land temperature differences showed that the loading of the drive plate and piston were not uniform, so the load pressure referred to here can only be understood in an average sense. In Figure 14 the average load pressure data show that the coefficient of friction increased by about 20% as average load decreased from 650 to 200 kPa. At lower load pressures, clutch ΔP and torque were small and therefore more difficult to measure, causing more scatter in the calculated friction coefficient. The dependence of friction coefficient on load pressure shown in Figure 14 is similar to what is seen for many sliding materials [8].

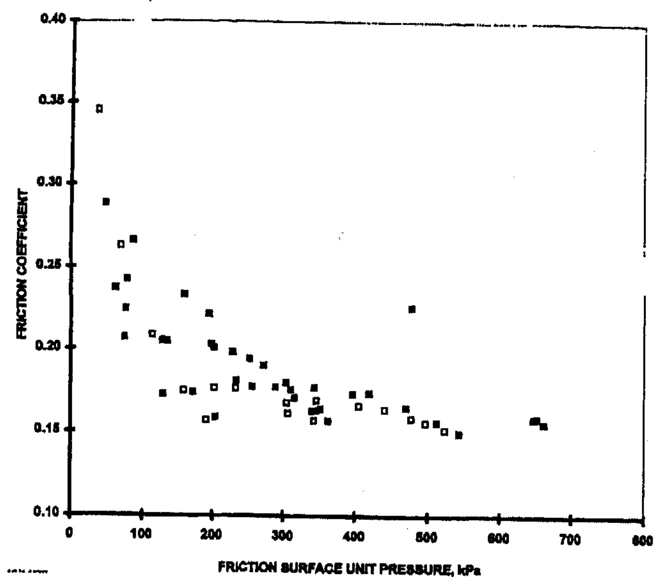

Figure 14 Friction coefficient vs. average load pressure. 73 °C sump (open squares), 93 °C (filled squares)

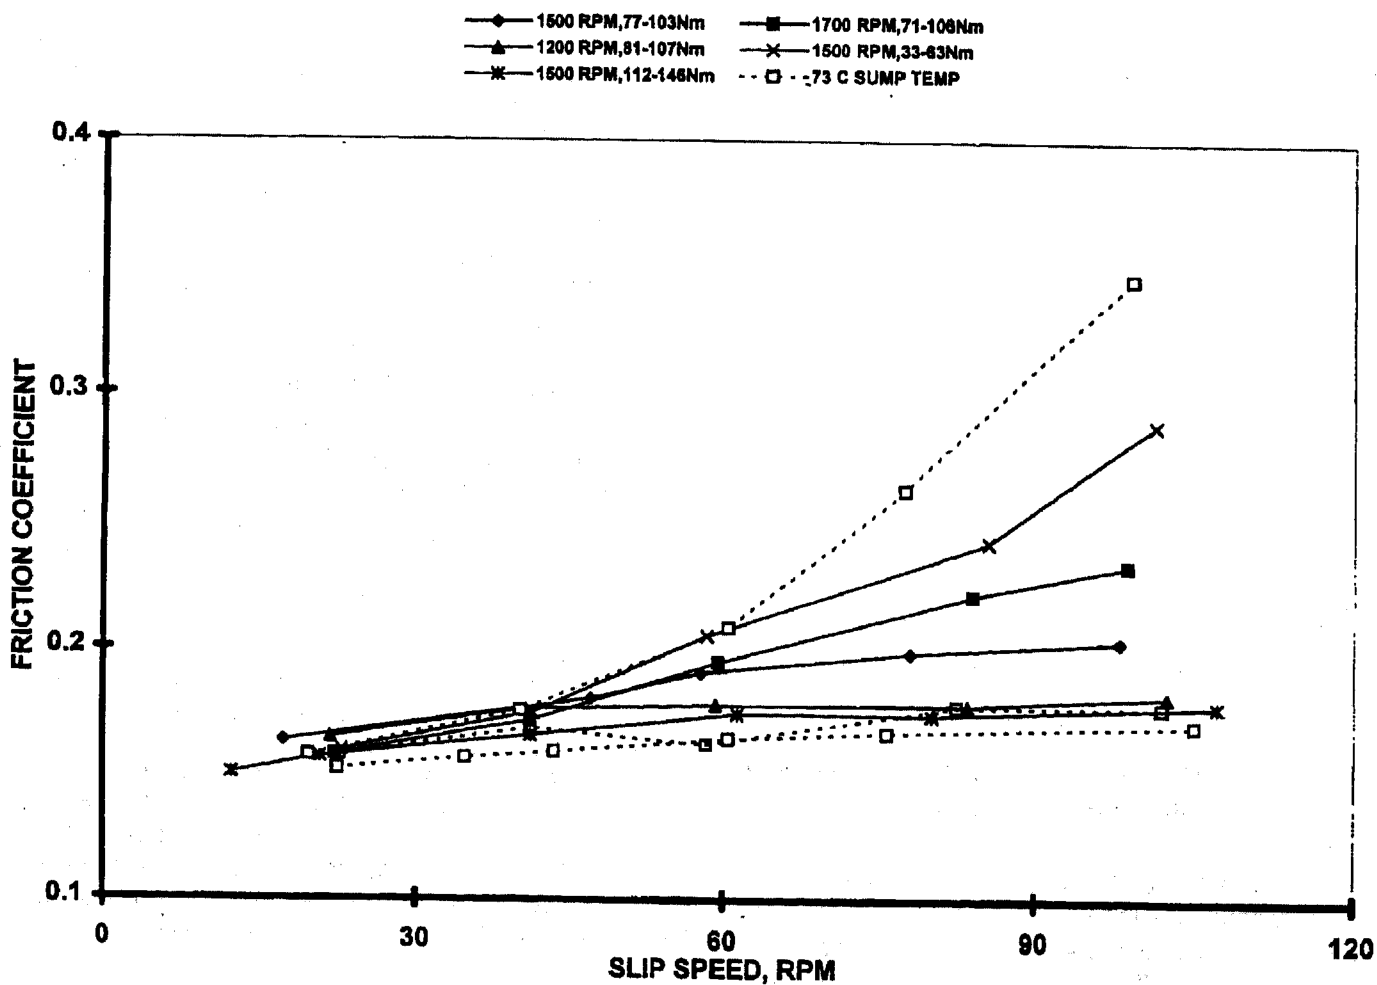

Figure 15 Friction coefficient vs. slip speed

Figure 15 shows friction coefficients for slip speed sweeps at constant output shaft torque and at 73 and 93 °C sump temperatures. The most important feature of Figure 15 is that the slope of the friction coefficient as a function of slip speed was everywhere flat or positive, as was expected for an undegraded friction material - ATF pair. Any friction material degradation leading to a negative friction coefficient slope was not expected for the duration of the experimental conditions reported here. Figure 15 also shows the friction coefficient decreased with increasing clutch torque (or average load pressure as in Figure 14) at a fixed slip speed, but the decrease was less evident at lower slip speeds. At 73 °C sump (for 1500 RPM only) the friction coefficient decreased even more rapidly with decreasing slip speed at a low output shaft torque (40 Nm) but was nearly flat at higher torques (70 and 90 Nm). The results of Figure 14 and 15 show that it is not possible to specify a universal friction coefficient value for all operating conditions.

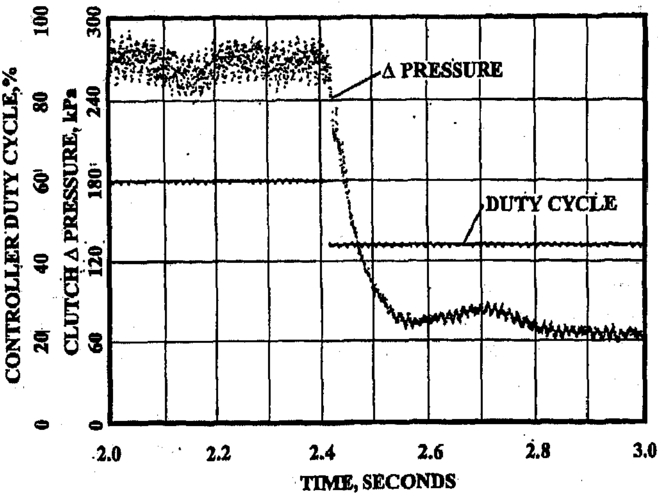

Figure 16 Clutch delta pressure following a step change in controller duty cycle.

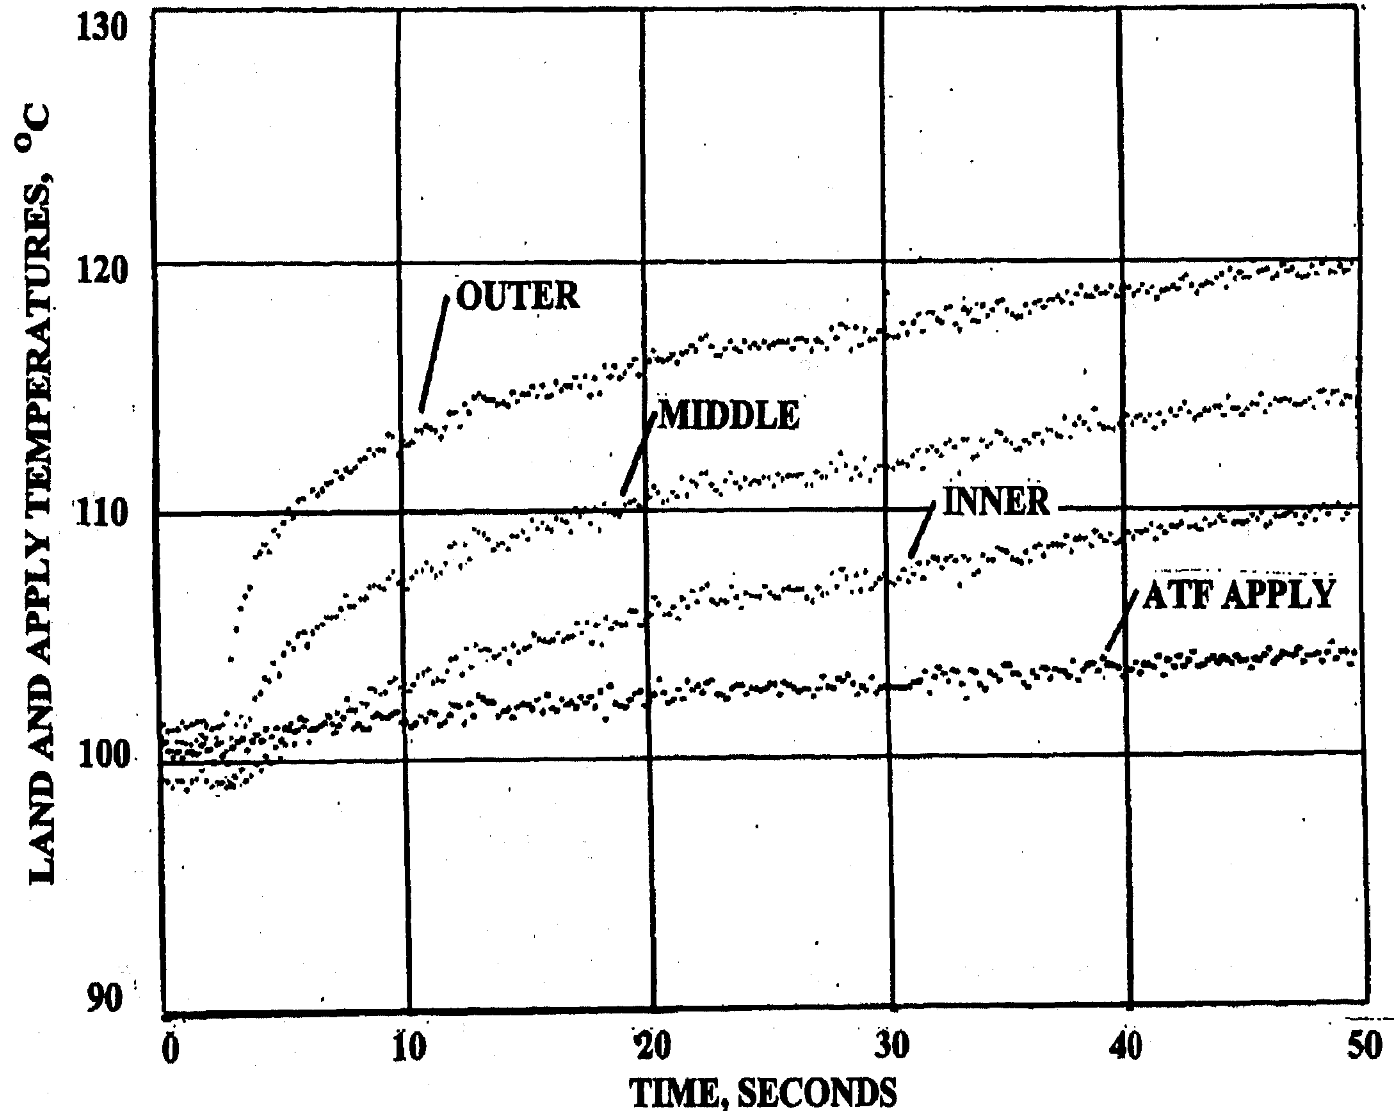

Figure 17 ATF apply and land temperatures following a step change in clutch Δ pressure

DYNAMIC TEMPERATURE MEASUREMENTS - An insight into mechanisms that contribute significantly to land temperature cooling can be gained by injecting a step change in heat flow into the system. An ideal heat flow step change was approximated by commanding a step change in the pulse width modulation of a solenoid controlling the ΔP across the continuously slipping clutch, which had the effect of stepping between an initial and final slip RPM. A step change also took place in the clutch torque, since the torque split between the clutch and the turbine depends on slip speed. The commanded percent pulse width modulation of the solenoid and the clutch ΔP response are shown in Figure 16 as a function of time. The clutch ΔP has a response close enough to a step for the purpose of understanding what happens to land and ATF temperatures following this step. The three land temperature responses are overlaid and shown with the apply temperature as a function of time in Figure 17, where the step command took place at 2.5 seconds. The three lands responded with a rapid temperature rise for a few seconds after the step, then continued to rise at a progressively slower rate for several minutes. After thermal equilibrium was reached, the final outer land temperature, for example, was 137 °C.

The temperature-time dependence was symmetric with respect to sign of the step change. As with the steady-state land temperature data, the transient land temperatures increased in the order inner, middle and outer. For the inner land, the rapid rise following the step input was significantly reduced compared to the other two lands. The rapid rise part of the temperature response is attributed to heating of that part of the drive plate between the friction material and the thermocouple

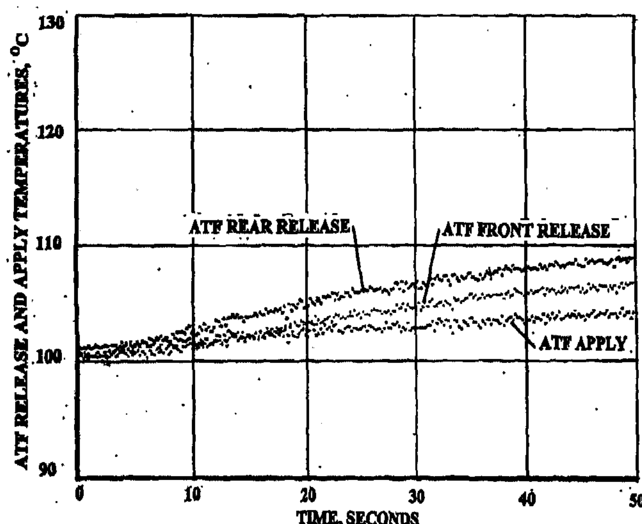

Figure 18 ATF apply and release temperatures following a step change in clutch Δ pressure

sensing element. The ATF apply and front release temperatures are shown in Figure 18. Neither shows the fast temperature rise component evident in the land temperature data. The slow rate of increase in apply temperature is consistent with the process of cover heating by the drive plate, followed by ATF heating by the rear of the piston and the cover upstream of the groove entrances. The process of cover heating is slow, because heat must be stored in the cover mass to raise its temperature. Assuming the front half of the torque converter cover plus piston weighed 5 kg, was isothermal, and using steady-state land temperature and clutch power data for the initial and final conditions of the step, the exponential time constant of the temperature rise was estimated to be 110 s. This is a lower limit, because not all the clutch power was available for cover and piston heating; at this operating condition, a substantial amount was carried away by apply and groove ATF flows. This time constant estimate was qualitatively consistent with the observed ATF temperature time constant of about 300 s.

CONCLUSIONS

- The inductively powered telemetry system was a powerful and reliable tool for measuring torque converter clutch performance under realistic operating conditions.
- Continuously slipping clutch interface temperatures were measured for each land over the clutch operating range on a running transaxle.
- Land temperatures differed significantly, decreasing in temperature from the outer to middle to inner land. The degree of wear observed on the piston and drive plate correlated with land temperature. When there are significant differences in land temperatures, it is not meaningful to use a single interface temperature to characterize the clutch thermal behavior.
- The highest land temperature observed was 163 °C at a clutch power dissipation of 1.63 kW. Friction material-ATF combinations exposed to the high end of the temperatures observed will degrade (i.e. acquire a negative slope coefficient of friction with respect to slip speed) over time.
- Land and land minus apply ATF temperatures increased nearly linearly with increase in clutch power dissipation. This was consistent with heat being removed from the lands primarily by conduction and laminar groove flow. The data were also consistent with some lesser heat removal by convection.
- Laminar heat transfer estimates for the groove and drive plate system were lower than experiment by a factor of roughly two.
- ATF was heated before entering the groove system. Estimates of cover and piston heating effects could account for the apply ATF temperature rise.
- Friction coefficient data were consistent with positive or flat slope with respect to slip speed. An increase in friction coefficient with decrease in average load pressure was observed.
- Friction material groove flow rate was generally proportional to ΔP and increased as clutch interface temperature or sump temperature increased. The

flows measured were consistent with a laminar flow model estimate.
Dynamic land temperature data were consistent with heating of the torque converter cover plus piston, with a fast temperature rise followed by a much slower temperature rise. The time constant for cover heating could be qualitatively reproduced.

ACKNOWLEDGMENTS

The authors thank V. Lambson, now of Lambson Engineering, for his skill and dedication in designing, building and installing the telemetry system in 120 days, and S. Bill of Wireless Data for expediting this process. F. MacDonald, S. Rosen, and J. Ward supplied the specially modified transaxle hardware. J. Kovach assisted with data acquisition and analysis. We also thank W.E. Tobler for his unwavering advocacy of and support for advanced torque converter instrumentation over the years.

ABSTRACT

A new experimental apparatus to visualize and measure the flow in the stator of a torque converter is proposed. A one-sided coaxial shaft constructed of an input shaft and an output shaft provides an open space inside the stator shaft for measurement. Through the window on the stator shaft, the flow in the stator can be directly observed. We also improved the laser sheet lighting method into the blade passage by using a mirror inside the blade.

By visualizing the flow with the laser sheet lighting method, we found that the flow around the leading edge has different separation regions along the blade span. Furthermore, by using a laser doppler velocimeter, velocity vectors and turbulence intensities were measured in three stator blades of different thicknesses with the same camber line. The thickness of the stator blades affects the flow patterns. Both the outlet flow rate and the average outlet flow angle show similar characteristics to the torque capacity coefficient when the stator blade thickness is altered. We have verified that the general flow characteristics are determined by the outlet flow rate, and are emphasized by the average outlet flow angle.

INTRODUCTION

In recent years, there has been a strong requirement for improvement in both fuel economy and acceleration performances of automatic transmissions. It is well known that a torque converter's characteristics significantly affect such performances. There are also constraints on the torque converter such as axial length due to the powertrain packaging of front-wheel-drive vehicles and lock-up clutch. To improve the torque converter's characteristics, it is necessary to understand in detail the fluid flow phenomena that occurs in a torque converter. However, it is very difficult to visualize the flow in a torque converter because closed-loop flow occurs in a very complicated geometric space where three coupled blade cascades rotate at different speeds (Fig. 1).

Some research on measuring flow in a torque converter have recently been documented:

1. Flow measurements of a stator using a hot-film anemometer with an X-type probe [1,2]
2. Flow measurements of a stator [3], pump [4] and turbine [5] of a torque converter constructed from Plexiglas using a laser doppler velocimeter
3. Exit flow measurements of a pump, a turbine, and a stator using 5-hole pitot tubes [6,7,8]
4. Measurements of pressure distribution on stator blades [9,10]
5. Flow visualizations of a pump, a turbine, and a stator using the oil-film method [11]
6. Flow visualizations of two-dimensional blade models of a stator [10].

There is no known published case of applying a flow visualization technique to a real torque converter because of its complex construction. We therefore proposed a new experimental apparatus to visualize and measure the flow in a stator of a torque converter[12]. With this visualized torque converter, the flow in a stator has been measured and analyzed using the tuft method, oil-film method and laser doppler velocimeter.

In this study, we further propose a new visualization technique applying the laser sheet lighting method to the visualized torque converter. By this method, the distribution of separation region along the stator blade span can be observed. Furthermore, using a laser doppler velocimeter, velocity vectors and turbulence intensities can be measured in three stator blades of different thicknesses with the same camber line. Finally, the effect of the thickness of the stator blades on the flow patterns can be measured and analyzed concerning the torque capacity coefficient.

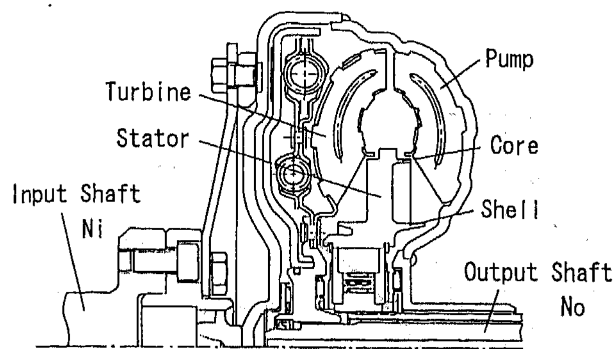

Fig. 1 Torque Converter

VISUALIZED TORQUE CONVERTER FOR OBSERVATION AND MEASUREMENT OF A STATOR FLOW

The construction of an apparatus for visualization of a stator is shown in Fig. 2. A conventional torque converter (shown in Fig. 1) has an input shaft (pump shaft) and an output shaft (turbine shaft) on each side. As shown in Fig. 2, a one-sided coaxial shaft consisting of an input shaft and an output shaft provides an open space inside the stator shaft for measurement. Through an acrylic window on the stator shaft and a mirror in the open space, the stator blades can be directly observed from inside of the stator shaft. With this construction, the whole image of the flow in the stator blade passage along the blade span can be observed. The laser sheet lighting method was applied to locate an observation section across the span. The laser sheet lighting method into the blade passage is shown in Fig. 3. A section of the metallic blade was replaced with an acrylic section with a mirror inside inclined to 45 degrees to the blade span. A laser light sheet was aimed at the mirror inside the stator shaft, and was reflected into the acrylic blade, and then reflected again off the mirror inside the blade. The laser light sheet then entered into the blade passage perpendicular to the span. The location of the reflecting mirror inside the blade determined the observation position of the spanwise direction. The span was divided into quarters and a reflecting mirror is placed at each of the three inside-points. The three blades, each with one mirror inside, can be removed and replaced as an attachment. Small bubbles were used as tracer particles for flow visualization, and were stirred with each rotating element.

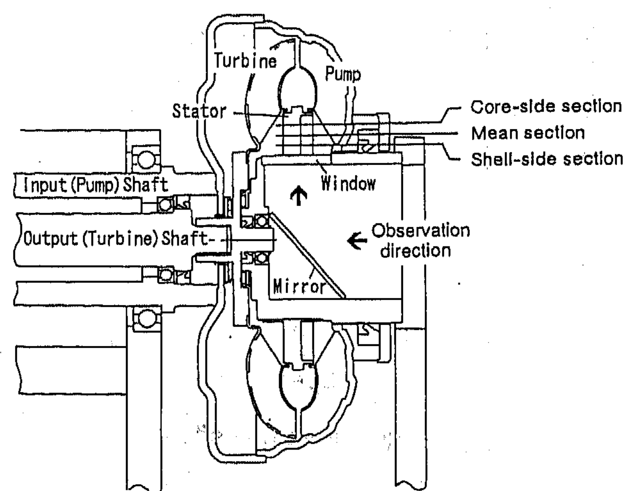

Fig. 2 Visualized torque converter for measurement of stator flow

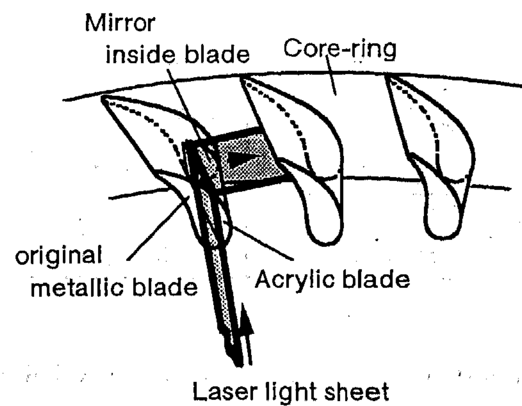

Fig. 3 Laser sheet lighting method

The experimental speed ratio (e=No/Ni; where Ni and No are the input shaft and output shaft speeds, respectively) is limited within the torque conversion range. A motor drives the input and output shafts connected to a continuous variable transmission (Fig. 4). Transparent, low viscous spindle oil was used in place of the red copper colored, high viscous torque converter oil. Experimental conditions are presented in Table 1.

When the scale of the torque converter and the order of the meridional velocity under the operating conditions are considered, the Reynolds number, Re($=uc/\nu$), is about 2×10^4, of which the reference length c is 0.02m, the reference velocity u is 2m/s and the kinematic viscosity ν is about 2.5×10^{-6}m²/s.

TEST STATOR BLADES OF VARIOUS THICKNESS

The test stator blade shape is shown in Fig. 5. The blades had the same camber lines but three different thicknesses. The thin blade was 0.635 times as thick as the thick blade, and the plate blade was 2mm thick. Performance curves for the three torque converters showing efficiencies, torque ratios (output torque/input torque) and torque capacity coefficients (input torque/input speed^2) versus speed ratio are shown in Fig. 6. The torque converter pump, turbine and stator consisted of 31, 29 and 20 blades respectively. The inlet and outlet angles of the stator blade at the mean section were 0° and -49.5° respectively. The torque ratio decreases slightly as the blade thickness decreases. On the other hand, the torque capacity coefficient has characteristic curves according to the blade thickness. Thus we have found that the blade thickness of the stator affects the torque capacity coefficient.

FLOW VISUALIZATION IN THE STATOR BLADE USING LASER SHEET LIGHTING METHOD

Figure 7 shows flow observation photographs using the laser sheet lighting method. This figure shows visualization photographs at the shell-side, mean and core-side sections respectively at a speed ratio of e=0. Observation regions are within the limits of the leading edge area of the blade's suction surface at the location of the reflecting mirror. The separation regions at each section of the span are clearly observed as bright areas.

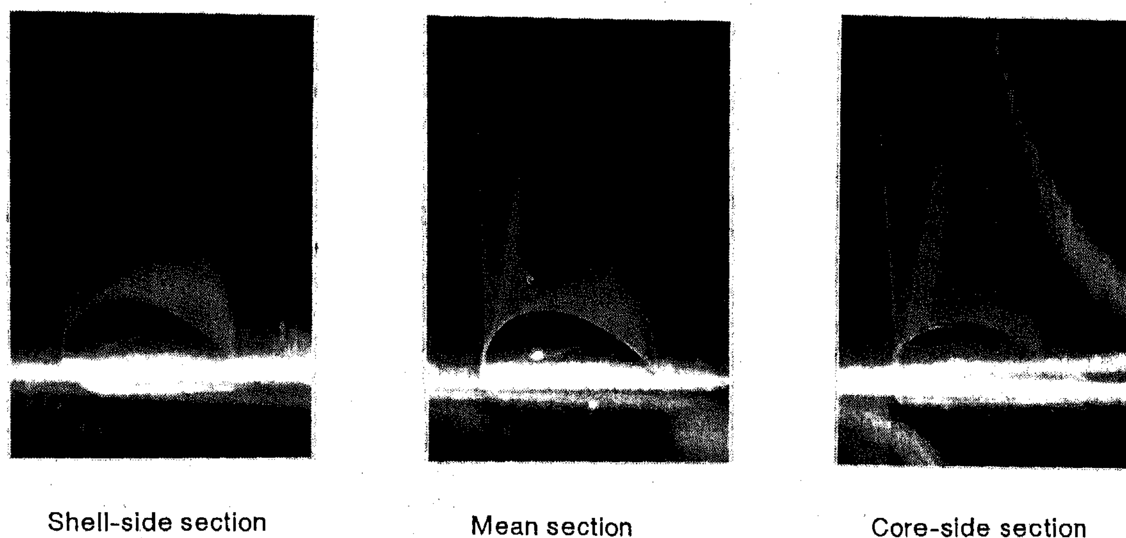

Fig. 7 Photographs using laser sheet lighting method, Thick blade , e=0.2

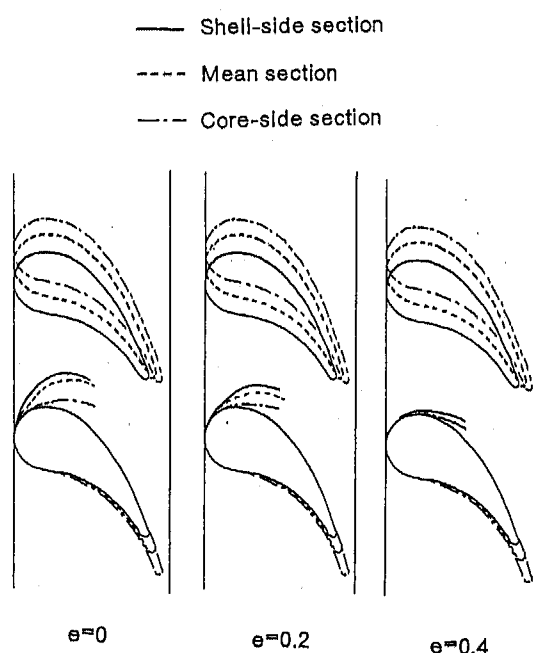

Fig. 8 Spanwise distribution of separation region

Figure 8 shows the separation regions at the shell-side, mean and core-side sections at e=0, 0.2 and 0.4. At e=0 and 0.2, separation regions at the shell-side and mean sections are larger than that of the core-side section. In addition, the area of separation regions decreases as the speed ratio increases. In other words, a large separation region is distributed uniformly from the shell-side to the mean section, as opposed to the small separation region of the core-side section at low speed ratios. The separation region area decreases as the speed ratio increases, and has uniform distribution along the span.

FLOW MEASUREMENT IN THE THREE STATOR BLADES OF DIFFERENT THICKNESS USING LASER DOPPLER VELOCIMETER

MEASUREMENT PROCEDURE - In this section, we quantify the flow in the three kinds of stators using a laser doppler velocimeter (LDV). The LDV system was a one-directional frequency shifted backscatter dual beam LDV (TSI) with a 15mW He-Ne laser. The system had a probe volume of 0.1mm in diameter and 1.4mm in length. The laser and optics mounted on a three-dimensional traversing table were operated by remote control. Flow velocity measurement sections were selected at the shell-side, mean and core-side sections across the span (shown in Fig. 2). Flow vectors were obtained by measuring the velocities of the flow in each direction crossing at right angles at the same points. A cylindrical acrylic window on the stator shaft refracts laser beams which enter toward the blade passages. The refractive angle and the crossing point of the two laser beams change according to the distance between the axis and the measuring point. The angle and crossing position of the intersecting two beams were therefore modified according to this distance. The signal processor was a digital burst correlator. A personal computer calculated the time-averaged velocities and turbulence intensity distributions from a data group of 1024 sampling points. To obtain high quality LDV signals, appropriate particle seeding in the flow must be present. In the present work, small bubbles were used into the flow and were stirred with each rotating element.

DISTRIBUTION OF VELOCITY VECTOR AND TURBULENCE INTENSITY - Figure 9 shows the time-averaged velocity vectors $\overline{U}$ and turbulence intensities σ ($=\sqrt{(\sigma_x^2+\sigma_y^2)/2}$), distribution at e=0.2 measured by LDV, where σ_x and σ_y are the root mean square of velocity fluctuations at right angles. The reason why some data for the core-side measurement are not shown is because of the removal of raw data. Larger refraction angles at the cylindrical acrylic window results in large distances between two intersection points consisting of two laser beams at right angles.

At e=0.2, flow patterns at the shell-side section are similar to those at the mean section as opposed to those at the core-side section for all three blades. In other words, at the shell-side and the mean sections, turbulence intensity becomes large in the region after the leading edge of the suction surface. This region corresponds to the separation region of the thick blade observed by the laser sheet lighting method (shown in Fig. 7). Thus the separation regions can be estimated from the scale of the turbulence intensity. The separation region at the shell-side section is almost the same as that at the mean section for thick and thin blades. But the separation region at the shell-side section of the plate blade is larger than that of the other sections. On the other hand, no separation regions are observed at the core-side section. We concluded that the separation significantly increases the turbulence intensity in the blade passage and diffusion of turbulence, due to the fact that the separation increases the turbulence intensity more at the outlet than at the inlet. The separation on the suction surface affects the outlet flow angle greatly. There are two types of effects. First, in the case of the shell-side section of the thick blade, continuous separation from the leading edge to the trailing edge increases the outlet flow angle compared to the outlet blade angle (considering the sign, positive or negative). Second, in the case of the shell-side section of the plate blade, re-attachment of separation decreases the outlet flow angle compared to the outlet blade angle. From these results, we understood that blade thickness changes the separation and thus affects the flow at the blade and outlet passage. In particular, the flow velocity and the angle at the inlet and outlet passages are important as it pertains to angular momentum change.

FLOW VELOCITY AND ANGLE DISTRIBUTION AT INLET PASSAGE - Figure 10 shows the circumferential (blade pitch direction) distribution of the meridional velocity and the flow angle at the front line on the mean section of the inlet passage. Meridional velocity distributions versus speed ratio change are basically the same for each blade. In other words, the flow is biased to the suction side at e=0 to 0.6, and becomes uniform with the increase of speed ratio, and is slightly biased to the pressure side at e=0.8. At the same speed ratio, however, the incline of the change in meridional velocity decreases in the order of thick, thin and plate blade, as their curves become as their curves flatten. This is because the shapes of the leading edge of the three stator blades affects the inlet flow patterns. The flow angle shows a decrease at e=0 to 0.8. The flow angle curves for the thin blade are similar to those for the plate blade. In the thick blade, there are a few changes versus speed ratio between the central part to the suction side. The influence of the blade thickness at the inlet passage is small as mentioned above.

FLOW VELOCITY AND ANGLE DISTRIBUTION AT OUTLET PASSAGE - Figure 11 shows the circumferential (blade pitch direction) distribution of the meridional velocity and flow angle at an end line on the mean section of the outlet passage. The thick blade has a non-uniform meridional velocity distribution at low to middle speed ratios, and the distribution becomes more uniform in the order of thin, and plate blade. Thick, thin and plate blades have the maximum meridional velocity at e=0.2, 0.4 and 0, respectively. The blade thickness greatly affects the outlet flow angle distribution. In the case of the thick blade, the flow angle changes slightly for each speed ratio, but shows a large increase at e=0.2 and 0.4 at the central part of the outlet passage. We concluded that the increase is caused by the wake at the trailing edge of the blade. The flow angle distributions for the thin and plate blades are more uniform than that for the thick blade. But the thin and plate blades have large flow angle changes compared to the thick blade. Thin and plate blades have the maximum flow angle at e=0.4 and 0.6, respectively. As a result, blade thickness affects the outlet flow. However it is difficult to distinguish the characteristics of blade thickness influence on the outlet flow angle clearly.

SPANWISE DISTRIBUTIONS OF OUTLET FLOW RATE AND ANGLE - Flow rate and flow angle at the outlet end line of the three sections across the span are calculated from the data of a group as shown in Fig. 11. We describe the flow rate at the outlet end line Q'(m^2/s) of three sections by the following expression.

Q'=(average meridional velocity) $\times$ (blade pitch length)

We also define the average outlet flow angle as the angle of a triangle consisting of the average meridional flow velocity component and the average circumferential flow velocity component.

Figure 12 shows the distribution of the flow rate and the average flow angle at the outlet end line for three blades. The flow rate and the average flow angle at the outlet end line for each section show the same tendency versus speed ratio, regardless of the blade shape. In other words, quantity relation of the flow rate is similar to the average flow angle for each blade at a certain speed ratio. The flow rate at each section becomes equal as the speed ratio increases. At the core-side section, flow rate decreases linearly for the speed ratio except at e=0 of the plate blade. In the case of the thick blade, the flow rates at shell-side and mean section are smaller than that at the

core-side section at e=0 and show the maximum at e=0.2 and decreases linearly as the speed ratio increases. In the case of the thin blade, the flow velocity has a non-uniform distribution at the shell-side and mean sections at e=0 and 0.2 and becomes equal for the above e=0.4 at each section. In the case of the plate blade, the flow velocity has a large non-uniform distribution at e=0, 0.2 and 0.4 but becomes equal at e=0.6.

On the other hand, the average flow angle at the core-side section shows the same value for any speed ratio for each blade. The average flow angles at the shell-side and mean sections increase as the speed ratio increases and becomes equal to that of the core-side section. The speed ratio at which the average flow angle becomes the same value are 0.2, 0.4 and 0.6 at thick, thin and plate blades respectively. This characteristic is similar to that of the flow rate. In other words, the characteristics of the flow rate and the average flow angle at each section reveal that, for smaller blade thicknesses, sectional distributions along the blade span at the same speed ratio become more non-uniform and the non-uniformity lasts until a high speed ratio is attained..

(a) Flow rate

(b) Flow angle

Fig. 13 Distributions of outlet flow rate and flow angle in various thickness blades

DISTRIBUTION OF OUTLET FLOW RATE AND ANGLE IN THE VARIOUS THICKNESS BLADES - Meridional flow rate between the core-side section and the shell-side section along the blade span is integrated from the data of Fig. 12 with a trapezoidal rule. Also, from the data of the circumferential flow rate at each section along the span, the circumferential flow rate between the core-side section and the shell-side section along the span is integrated using the same trapezoidal rule. Finally, we define the average outlet flow angle between the core-side section and the shell-side section as the angle of a triangle consisting of meridional and circumferential flow rates.

Figure 13 shows the outlet meridional flow rate and average outlet flow angle between the shell-side and core-side sections for the three kinds of blades. Generally, meridional flow rates decrease as the speed ratio increases for each blade. It was observed that the meridional flow rate characteristics are very similar to those of the torque capacity coefficient as shown in Fig. 6. The condition of the general curves and value size relation of each blade is similar except at e=0.4. On the other hand, the average flow angle has the maximum at middle speed ratios. Also, the average flow angle characteristics are very similar to those in Fig. 6 with regard to the value relation except for the thin blade's angle at low speed ratios. We ascertained experimentally that the outlet flow rate and the average flow angle greatly influence the torque capacity coefficient. In other words, the general characteristics are decided by the outlet flow rate, and then the characteristics are emphasized by the average outlet flow angle.

CONCLUSIONS

This paper describes the blade thickness effects to the flow in the stator by flow visualization and measurement with a new visualized torque converter.

1. The thickness of the stator blade affects the torque capacity coefficient characteristics more than the efficiency and torque ratio characteristics.

2. At low speed ratios, the flow around the leading edge has different separation regions along the blade span.

3. The thickness of the stator blades affects the flow patterns.

4. Both the average meridional flow velocity and average flow angle at the outlet line have non-uniform distributions along the blade span.

5. The thickness of the stator blade affects the outlet flow rate and the average outlet flow angle significantly.

6. The outlet flow rate and the average outlet flow angle show similar characteristics to the torque capacity coefficient.

7. The general characteristics of the torque capacity coefficient are decided by the outlet flow rate, and the characteristics are emphasized by the average outlet flow angle.

ABSTRACT

In 1973, Sauzedde [1] wrote a paper that is commonly considered the benchmark document on roller One-Way Clutch (OWC) analysis and design. Among other topics, Sauzedde led the reader through analyses on contact stress, outer ring hoop stress, and roller centrifugal force computations. Following this seminal paper, several enhancements were presented, further refining the original equations [2] and better describing roller mechanics [3]. At the time these papers were written, the automotive industry in the U.S. predominantly used the English system of measure. The use of English units often obscured the original derivations of constants used in the equations. The purpose of this paper is to present the equations used in roller OWC analysis and design in terms of dimensionless units.

INTRODUCTION

There are two types of the roller One-Way Clutch (OWC) commonly used in the automotive industry. The first has the roller cams located in the outer race, and is referred to as an outer cam design. The second has the roller cams located in the inner race, and is referred to as an inner cam design. Each design has its own advantages and disadvantages, the discussion of which is outside the scope of this paper. However, the analytical techniques developed for one design can easily be applied to the other.

The OWC has two modes of operation: 1. The freewheel mode, and 2. The engaged mode. Each mode has its unique requirements and related analytical techniques. In this paper we will present various techniques commonly used in the design and analysis of the roller OWC.

While in the engaged mode of operation, the OWC transmits a torque from the inner race to the outer race (or *vice-versa*) through the rollers. Significant contact forces are generated at the contact points between the roller and the races. These loads are known as the *strut forces*. Contact stresses and hoop stresses are the primary concerns in the engaged mode of operation. The standard analytical techniques for the computation of these stresses are presented in the CONTACT STRESS and HOOP STRESS Sections.

During the freewheel mode, there is relative motion between the inner and outer races. If the cammed race is spinning, the rollers revolve with it and, with the aid of an energizing spring, stay in contact with the *rollerway*[1] of the other race. The main concerns in this mode of operation are:

1. Wear of the rollers and races,
2. Proper positioning of the roller, and
3. Fatigue of the energizing spring.

Because of the multitude of parameters that influence it, wear is more of an empirical problem. On the other hand, the positioning of the roller and spring fatigue are primarily a function of the roller inertia forces and the spring force, and can be approached analytically. The standard analytical techniques for the prediction of these forces are presented in the ROLLER DYNAMICS Section.

EQUILIBRIUM

The first step in understanding the stresses acting on a roller OWC is to understand the balance of forces and torques acting upon an engaged roller. Figure 1 and Figure 2 show the free body diagram of a roller in an outer cam and inner cam OWC, respectively. As shown, the geometry is slightly different because of the cam location, however, free body analysis is fundamentally the same. The contact force between a roller and the races is on the order of several thousand Newtons. The spring force acting on the roller is generally less than 10 N. Therefore, without loss of accuracy, we can

[1]The rollerway is the smooth cylindrical surface of the non-cammed race that contacts the roller (see Figure 5).

neglect the spring load in our equilibrium analysis. This is the underlying assumption used in the following analysis.

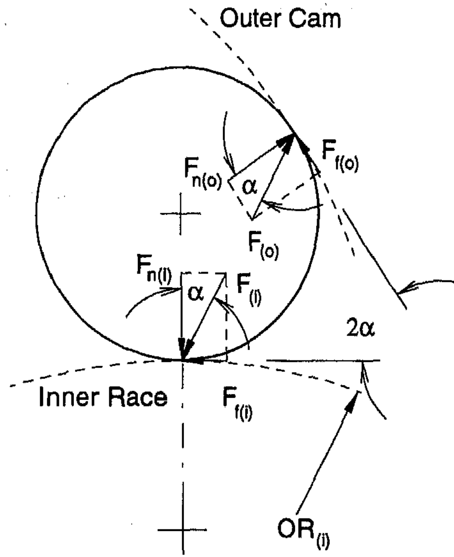

Figure 1: Free body diagram of the roller in an outer cam OWC.

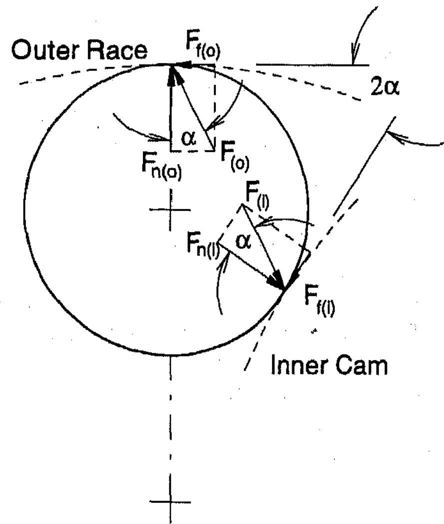

Figure 2: Free body diagram of the roller in an inner cam OWC.

The roller is in equilibrium, and thus the total force acting between the inner race and roller ($F_{(i)}$) is equivalent to the total force acting between the outer race and roller ($F_{(o)}$). That is,

$$F_{(i)} = F_{(o)} \tag{1}$$

The *tangential* force acting between the inner race and roller ($F_{f(i)}$) is a trigonometric function of the total force between the inner race and roller ($F_{(i)}$) and the strut angle (α)

$$F_{f(i)} = F_{(i)} \cdot \sin\alpha \tag{2}$$

The final step in balancing the forces on a roller is to derive the *normal* force ($F_{n(i)}$) acting on the roller.

$$F_{n(i)} = F_{(i)} \cdot \cos\alpha \tag{3}$$

The *total* torque between the inner race and rollers ($T_{(i)}$) for an outer cam roller clutch is the product of the tangential force between the inner race and a roller ($F_{f(i)}$), the moment arm ($OR_{(i)}$), and the number of rollers ($N_{(r)}$).

$$T_{(i)} = F_{f(i)} \cdot OR_{(i)} \cdot N_{(r)} \tag{4}$$

Equation (2) showed that the tangential force between the inner race and a roller ($F_{f(i)}$) is a trigonometric function of the total force between the inner race and a roller ($F_{(i)}$). That is, $F_{f(i)} = F_{(i)} \sin\alpha$, and EQ (4) becomes

$$T_{(i)} = F_{(i)} \cdot \sin\alpha \cdot OR_{(i)} \cdot N_{(r)} \tag{5}$$

Solving EQ (5) for total force per roller ($F_{(i)}$), rather than torque, results in

$$F_{(i)} = \frac{T_{(i)}}{N_{(r)} \cdot OR_{(i)} \cdot \sin\alpha} \tag{6}$$

STRUT ANGLE LIMITS

In the previous section it was demonstrated that the strut forces $F_{(i)}$ and $F_{(o)}$ can be decomposed into their tangential and normal components, as is shown in EQ (2) and EQ (3), respectively. The basic relationship between the tangential and normal forces and the strut angle is obtained by dividing EQ (2) by EQ (3)

$$\frac{F_{f(i)}}{F_{n(i)}} = \frac{F_{(i)} \cdot \sin\alpha}{F_{(i)} \cdot \cos\alpha} = \tan\alpha \tag{7}$$

The tangential force $F_{f(i)}$ is also the frictional force of the system. Its magnitude is dependent on the normal force $F_{n(i)}$ and is limited by the static coefficient of friction μ. That is,

$$F_{f(i)} \le \mu F_{n(i)} \tag{8}$$

Equations (7) and (8) define the same system and, therefore, are interdependent. Substituting EQ (7) into EQ (8), and simplifying, we get

$$\tan\alpha \le \mu \qquad (9)$$

This expression sets the upper limit for the value of the strut angle α.

The coefficient of static friction μ of the clutch environment is not a single-valued variable, but has a range of values. It depends upon factors which can change during the life of the clutch. These factors include:

1. The race and roller surface finish
2. The lubrication fluid composition
3. The lubrication fluid temperature

The value of μ for hardened steel on hardened steel bathed in automatic transmission fluid is generally between 0.080 and 0.120. Using the lower limit of 0.080 as our value for μ, EQ (9) yields a maximum strut angle value of

$$\alpha \le 4.574^{\circ} \qquad (10)$$

During operation of the clutch, the strut angle must never exceed this limit or the rollers may slip when the clutch engages. Dimensional variations during component manufacture, or wear as a result of clutch operation, can cause the strut angle to deviate from the desired value. Therefore, it is prudent to specify a strut angle which is less than the maximum.

Equation (10) defines the upper limit of the strut angle. There are practical limits on the minimum strut angle, also. For example, a strut angle of 1° is feasible; however, the release of the elastic strain energy in the clutch system (when the transmitted torque drops to zero) tends to trap the roller and prevent a smooth disengagement of the clutch. In addition, a greater normal force is required to transmit a given operating torque as the strut angle decreases and this, in turn, increases the contact and hoop stresses generated in the races. Figure 3 exemplifies this relationship, wherein we have plotted the strut component force ratio versus the strut angle.

CONTACT STRESS

Spalling and brinelling are two possible failure modes of a roller OWC. Both are contact stress related. Computation of the contact stress and how it relates to OWC design is discussed in this section.

We assume that the roller OWC has multiple rollers, each carrying an equal portion of the load. Therefore, examining one roller is representative of all rollers within the clutch. The race/roller contact in a roller OWC is either concave/convex, as between the outer race and roller; or convex/convex, as between the inner race and roller. The former is referred to as *conformal* contact, whereas the latter is referred to as *non-conformal* contact. Non-conformal contact loads lead to higher contact stresses, and therefore, we are only concerned with inner race/roller contact stresses. The variables used in the following discussion are defined in Figure 4.

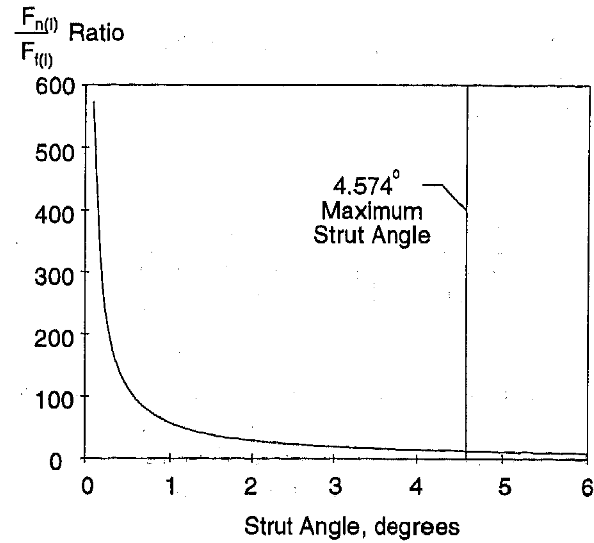

Figure 3: Ratio of the strut force components as a function of strut angle.

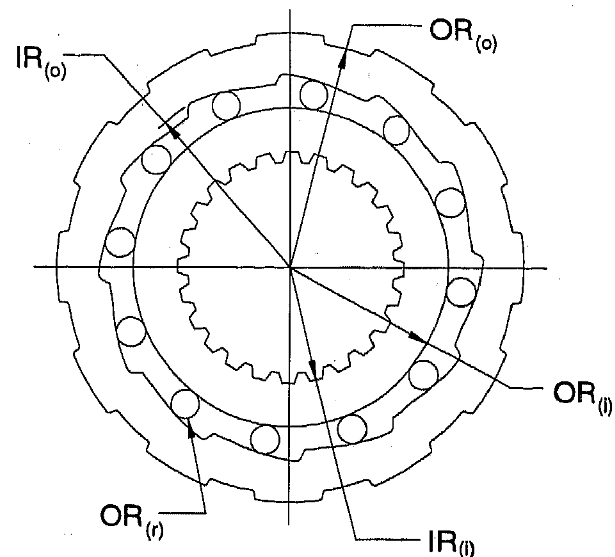

Figure 4: Geometry definition of outer cam roller clutch.

The equation to determine maximum hertz stress ($\sigma_{c(max)}$) between two convex surfaces is defined by Young [4] in terms of the resultant force between the inner race and roller ($F_{(l)}$), outer radius of the inner race ($OR_{(l)}$), roller radius ($OR_{(r)}$), length of the roller ($L_{(r)}$), and material properties of the inner race and roller ($v_{(l)}$, $E_{(l)}$, $v_{(r)}$, $E_{(r)}$):

$$\sigma_{c(max)} = \sqrt{\frac{2\cdot F_{(l)}\cdot\left(\frac{1}{OR_{(l)}}+\frac{1}{OR_{(r)}}\right)}{\pi\cdot L_{(r)}\cdot 4\cdot\left(\frac{(1-\upsilon_{(l)}^2)}{E_{(l)}}+\frac{(1-\upsilon_{(r)}^2)}{E_{(r)}}\right)}} \qquad (11)$$

A commonly used derivation of EQ (11) defines hertz stress in terms of its mean value ($\sigma_{c(mean)}$), rather than maximum value [5,6]:

$$\sigma_{c(mean)} = \frac{1}{2}\cdot\sqrt{\frac{F_{(i)}\cdot\pi\cdot\left(\frac{1}{OR_{(i)}}+\frac{1}{OR_{(r)}}\right)}{L_{(r)}\cdot 4\cdot\left(\frac{(1-\upsilon_{(i)}^2)}{E_{(i)}}+\frac{(1-\upsilon_{(r)}^2)}{E_{(r)}}\right)}} \qquad (12)$$

We use the equation for mean contact stress to derive an additional term for the total force per roller ($F_{(i)}$). The constants and material properties from EQ (12) (π, $v_{(i)}$, $v_{(r)}$, $E_{(i)}$, $E_{(r)}$) are brought outside the radical and named c_1:

$$c_1 = \frac{1}{2}\cdot\sqrt{\frac{\pi}{\left(\frac{4(1-\upsilon_{(i)}^2)}{E_{(i)}}+\frac{4(1-\upsilon_{(r)}^2)}{E_{(r)}}\right)}} \qquad (13)$$

Then, EQ (12) simplifies to:

$$\sigma_{c(mean)} = c_1\cdot\sqrt{\frac{F_{(i)}\cdot\left(\frac{1}{OR_{(i)}}+\frac{1}{OR_{(r)}}\right)}{L_{(r)}}} \qquad (14)$$

Solving EQ (14) in terms of total force per roller ($F_{(i)}$) results in the following equation:

$$F_{(i)} = \frac{L_{(r)}\cdot\left(\frac{\sigma_{c(mean)}}{c_1}\right)^2}{\frac{1}{OR_{(r)}}+\frac{1}{OR_{(i)}}} \qquad (15)$$

For an outer cam roller clutch, we now have two equations (EQ (6) and EQ (15)) that solve for total force per roller ($F_{(i)}$). We set EQ (6) equal to EQ (15) and obtain the following:

$$\frac{T_{(i)}}{N_{(r)}\cdot OR_{(i)}\cdot\sin\alpha} = \frac{L_{(r)}\cdot\left(\frac{\sigma_{c(mean)}}{c_1}\right)^2}{\frac{1}{OR_{(r)}}+\frac{1}{OR_{(i)}}} \qquad (16)$$

In a realistic design of an outer cam roller clutch, we want to determine the optimal inner race outer radius ($OR_{(i)}$) given material property and loading characteristics. That is, EQ (16) is solved in terms of the inner race outer radius ($OR_{(i)}$). Equation (16) does not have a simple solution for the inner race outer radius ($OR_{(i)}$), however, it is a quadratic equation in the following form:

$$0=\left(OR_{(r)}\cdot N_{(r)}\cdot\sin\alpha\cdot L_{(r)}\cdot\left(\frac{\sigma_{c(mean)}}{c_1}\right)^2\right)\cdot OR_{(i)}^2 + \left(-T_{(i)}\right)\cdot OR_{(i)} + \left(-T_{(i)}\cdot OR_{(r)}\right) \qquad (17)$$

and the quadratic equation that solves for the inner race outer radius ($OR_{(i)}$) is:

$$OR_{(i)} = \frac{T_{(i)} \pm \sqrt{T_{(i)}^2 - 4\cdot\left(OR_{(r)}\cdot N_{(r)}\cdot\sin\alpha\cdot L_{(r)}\cdot\left(\frac{\sigma_{c(mean)}}{c_1}\right)^2\right)\cdot\left(-T_{(i)}\cdot OR_{(r)}\right)}}{2\cdot\left(OR_{(r)}\cdot N_{(r)}\cdot\sin\alpha\cdot L_{(r)}\cdot\left(\frac{\sigma_{c(mean)}}{c_1}\right)^2\right)} \qquad (18)$$

That is, given load, material property, and roller parameters, EQ (18) calculates the outer radius of the inner race for an outer cam roller clutch.

To use EQ (18), we must select an operating contact stress at which the roller OWC will operate. Application history has shown that limiting the mean contact stress to 3.79 GPa (550,000 psi) is reasonable for roller OWC applications. Equation (18) yields two real roots, one negative and one positive. The negative root is meaningless when discussing magnitudes of length, and therefore only the positive root is considered.

HOOP STRESS

Contact forces between the rollers and races create a circumferential (*hoop*) stress in the outer and inner races. The hoop stress on the inner race is compressive, and steel does not typically fatigue due to compressive stresses. However, the outer race experiences tensile hoop stresses, which is a typical mode of fatigue failure for steel. Therefore, we consider hoop stress for the outer race only.

The discrete nature of the contact forces also creates bending stresses. If the number of rollers is very low, then the bending has a significant contribution to the circumferential stress. However, if the number of rollers is relatively large (>8), then the circumferential stresses in the outer race are predominantly hoop stresses. Therefore, in the discussion below, we assume the number of rollers is greater than eight and use the average hoop stress equation.

The governing equation for the mean hoop stress in the outer race ($\sigma_{h\,(mean)}$), as defined by thick cylinder analysis, is a function of the pressure on the interior surface of the outer race ($Q_{(o)}$), and the wall thickness of the outer race ($OR_{(o)}$ and $IR_{(o)}$) [7,8]:

$$\sigma_{h(mean)} = Q_{(o)}\cdot\left(\frac{OR_{(o)}^2+IR_{(o)}^2}{OR_{(o)}^2-IR_{(o)}^2}\right) \qquad (19)$$

The pressure on the inner surface of the outer race ($Q_{(o)}$) of an outer cam roller clutch is a function of the radial force per roller ($F_{(o)} \cdot \cos\alpha$), the number of rollers ($N_{(r)}$), and the total inner surface area of the outer race ($2 \cdot \pi \cdot r \cdot l = 2 \cdot \pi \cdot IR_{(o)} \cdot L_{(o)}$).

$$Q_{(o)} = F_{(o)} \cdot \left(\frac{N_{(r)} \cdot \cos\alpha}{2 \cdot \pi \cdot IR_{(o)} \cdot L_{(o)}} \right) \quad (20)$$

If we assume that the length of the roller is equal to the length of the outer race ($L_{(r)} = L_{(o)}$), and substitute EQs (1), (15), and (20) into EQ (19), then the following equation is derived for the mean hoop stress ($\sigma_{h(mean)}$) in the outer race:

$$\sigma_{h(mean)} = \left(\frac{\sigma_{c(mean)}}{c_1} \right)^2 \cdot \left(\frac{OR_{(r)} \cdot OR_{(i)} \cdot N_{(r)} \cdot \cos\alpha}{\left(OR_{(r)} + OR_{(i)}\right) \cdot 2 \cdot \pi \cdot IR_{(o)}} \right) \cdot \left(\frac{OR_{(o)}^2 + IR_{(o)}^2}{OR_{(o)}^2 - IR_{(o)}^2} \right) \quad (21)$$

However, we want to *assume* the average hoop stress ($\sigma_{h(mean)}$) that the outer race will encounter, and calculate the outer radius accordingly ($OR_{(o)}$). Note that the inner radius of the outer race ($IR_{(o)}$) is determined based upon the geometry of the inner race calculated earlier via EQ (18) and the geometry of the rollers.

Therefore, EQ (21) is put in terms of the outer radius of the outer race, where the pressure on the interior surface of the outer race ($Q_{(o)}$) was previously defined in EQ (20).

$$OR_{(o)} = \sqrt{\frac{Q_{(o)} \cdot IR_{(o)}^2 + \sigma_{h(mean)} \cdot IR_{(o)}^2}{\sigma_{h(mean)} - Q_{(o)}}} \quad (22)$$

ROLLER DYNAMICS

Roller float is defined as a condition wherein the roller loses contact with the rollerway. In certain applications (e.g. in the torque converter) this is a design objective of the OWC engineer. However, in most applications roller float is deleterious to the operation of the clutch, as will be explained later.

There are two conditions that may cause roller float. The first occurs in clutches of outer cam design and happens when the clutch and outer race are spinning. The centrifugal force acting on the roller as a result of this rotary motion "pulls" the roller away from the center of rotation and, hence, away from the rollerway. We refer to this condition as *centrifugal roller float*. In applications where the inner race is grounded, such as in the torque converter, this type of roller float is advantageous in that the roller/inner race contact is lost, thereby reducing wear and spin losses. If, however, the clutch must be "engagement ready" with the outer race spinning, this type of roller float is detrimental because the clutch cannot engage unless there is contact between the rollers and the inner race.

The second type of roller float can occur in clutches of either outer or inner cam design, and is called *eccentricity roller float*. This type of roller float is the result of a rollerway that has a finite eccentricity (or runout) with respect to the cammed race. As one race rotates with respect to the other, the roller will travel "up" and "down" the cam surface while tracking the rollerway. If the over-running speed is great enough and the eccentricity large enough, the race will "throw" the roller off of the rollerway.

During the operation of a roller OWC, either of these conditions can occur. In some cases, the inertia forces that lead to these float conditions can occur simultaneously. Should this happen, the effects are additive. Hence, each condition will be addressed separately in the following sections.

CENTRIFUGAL ROLLER FLOAT - In certain applications, the outer race of a roller OWC freewheels about its axis. If the clutch is an outer cam design, then the rollers of the clutch will revolve with the outer race. As a result of this motion, the roller must accelerate towards the center of rotation to maintain its position relative to the outer race. This is known as *centripetal acceleration* and, by Newton's second law, the force needed to create this acceleration is

$$P_{cen} = m_{(r)} a = m_{(r)} c\, \omega_{(o)}^2 \quad (23)$$

where P_{cen} is the roller centrifugal force, $m_{(r)}$ is the mass of the roller, a is the acceleration of the roller, c is the distance from the center of the clutch to the center of the roller, and $\omega_{(o)}$ is the angular velocity of the outer race. The resulting system of forces is shown in Figure 5.

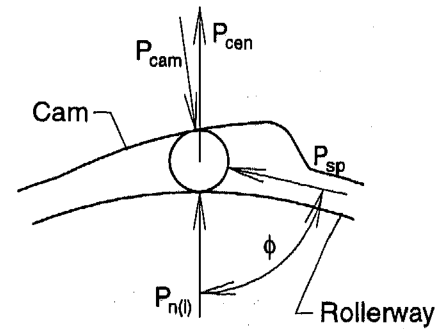

Figure 5: Forces acting on the roller for the centrifugal roller float analysis.

There exists an outer race speed above which the centrifugal roller force P_{cen} overcomes the spring force P_{sp} and the roller loses contact with the inner race. This condition is called *centrifugal roller float*. As $P_{n(I)}$ reaches zero, we

have a condition of equilibrium in which the roller is acted upon by three forces: P_{sp}, P_{cen}, and P_{cam}. Utilizing a force triangle for this condition (Figure 6), the spring force can be derived using the law of sine's

$$P_{sp} = P_{cen}\frac{\sin(2\alpha)}{\sin(\phi-2\alpha)} = m_{(r)} c\,\omega_{(o)}^2 \frac{\sin(2\alpha)}{\sin(\phi-2\alpha)} \qquad (24)$$

where ϕ is the angle between the line of action of the centrifugal force P_{cen} and the spring force P_{sp}. Equation (24) is used to compute the spring force required to allow centrifugal roller float for a given clutch and outer race speed. Alternatively, we may re-arrange EQ (24) to obtain the roller float speed for a given spring load (EQ (25)).

$$\omega_{(o)} = \sqrt{\frac{P_{sp}}{c\,m_{(r)}}\frac{\sin(\phi-2\alpha)}{\sin(2\alpha)}} \qquad (25)$$

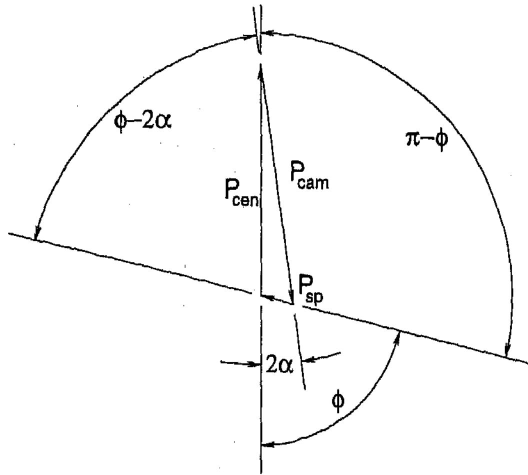

Figure 6: Force triangle for the centrifugal roller float analysis.

Another variation of this analysis (which actually is unrelated to roller float) is to develop a force triangle for the condition where the outer race is stationary, i.e. $\omega_{(o)}=0$. Performing this analysis, we obtain

$$P_{n(i)} = \frac{P_{sp}}{\tan 2\alpha} \qquad (26)$$

Using EQ (26) we obtain the nominal contact force between the roller and the rollerway as a function of the nominal spring force.

ECCENTRICITY ROLLER FLOAT - The function of the energizing spring is to position the roller for proper clutch operation. In the following analysis, proper operation is defined as maintaining contact between the roller and the rollerway during the freewheel mode of operation. In the event that the rollerway has a finite runout with respect to the cammed race, the roller will travel up and down the cam surface with each rotation of the rollerway. The energizing spring will compress and extend with each rotation, keeping the roller and rollerway in contact. This condition is illustrated in Figure 7, wherein the geometry of an outer cam OWC system has been utilized. We will be examining the outer cam OWC in this section; however, the following analysis can also be applied to a clutch having an inner cam configuration.

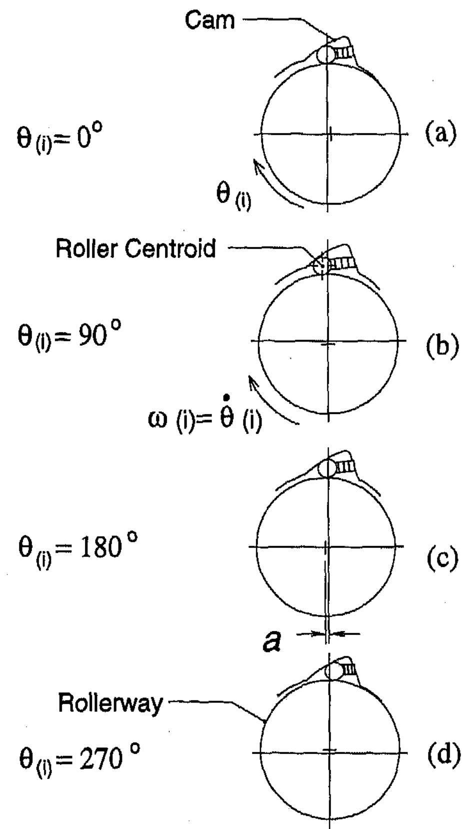

Figure 7: Roller motion due to rollerway eccentricity.

As the rotational speed of the rollerway increases, the translational inertia of the roller starts to play a significant role in the functioning of the clutch system. If the rotational speed is great enough and the eccentricity of the rollerway large enough, the roller inertia force will overcome the energizing spring force and the roller will lose contact with the rollerway. We call this condition *eccentricity roller float.* This condition is illustrated in Figure 7d, where the clutch is shown at an orientation of $\theta_{(i)} = 270°$. Elevated levels of spring compression may result from this condition, which could possibly lead to spring fatigue.

Using the method of kinematic equivalence [9], the dynamics of the roller can be examined using the analysis methods established for the four-bar mechanism [10]. A synopsis of this analysis is presented in this section, and the reader is directed to Reference [11] for a detailed discussion.

In Figure 8 the schematic of the clutch in the 0° orientation is shown. The eccentricity of the system has been exaggerated to help emphasize the definition of some of the parameters listed in the figure. It is our objective to define the position, velocity, and acceleration of point $C_{(r)}$, the centroid of the roller. To facilitate this, a number of derived dimensions are needed, and are listed below without further elaboration.

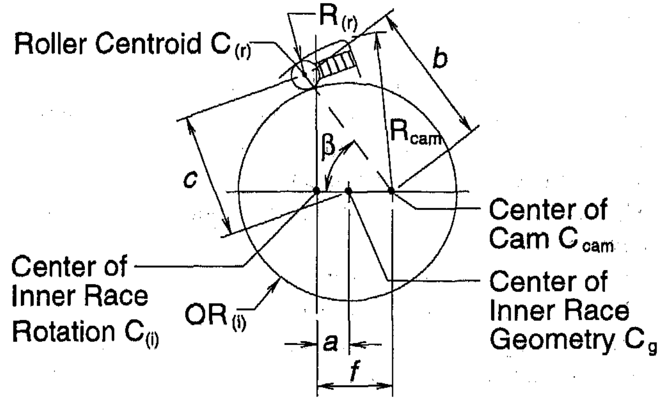

Figure 8: Definition of the *eccentricity* roller float analysis variables.

$$b = R_{cam} - R_{(r)} \qquad (27)$$

$$c = OR_{(i)} + R_{(r)} \qquad (28)$$

$$d = \sqrt{a^2 + f^2 - 2\,a\,f\cos\theta_{(i)}} \qquad (29)$$

$$\delta = \arctan\left(\frac{a\sin\theta_{(i)}}{f - a\cos\theta_{(i)}}\right) \qquad (30)$$

$$\lambda = \arccos\left(\frac{d^2 + b^2 - c^2}{2\,b\,d}\right) \qquad (31)$$

$$\beta = \delta + \lambda \qquad (32)$$

$$\gamma = \arctan\left(\frac{b\sin\beta - a\sin\theta_{(i)}}{f - b\cos\beta - a\cos\theta_{(i)}}\right) \qquad (33)$$

Note that, in the above equations, the parameter a is the eccentric offset of the geometric center C_g of the inner race from the rotational center $C_{(i)}$. The parameter β is the angular coordinate of the roller centroid with respect to the center of curvature of the cam C_{cam}. Taking the derivative of EQ (32) and EQ (33) with respect to time, we obtain the angular velocities $\dot{\beta}$ and $\dot{\gamma}$, which are given as

$$\dot{\beta} = \frac{a\,\sin(\gamma - \theta_i)}{b\,\sin(\gamma + \beta)}\dot{\theta}_{(i)} = k_\beta \dot{\theta}_{(i)} \qquad (34)$$

and

$$\dot{\gamma} = \frac{-a\,\sin(\beta + \theta_i)}{c\,\sin(\gamma + \beta)}\dot{\theta}_{(i)} = k_\gamma \dot{\theta}_{(i)} \qquad (35)$$

respectively. Therein, $\dot{\theta}_{(i)}$ is the angular velocity of the rollerway (which is also listed in this paper as $\omega_{(i)}$), and $\dot{\beta}$ is the angular velocity of the roller about the center of curvature of the cam. Note that in EQ (34) and EQ (35) we have implicitly defined the coefficients k_β and k_γ.

Taking the derivative of EQ (34) with respect to time, the angular acceleration of the roller about C_{cam} is obtained

$$\ddot{\beta} = k_\beta \ddot{\theta}_{(i)} + k'_\beta \dot{\theta}^2_{(i)} \qquad (36)$$

where the coefficient k'_β is defined as

$$k'_\beta = k_\beta\left[\left(k_\gamma - 1\right)\cot\left(\gamma - \theta_{(i)}\right) - \left(k_\gamma + k_\beta\right)\cot(\gamma + \beta)\right] \qquad (37)$$

A study of the relative magnitude of each of the two components on the right hand side of EQ (36) has shown that the term $k_\beta \ddot{\theta}_{(i)}$ is insignificant when compared to $k'_\beta \dot{\theta}^2_{(i)}$, especially at the critical orientation of $\theta_{(i)} = 270°$ [11]. Hence, with little loss of accuracy, the angular acceleration of the roller $\ddot{\beta}$ can be approximated by $k'_\beta \dot{\theta}^2_{(i)}$. The tangential component of the roller inertia force is then given as

$$P_{t(r)} = m_{(r)} b \ddot{\beta} = m_{(r)} b\, k'_\beta \dot{\theta}^2_{(i)} \qquad (38)$$

Equation (38) yields the eccentricity roller float force, $P_{t(r)}$. We may say that $P_{t(r)}$ is the force which we must supply to the roller for it to remain in contact with the inner race roller-way. This force is supplied via the energizing spring.

Another component of the roller inertia force is due to the angular velocity of the roller about the center of curvature of the cam. This force is given as

$$P_{n(r)} = m_{(r)} b \dot{\beta}^2 = m_{(r)} b\, k^2_\beta \dot{\theta}^2_{(i)} \qquad (39)$$

Equation (39) defines the contact force between the roller and the cam surface. The forces acting on the roller are depicted in Figure 9.

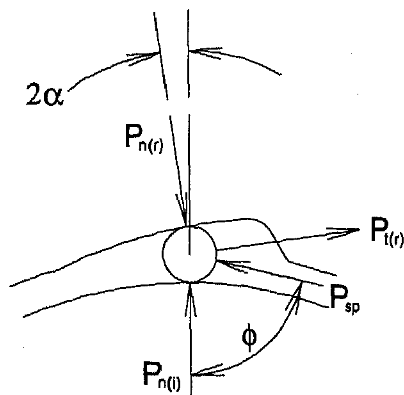

Figure 9: Forces acting on the roller for the eccentricity roller float analysis.

In the event of roller float, $P_{n(i)}$ is equal to zero. As with the previous analysis, we can build a force triangle (see Figure 10) from the remaining loads. Applying the law of sine's to the force triangle, then substituting EQ (38) and re-arranging, we obtain the rollerway speed at which *eccentricity roller float* will occur for a specified spring force

$$\dot{\theta}_{(i)} = \sqrt{\frac{P_{sp}\sin(\phi - 2\alpha)}{m_{(r)} b\, k'_\beta}} = \omega_{(i)} \qquad (40)$$

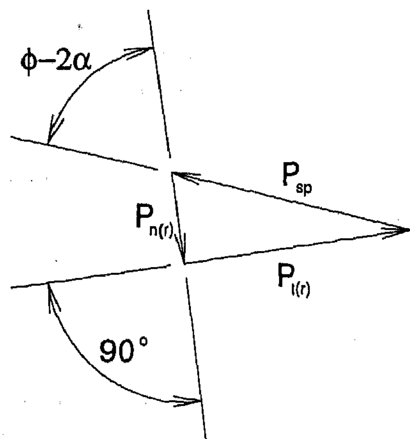

Figure 10: Forces triangle for the eccentricity roller float analysis.

As you may note from Figure 9 and Figure 10, we are neglecting the frictional forces which act between the roller and the spring, outer race, and inner race. It can be shown that by ignoring the frictional forces we compute a more conservative roller float speed.

As an alternative analysis, we can re-write EQ (40) to give us the spring force required to prevent *eccentricity roller float* for a given clutch and inner race overrunning speed. This is given as

$$P_{sp} = \frac{m_{(r)} b k'_\beta \omega_{(i)}^2}{\sin(\phi - 2\alpha)} \qquad (41)$$

wherein we have substituted $\omega_{(i)} = \dot{\theta}_{(i)}$. With the spring force obtained via EQ (41), the OWC engineer can compute the stress level in the selected energizing spring. This, in turn, can be compared to the endurance limit of the selected spring material to evaluate the spring fatigue life for the application.

SUMMARY

This paper described the static (engaged) and dynamic (freewheel) behavior of an outer cam roller one-way clutch. Explicitly derived were equations for:

- The free body forces acting on a roller,
- The limit to the strut angle based upon the operating environment,
- The contact stress on the inner race,
- The hoop stress on the outer race,
- The centrifugal roller float speed, in which the roller loses contact with the inner race due to outer race rotational speed, and
- The eccentricity roller float force, in which the roller loses contact with the inner race due to the lack of concentricity.

Although the equations were derived for outer cam roller clutches, they can easily be derived for inner cam roller clutches.

The objective of the paper was to re-derive the fundamental equations used by engineers and designers when designing roller one-way clutches. The derivation of the equations enable an engineer to better understand the mechanics of a one-way clutch. The equations are derived in terms of dimensionless units, and free the engineer from the implied constraints of using either metric or English units, exclusively.

APPENDIX A: RACE DESIGN

This section contains an annotated example of a typical design sequence of a roller clutch. The discussion shows the practical application of the earlier described equations that answers:

Given the following load and materials, is it possible to construct an outer cam roller clutch in the size indicated by the packaging constraints?

A. Inputs

Cam Type:	Outer Cam
Packaging Constraints:	
Minimum Effective Radius ($IR_{(min)}$)	30 mm
Maximum Effective Radius ($OR_{(max)}$)	60 mm
Maximum Length ($L_{(max)}$)	12 mm
Materials:	
Outer Cam	1020 Steel
Inner Race	1020 Steel
Rollers	1020 Steel
Torque:	800 N-m

B. Approach

1. Set the effective inner radius of the inner race ($IR_{(i)}$) equal to the minimum effective radius ($IR_{(min)}$). That is, we are using the packaging constraint for the minimum radius as the smallest possible dimension that the roller clutch may have.

2. Calculate the outer radius of the inner race ($OR_{(i)}$) based upon the equation derived for contact stress (EQ (18)).

3. Determine the effective inner radius of the outer race ($IR_{(o)}$) based upon the outer radius of the inner race ($OR_{(i)}$), roller radius ($OR_{(r)}$), and strut angle (α).

4. Calculate the effective outer radius of the outer race ($OR_{(o)}$) based upon the equation derived for hoop stress (EQ (22)).

5. Compare the effective outer radius of the outer race ($OR_{(o)}$) with the maximum effective radius ($OR_{(max)}$). If the packaging constraint ($OR_{(max)}$) is less than the calculated radius ($OR_{(o)}$), then a roller clutch with the given materials and load requirements cannot be constructed in the given packaging constraints.

C. Calculations

The initial goal of the calculations is to determine the outer radius of the inner race ($OR_{(i)}$) using EQ (18). The calculation of $OR_{(i)}$ is dependent upon c_1 (EQ (13)). The inner race and rollers are both 1020 steel, and therefore the material properties are [12]:

$\upsilon_{(i)}$	0.29
$E_{(i)}$	2.07E11 Pa (30E6 psi)
$\upsilon_{(r)}$	0.29
$E_{(r)}$	2.07E11 Pa (30E6 psi)

and c_1 is calculated as 1.489E5.

The outer radius of the inner race ($OR_{(i)}$) is calculated using c_1 and some additional inputs. Specifically, the inputs that are required are the torque ($T_{(i)}$), default values for the rollers ($N_{(r)}$, $L_{(r)}$, $OR_{(r)}$), the strut angle (α), and the mean contact stress for the inner race ($\sigma_{c(mean)}$). The values are as follows:

$T_{(i)}$	800 N-m (590.05 ft-lbs)	(input)
$N_{(r)}$	12	(default)
$L_{(r)}$	0.012 m (12 mm)	(default)
$OR_{(r)}$	0.004 m (4 mm)	(default)
α	0.0698 rad (4°)	(default)
$\sigma_{c(mean)}$	3.79E9 Pa (550,000 psi)	(empirical limit)

Substituting the above values into EQ (18) results in the outer radius of the inner race ($OR_{(i)}$) equaling 0.03409 m (34.09 mm). Based upon the geometry of the inner race and

rollers, the effective inner radius of the outer race ($IR_{(o)}$) is 0.043023 m (43.023 mm).

The next step is to solve for the effective outer radius of the outer race ($OR_{(o)}$) using EQ (22). However, prior to solving for $OR_{(o)}$, the pressure on the inner surface of the outer cam ($Q_{(o)}$) is required and is calculated using EQ (20). We use the following values:

$N_{(r)}$	12	(default)
$L_{(r)}$	0.012 m (12 mm)	(default)
$OR_{(r)}$	0.004 m (4 mm)	(default)
$\sigma_{c(mean)}$	3.79E9 Pa (550,000 psi)	(empirical limit)
c_1	1.489E5	(EQ (13))
$OR_{(i)}$	0.03409 m (34.09 mm)	(EQ (18))
$IR_{(o)}$	0.04302 m (43.02 mm)	
$L_{(o)}$	0.01200 m (12 mm)	(input)

These values are used to determine the pressure on the inner surface of the outer race ($Q_{(o)}$ = 1.0346E8 N/m^2).

Finally, we assume that the endurance limit for the outer race material is 4.48E8 Pascal (65,000 psi), and set the mean hoop stress of the outer cam ($\sigma_{h\ (mean)}$) to this value. Then we substitute the pressure on the inner surface of the outer cam ($Q_{(o)}$) into EQ (22), and obtain the effective outer radius of the outer race ($OR_{(o)}$ = 0.05443 m = 54.43 mm).

The conclusion from this section is that it is possible to design an outer cam roller clutch that meets the input requirements and has the following dimensions:

$OR_{(r)}$	4.00 mm
$IR_{(i)}$	30.00 mm
$OR_{(i)}$	34.09 mm
$IR_{(o)}$	43.02 mm
$OR_{(o)}$	54.44 mm

and withstands a 3.79E9 Pascal (550,000 psi) mean contact stress on the inner race and a 4.48E8 Pascal (65,000 psi) mean hoop stress on the outer race. Note that the original maximum effective radius ($OR_{(max)}$) defined in INPUTS was 60 mm. Therefore, since the calculated outer radius of the outer race ($OR_{(o)}$ = 54.43 mm) is less than the allowed outer radius of the outer race ($OR_{(max)}$ = 60 mm), then there is additional space that is usable to increase the safety factor for the one-way clutch.

APPENDIX B: DYNAMIC ANALYSIS

In this appendix we will explore the dynamics of the hypothetical clutch design in the previous section. To enable us to do this, we will assume a duty cycle for the clutch, create an energizing spring specification, and finalize the outstanding cam design parameters. In Table 1 the hypothetical operating conditions for our clutch are given, and in Table 2 we have the cam and energizing spring design parameters. Note that the cam data presented in Table 2 was computed given the data developed in Appendix A. These computations, however, are outside the scope of this paper.

Table 1: Duty Cycle for the Hypothetical Roller Clutch

Gear	Race Speed (rpm)			Torque (N-m)
	Inner	Outer	Overrun	
R	-4800	-4800	0	0
1	0	0	0	800
2	0	0	0	250
3	4000	0	4000	0
4	8800	0	8800	0

Table 2: Assumed Cam and Spring Design Parameters

Parameter	Variable	Value
Roller, Rollerway and Cam Data:		
Roller Mass Density	$\rho_{(r)}$	7800 kg/m^3
Critical Rollerway Orientation	$\theta_{(i)}$	270°
Cam Radius	R_{cam}	42.464 mm
Cam Offset	f	5.353 mm
Rollerway Eccentricity	a	0.051 mm
Spring Data:		
Free Height	H_f	13.72 mm
Nominal Working Height	H_w	9.53 mm
Spring Rate	k	0.3 N/mm
Nominal Spring Force	P_{sp_nom}	1.47 N
Spring Orientation	ϕ	85°

From Table 1 we see that the maximum overrunning speed for the clutch occurs in fourth gear, and is 8800 rpm. This occurs with the outer race grounded. These are the conditions for which we will evaluate the clutch for *eccentricity roller float.*

In reverse we see that both races are rotating, but no torque is being transmitted. From this we can deduce that the inner race is driving the outer race, and is working against outer race inertia and friction clutch drag alone. To function properly in this environment our roller clutch must remain engaged while in reverse gear, or else the clutch will disengage due to *centrifugal roller float* forces. This would be followed by an impact re-engagement when the outer race and clutch slow down due to friction clutch drag. Such a sequence of events would lead to degradation and possibly failure of the OWC.

Applying the clutch data given above to the equations provided in the ROLLER DYNAMICS Section, we obtain the computed data given in Table 3. Note that in applying these equations, we must use consistent units. For example, when using the SI system, *meters* (instead of millimeters) should be used throughout. Also, angular coordinates must be entered in *radians* and angular velocities in *radians per second,* regardless of the measurement system employed. These

conversions have been done for the reader in this example problem.

Table 3: Intermediate Computational Results for Roller Dynamic Analysis

Variable	Equation No.	Value
$m_{(r)}$		0.0047 kg
b	27	0.0385 m
c	28	0.0381 m
d	29	0.0054 m
δ	30	-0.0094 rad
λ	31	1.4312 rad
γ	33	-1.5613 rad
$\dot{\gamma}$	35	1.3119 rad/sec
β	32	1.4217 rad
$\dot{\beta}$	34	-0.0829 rad/sec
$\ddot{\beta}$	36	8046 rad/sec^2
k_γ	35	1.424 E-3
k_β	34	-8.996 E-5
k'_β	37	9.474 E-3

In applying the results of Table 3 to the analysis of *eccentricity roller float*, we find that we can either assume that the spring force remains constant during the cycle depicted in Figure 7, or we can compute the change in the spring force (i.e. due to the kinematic roller travel) as the clutch progresses from configuration (c) to configuration (d) in Figure 7. Doing the latter, we define the roller travel as

$$H_\delta = b \cdot \left(\beta|_{\theta=270} - \beta|_{\theta=180} \right) \qquad (42)$$

where H_δ is the change in the spring height and, for example, $\beta|_{\theta=270}$ is the value of β when $\theta_{(I)}$ equals 270°. For our hypothetical clutch, the roller travel (and, hence, the additional spring compression) is computed to be 0.365 mm. This translates to an increase in spring load of 0.13 N. Therefore, the spring force P_{sp} that we use in EQ (40) is 1.60 N. (Note that if we assume that the spring force is constant, we will be inducing a "conservative" error of 8.8% into our computations for *this* example application.) Applying EQ (40) we find that the *eccentricity roller float* speed is 952 radians per second (9090 rpm). From these results we conclude that our clutch will operate with a very small margin of safety in the freewheel mode of operation.

When the transmission is in reverse, we must apply our *centrifugal roller float* analysis. Applying the results of Table 3 to the equations of that section, we note that we must use the nominal spring force in EQ (25). The result of this exercise is a computed centrifugal roller float speed of 239 radians per second (2286 rpm). This is significantly less than the 4800 rpm required by the application. Hence, we must conclude that our hypothetical energizing spring is inadequate in maintaining the clutch in an *engagement ready* state, and that we must go back and redesign the spring-roller system.

A Study of Forces Acting on Rings for Metal Pushing V-Belt Type CVT

Hideaki Yoshida
Honda R&D Co., Ltd.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Four forces act in rings for a metal pushing V-belt. These forces are: two kinds of intercepting forces which prevent blocks from going outside of pulleys (one caused by pulley thrust, the other caused by centrifugal force), frictional force acting between the rings and the blocks, and bending force in longitudinal direction.

In the previous paper [1] [2] [3] [5], distribution of three forces, excluding centrifugal force, were presented at low belt speed. We successfully measured all four kinds of forces including centrifugal force continuously at practical operation conditions for layered rings. In this paper, distribution of these four forces on the innermost ring is described at steady states.

INTRODUCTION

A metal pushing V-belt (in short, metal V-belt) which is used in Continuously Variable Transmission (CVT), is composed of steel rings and blocks. Fig.1 shows the structure of the metal V-belt assembly. Various forces act on these rings. To grasp forces acting on rings is very important for argument of a metal V-belt's durability. It has been shown experimentally that the durability of a metal V-belt depends on belt speed. To grasp forces acting on rings, including centrifugal force, at high belt speed is very important for design of transmission. Although there have been some papers on the study of forces acting on rings recently, it has not been shown what the distribution of forces is acting on rings at high belt speed. The purpose of this study is to reveal the effect on the metal V-belt's life by measuring the distributions of the four forces acting on rings at practical operation conditions.

EXPERIMENT

STRUCTURE OF A METAL V-BELT

A metal V-belt developed by Van Doorne's Transmissie b.v. consists of a number of thin, flat rings and metal V-blocks which fill the entire length of the rings. Fig.1 shows the metal V-belt assembly. Each ring is approximately 0.2mm thickness. Thin blocks are strung together by 2 sets of the thin rings positioned in slots at each sides of the blocks.

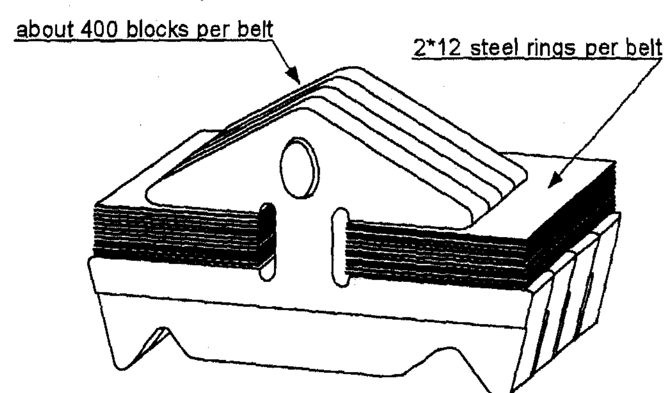

Fig.1 Structure of the metal V-belt assembly

EXPERIMENTAL APPARATUS

Fig.2 shows an assembly drawing of a testing machine for the metal pushing V-belt type CVT. The driving pulley is placed on a slide rail, held by a load cell. The force which acts between the two pulley shafts is measured by the load cell. The driving pulley is rotated by an electric motor. The driven pulley is connected to an eddy-current dynamometer.

Table 1 Test conditions

Speed ratio i=Nin/Nout	2.46, 1.00, 0.61, 0.46
Rotational speed of the driving pulley Nin [rpm]	100, 1000, 2000
Transmitted torque Tin [Nm]	0.0
Thrust of the driven pulley Qdn [N]	17.7, 35.5, 53.2
Oil temperature T_{ATF} [°C]	40

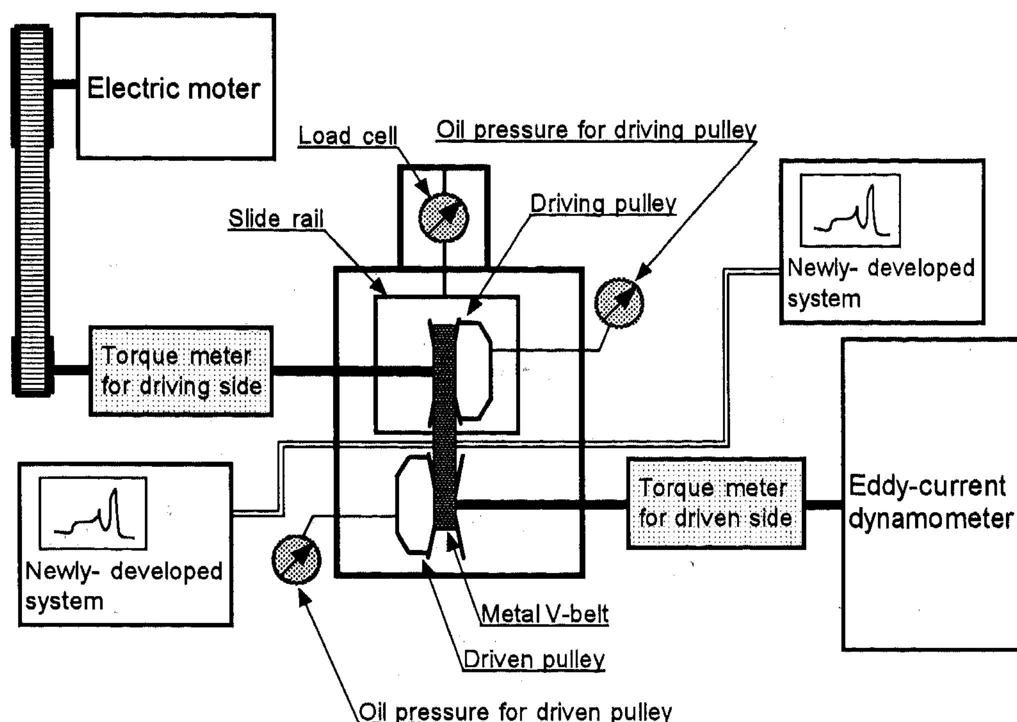

Fig.2 Assembly drawing of a testing machine for the metal pushing V-belt type CVT

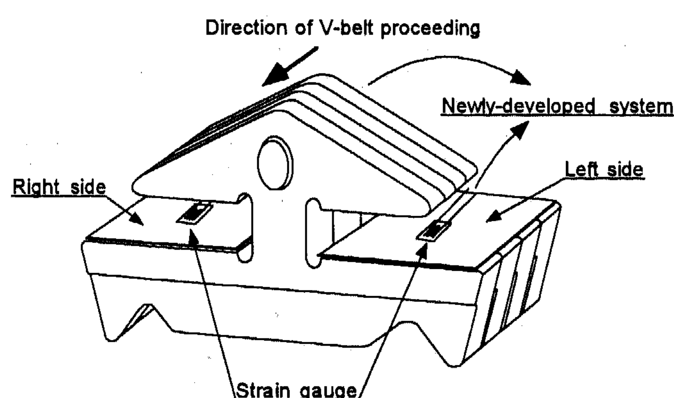

Fig.3 Location of the strain gauges on both innermost rings

EXPERIMENTAL PROCEDURE

Strain gauges are pasted on outer surfaces of both innermost rings. These are the only rings which are set in the metal V-belt (Fig.3). Signals from strain gauges are continuously measured in practical operation conditions by a newly-developed system. Test conditions are given in Table 1 with the definition of each measured item. Speed ratio is defined as rotational speed of the driving pulley divided by that of the driven pulley.

RESULTS AND DISCUSSION

DISTRIBUTION OF RING STRESS

Fig.4,6,7 and 8 show distribution of ring stress for several ring speeds and for various driven pulley thrusts. Abscissa denotes normalized time. Ordinate denotes ring stress.

A distribution of ring stress is reviewed using one of the test conditions as a sample : speed ratio i=0.61, rotational speed of the driving pulley Nin=1000[rpm], driven pulley thrusts Qdn=17.7[N], transmitted torque Tin=0.0[Nm] (Fig.4). In the figure, region a-b and region c-d designate that the strain gauge is in the driving and driven pulley grooves, respectively. Region b-c is the string where the metal V-belt goes from the exit of the driving pulley to the entrance of the driven pulley, and region d-a designates the string where the metal V-belt goes from the exit of the driven pulley to the entrance of the driving pulley. In the figure, ring stress of the left side is moved right slightly, for easier understanding. Definition of right and left sides for rings are shown in the figure 3.

(1) Distribution of ring stress in both pulleys

The ring stress increases suddenly because of the bending stress in region a-b and region c-d. Ring stress in these regions is different for each cycle. Especially, distribution of ring stress in the driven pulley grooves is not equal to that of strain wave figure model (Fig.5(1)) , but changes in a complicated manner.

Saddle surface speed takes different value on each pulley due to the separation between saddle surface and pitch radius. Saddle surface speed is faster than ring speed on the small pitch radius pulley, which will cause unstable behavior of blocks. It seems that the shape of the saddle surface and tilting motion due to the unstable behavior of blocks have detrimental effects on bending stress in the driven pulley grooves.

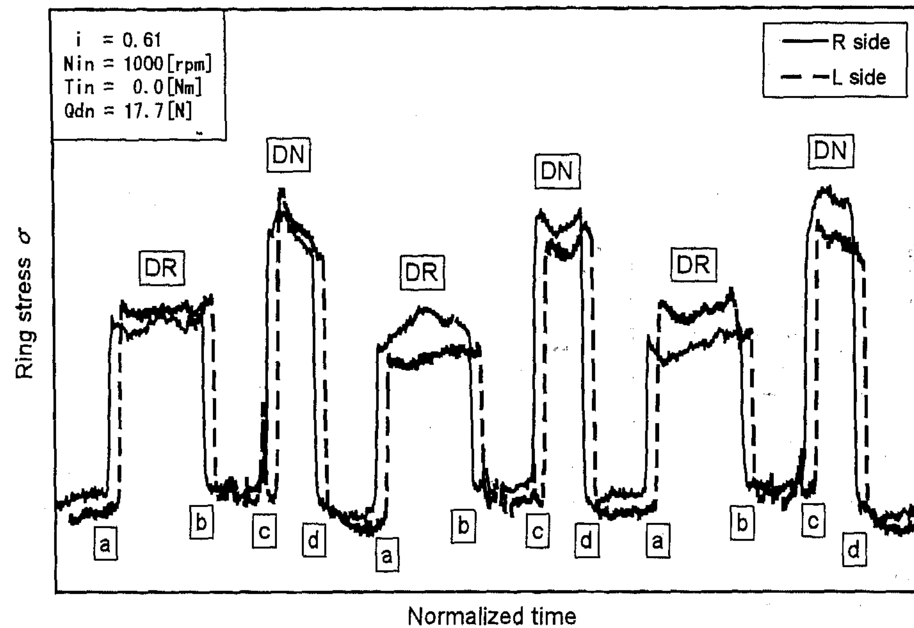

Fig.4 Distribution of ring stress

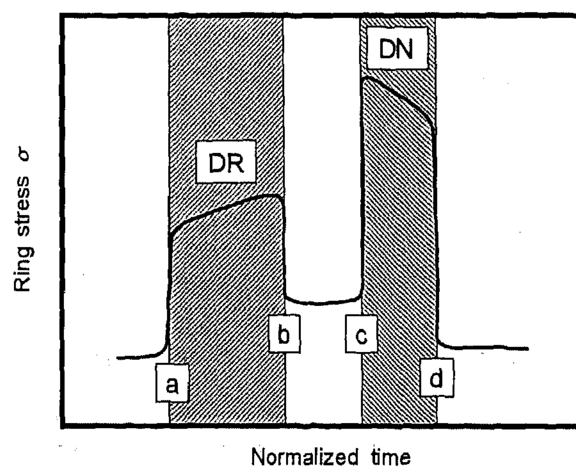

Fig.5(1) Model of strain wave figure

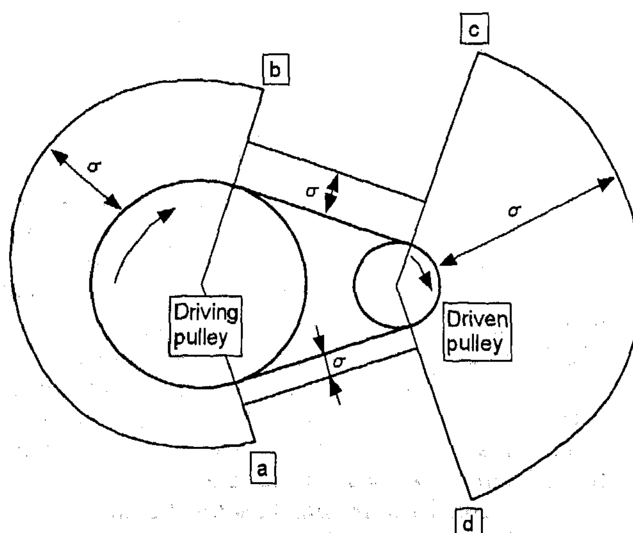

Fig.5(2) Graphic distribution of ring stress

(2) Ring stress at strings

Fig.6 shows distribution of ring stress at several speed ratios. Ring stress in region b-c and region d-a is equal at speed ratio i=1.0. However, at speed ratio i=2.46, ring stress in region d-a is higher than region b-c. And at speed ratio i=0.46, ring stress in the region b-c is higher than the region d-a. This means that the string where the ring stress is higher changes with change of speed ratio. Therefore, ring stress at the string which is the entrance of the small pitch radius pulley is usually higher. Fig.4 and 8 show the same tendency of the ring stress.

In Fujii's paper [5], it is described that difference of ring stress between strings is caused by speed difference of saddle surfaces between two pulleys.

By measuring ring stress at the strings at high belt speed in this study, this tendency which is already revealed at low belt speed is confirmed.

(3) Distribution of ring stress at both right and left sides

Ring stress at region b-c and region d-a is equal on both right and left sides. However, bending stress acting on rings in both pulley grooves is not equal on both sides. Especially, this tendency appears notably in the driven pulley. And this tendency is the same for all conditions. It seems that bending stress changes in a complicated manner due to a little difference in shape of each right and left saddle surface and a little difference in tilting motion of blocks. This is the same reason as considered in the "distribution of ring stress in the both pulleys".

Difference in ring stress acting on both right and left layered rings is a significant factor for life of the metal V-belts. To reveal the reason for this phenomenon is very important for assuming the metal V-belt's life, which is the purpose of this study

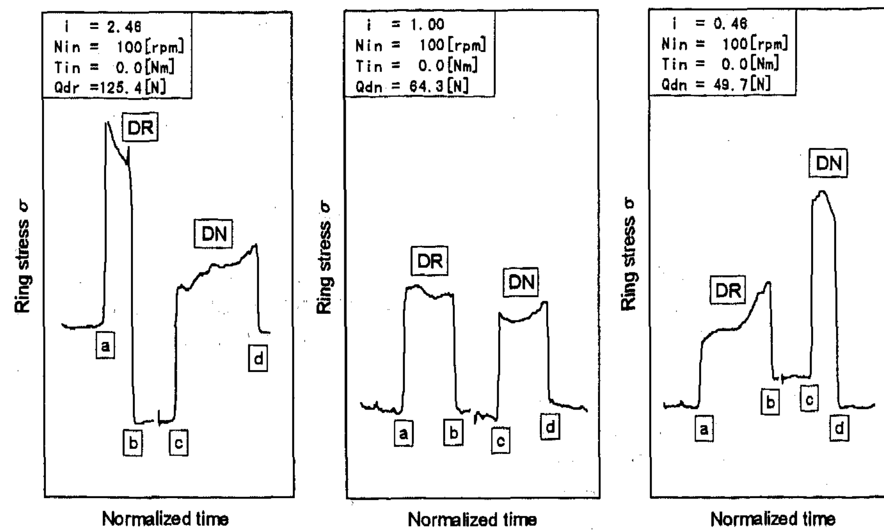

Fig.6 Distribution of ring stress at several speed ratio

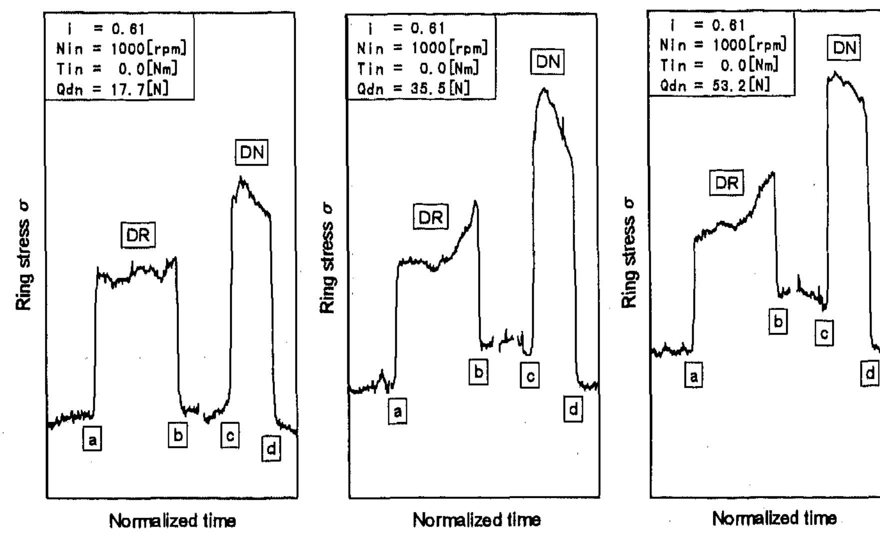

Fig.7 Distribution of ring stress for several driven pulley thrusts

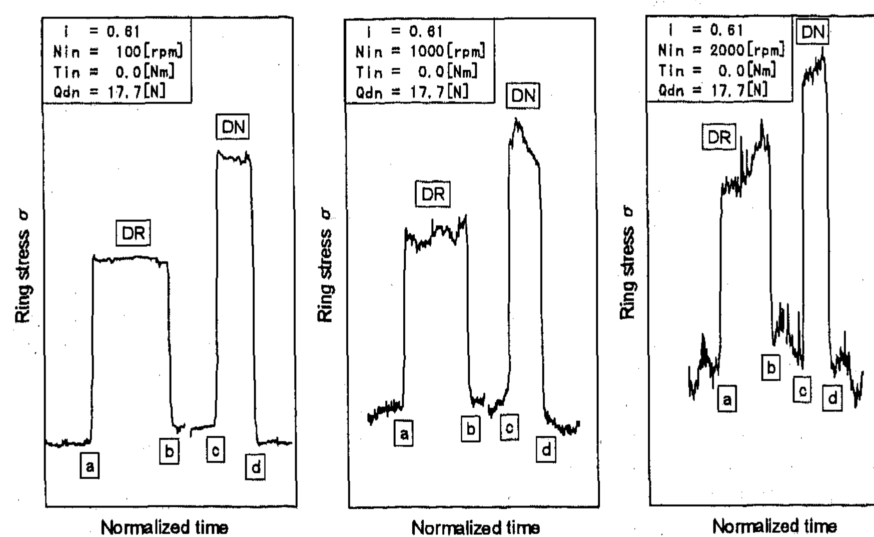

Fig.8 Distribution of ring stress at several rotational speed of the driving pulley

RELATIONSHIP BETWEEN RING STRESS AT THE STRINGS AND THRUST OF THE DRIVEN PULLEY

Fig.7 shows distribution of ring stress for several driven pulley thrusts. Ring stress in both strings is increasing and difference in ring stress between the two strings is growing with increasing driven pulley thrust.

Eular's theory is usually used to analyze the behavior of elastic flat belts. Rings of the metal V-belt do not have the properties of gum elastic. However, Eular's theory may be able to be applied for analysis of this tendency.

Ring speed and saddle speed is different in the small pitch radius pulley. Namely, the innermost rings of both right and left sides are sliding on the saddle surfaces in the small pitch radius pulley. It is assumed that the active arc is spread over the inside surface of the ring which contacts the saddle surfaces in the small pitch radius pulley. The coefficient of friction between the rings and the saddle surfaces is calculated by use of the following Eular's expression.

$$\frac{T_1}{T_2} = e^{\mu \theta}$$

Each character are defined as follows :

T_1 : ring tension for tensile side
T_2 : ring tension for slack side
θ : wrap angle of active arc
μ : coefficient of friction between rings and the saddle surfaces

At several conditions, calculated coefficient of friction is approximately constant : μ=0.09~0.11. This calculated coefficient of friction is equivalent to the coefficient of friction between pulley and blocks. The calculated results are the same at several speed ratios. Therefore, relationship between speed ratio and ring tension ratio (=T_1/T_2 : ring tension for tensile side divided by ring tension for slack side) can be estimated easily. It seems that Eular's theory can be applied for analysis of the ring tension in a metal V-belt.

RELATIONSHIP BETWEEN RING STRESS AT THE STRINGS AND BELT SPEED

Fig.8 shows the distribution of ring stress at several rotational speeds of the driving pulley (Nin). Ring stress at the strings is growing with increasing rotational speed. Ring stress at the strings is constant at rotational speed : Nin=100[rpm]. However, it seems that ring stress at the strings changes in a complicated manner at rotational speed : Nin=1000,2000[rpm]. Especially, this tendency appears in region d-a. In this region d-a, there is no consistent block compression force. Therefore, blocks in the region d-a are free to move. Because of this situation, unstableness of block behavior increases with increasing rotational speed and blocks contact inside surface of the innermost rings. This is the reason why ring stress in region d-a is not constant but changes in a complicated manner.

Fig.9 shows the relationship between ring stress in the strings and rotational speed of the driving pulley. In this figure, ring stress at the strings is defined as an average value of ring stress in region b-c in Fig. 8. It seems that ring stress at the strings is growing on the traces of quadratic curves. Therefore, the relationship between centrifugal force acting on rings and belt speed is expected to be a quadratic curve. The calculated value by use of Kanehara's expression [8] is plotted in Fig.9. The experimental and calculated value are approximately coincident. The coincidence of the experimental value and calculated value confirm the reliability of Kanehara's expression.

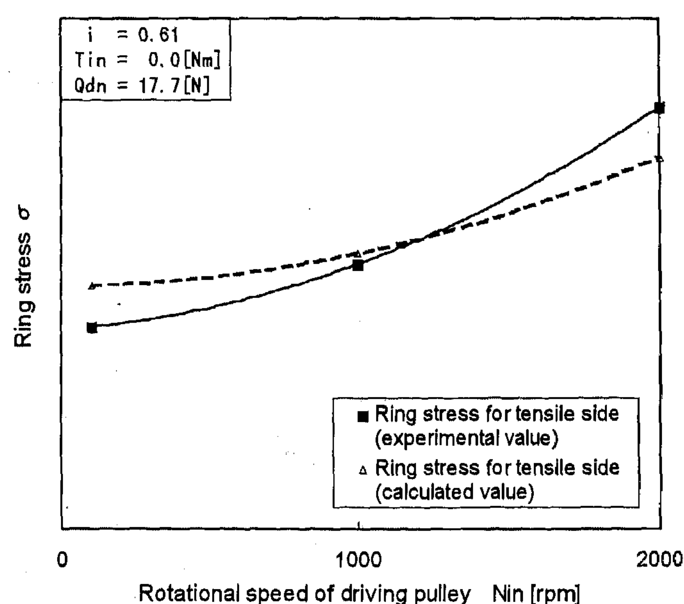

Fig.9 Relationship between ring stress at the strings and rotational speed of driving pulley

CONCLUSION

By measuring all four kinds of forces including centrifugal force continuously at practical operation conditions, the following conclusions have been deduced.

(1) Distribution of ring stress in both pulley grooves is not coincident with a model of strain wave figure which is presented in previous papers, but changes complicatedly.

(2) Ring stress acting on right and left rings is equal at strings, but bending stress acting on both rings is not equal between the two pulleys.

(3) Eular's theory can be applied for the analysis of the ring tension in a metal V-belt with the assumption that the active arc area is spread over the inner surface of the ring which contacts the saddle surfaces in the small pitch radius pulley.

(4)Relationship between centrifugal force acting on rings and belt speed is a quadratic curve.

Applications and Advances in Autodeposition Coatings

Thomas C. Jones and William E. Fristad
Parker Amchem, Henkel Corp.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

Increased restrictions on air and water emissions have led to expanded automotive industry applications for the environmentally-friendly autodeposition process which eliminates chemical conversion coatings, toxic metals and volatile organic compounds (VOC). Underbody suspension components and seating assemblies are currently being painted via autodeposition at many facilities worldwide, several of which have converted existing equipment to save on installation costs.

Daily line operations, control and maintenance of the process will be emphasized. Recent process improvements will also be discussed.

INTRODUCTION

The CLEAN AIR ACT AMENDMENTS (CAAA) of 1990 are now having an impact in the selection of finishing equipment and materials for the appliance industry. The delay in enactment of specific appliance regulations toward the type and quantity of organic emissions from a finishing operation has not diminished the Clean Air Act's impact on the selection of equipment and related processes. Several state environmental agencies have taken the initiative to enact regulations that are more restrictive and more timely than federal agencies. The large investment and relatively long life of finishing equipment mandates that regulations taking effect in 2000 or 2010 must be addressed with the best available technologies today.

Autodeposition is a totally-waterborne painting process which has enabled manufacturers and their toll-coating suppliers to improve the quality of finished products while achieving compliance with increasingly-restrictive environmental codes. The autodeposition coating process offers many advantages:

- Zero VOC content and high coating transfer efficiency performance to meet future air and water quality regulations.
- Less floor space and lower capital expense required than conventional phosphate plus topcoat systems.
- Excellent physical properties such as flexibility, hardness, and solvent resistance.
- Good performance in severe testing environments such as cyclic corrosion and extended salt fog exposure.
- Lower temperature cure (stoving) requirements, enabling entire assemblies to be coated without damage to temperature sensitive components. (Energy inputs are also dramatically reduced).
- Uniform coating thickness control and the ability to coat recessed areas and complex assemblies (i.e., no limitations on "throwing power" or "Faraday cage" effects).
- Safe operation due to absence of flammability

and externally applied current to create the coating reaction.

Ease of operations due to a minimum of chemical control checks and equipment requirements.

Since a zinc (or iron) phosphate pretreatment is **not** required, no toxic heavy metals (e.g., zinc, nickel, manganese) are present in the effluent from this process.

THE AUTODEPOSITION COATING PROCESS

Coating application occurs on metal (e.g., iron/steel) surfaces in an immersion step by the simple dissolution of the cleaned-only substrate by a mildly acidic (pH ~2.5) bath to form positive ions which immediately react with negatively charged latex particles to produce a tightly-adherent coating on the surface. The porosity of the wet film to the metal surface allows the deposition reaction to continue. Succeeding layers of coating provide a thicker barrier to diffusion resulting in increasingly slower deposition rates which effectively prevent the application of unnecessary paint. Because of this mechanism, the coating formation is diffusion controlled (self-limiting). The result is uniform film thickness over the entire part.

After the coating deposition stops, the wet film is water-rinsed to remove any paint puddles and also to render insoluble any unreacted ions. Residual water is next removed and the resins barrier crystalline structure is formed in the final drying step by heat-induced evaporation. While a drying time as low as four minutes (with an infrared oven) has been sufficient for some sheet metal parts, normal forced-air convection oven dwells range from twenty to thirty minutes to allow for substrates of any thickness and to ensure complete water removal from severely recessed areas.

Dry film thickness ranges from 0.5 to 1.0 mil (12 to 25 microns) and is easily controlled by slight changes in paint bath solids and/or the rate of paint tank circulation achieved by variable-speed propeller-type mixers. The length of immersion time in the paint bath directly affects film thickness; however, this time is almost always fixed by the production rate and tank size and is normally not varied in production.

AUTODEPOSITION: EVALUATING COATING UNIFORMITY

Autodeposited coatings are resistant to the "wedge" effect which is an increase in film thickness from the top to the bottom of the vertical dimensions of a work piece and which results from the need for unattached liquid to "flow downhill." This is a typical problem in conventional waterborne immersion paint systems which are both low in viscosity and solids. With the autodeposition process, the coating is chemically reacted to the substrate and any "wedge" effect is minimized.

In a test conducted to demonstrate this, a steel test panel was immersed in a water-reducible alkyd enamel having a viscosity of 18 seconds with a Number 2 Zahn cup. The average film thickness was 1.1 mils.

A second steel test panel was immersed in an autodeposition bath to develop the same film thickness as a baseline. (Note that commercially used autodeposited films are not this high, since 500+ salt spray hours are readily achieved at 0.6 mil.)

On each panel fifty thickness measurements were made using a 5-down and 10-across pattern. The alkyd enamel panel showed thickness variations from 0.4 to 2.4 mils. (The average "wedge" down a vertical surface was 0.5 mil to 1.7 mil.) In contrast, the panel coated by autodeposition showed an overall range of only 0.9 to 1.3 mils, with an average "wedge" variance of $\pm$ 0.2 mils.

AUTODEPOSITION: EVALUATING UNLIMITED THROWING POWER

Although conventional immersion processes have theoretically unlimited throwing power, wet films cannot be rinsed to remove puddled volumes. Furthermore, paint formulations containing volatile organics allow "solvent wash" within restricted substrate areas (where solvent vapors actually dissolve the coating). Autodeposited coatings can be rinsed and dried without removal of coatings from interior sections of parts.

One measure of "throwing power" is the ability of an immersion coating process to produce films inside a standard box:

> Two 4 x 18-inch test panels separated by 3/8-inch strips of a non-conductive plastic spacer are assembled. Both sides of the "box" are contained with adhesive tape leaving the top and bottom areas open, yet allowing liquid access only from the bottom in an immersion process.

The box is coated, water-rinsed, placed in an oven to allow paint cure, and then opened to allow a comparison of coating formation between the inner surface (masked) and the outer (exposed). With autodeposition, both inner and outer surfaces are coated to the level of immersion.

AUTODEPOSITION PERFORMANCE:

Cured film performance properties are listed in Table 1. The most common latex polymer used for deposition is a PVDC (polyvinylidene chloride) copolymer with excellent barrier properties. This resin has been widely used in the food packaging industry for many years to ensure a barrier to moisture and oxygen. The film produced is both hard (for durability) and flexible. The latter property allows post-forming of painted shapes.

INDUSTRIAL APPLICATIONS

Autodeposition is not new. This process highlighted here represents the third generation of polymer technologies. Commercial history covers twenty years. Some commercial applications are listed below.

AUTODEPOSITION APPLICATIONS

- Automotive Jacks
- Fan Blower Housings
- Automotive Lighting
- Leaf Springs
- Seat Tracks/Frames
- File Frames
- Refrigeration Condensers
- Ride Control Equipment
- Suspension Components
- Steering Components
- Brake Boosters
- Drawer Slides
- Outdoor Furniture
- HVAC Equipment

EQUIPMENT CONSIDERATIONS

Since the autodeposition process does not require a zinc or iron phosphate pretreatment, less floor space (and capital equipment costs) are required in comparison with other quality paints which do require a surface conversion coating for optimum performance. This effect is summarized in Table 2. The assumption is made that equivalent substrate cleaning (usually one minute alkaline spray followed by two minutes alkaline immersion) and post-cleaner water rinsing (normally two separate one-minute cascading stages) is required. The autodeposition process gains its time/space advantage in the absence of a chemical pretreatment process and a shorter oven due to lower curing requirements.

Similarly, a lower number of control and maintenance procedures are required (Tables 3 and 4), again primarly due to the absence of stages required by a conversion coating process.

While the specific comparisons are with a waterborne coating, similar comparisons are valid with other quality stoving finishes (e.g., powder, high-solids enamels).

The equipment involved for an autodeposition process is simple with all stages, with the exception of the coating tank, identical to those employed in other finishing processes. For this reason, retrofit of an existing coating system to autodeposition is a direction that should be followed when possible. Both conveyor and hoist designs are used.

.New equipment technology has been introduced which now gives the ability to treat the coating bath solution in-line with an ion exchange system, greatly extending bath life, reducing solid waste effluent, and increasing the transfer efficiency level to that of powder coating and electrodeposition processes.

AUTODEPOSITION APPEARANCE

Standard autodeposited paint films have a black, matte appearance with typical 60 degree gloss readings of 5-15%. The value of the autodeposited coating to the user is usually seen in terms of its overall function in corrosion protection. However, recent developments have made significant improvements in the overall appearance of the coating on parts. The appearance and gloss of the film can be controlled within the autodeposition process by varying the process chemistry. New rinse technologies have been able to increase the gloss level while simultaneously improving the overall surface uniformity. Gloss values in the 15-25% and 25-35% range are attained and the improved overall appearance can meet furniture needs. (Table 5)

ENVIRONMENTAL COMPLIANCE

Federal, state, and local agencies are generating new regulations involving environmental compliance and worker safety. Additionally, there are a number of environmental "volume of compliance" laws affecting the coatings industry today. The most significant laws are the Clean Air Act Amendments of 1990 (CAAA), Superfund Amendments and Reauthorization Act (SARA), Resource Conservation and Recovery Act (RCRA) and Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA). These enactments deal with air quality, chemical inventory reporting, hazardous waste management, and waste site remediation, respectively.

A complete review of the current and proposed legislation surrounding compliance issues is far too lengthy to address in this format. The use of solvents in organic coatings manufacture and application is constantly evolving. Years ago, the coatings formulator and applicator had the luxury of focusing only on the polymeric properties of the system to meet performance requirements. Today, we must analyze every ingredient and its environmental impact on the system as a whole. This includes polymers, pigments, extender pigments, biocides, surface active agents, rheological modifiers, **and** solvents.

Autodeposition coating chemicals, because of their aqueous nature, allow the formulation of coating systems which are naturally low in coalescent solvent. There are, in fact, resin species which require only water for manufacture and application. Because of relatively low glass transition temperature (Tg), these polymeric species require no solvents and very low baking temperatures to yield continuous, well-formed, coating films.

One such (low Tg) resin species is polyvinylidene chloride (PVDC). In emulsified and pigmented form, PVDC can be applied while complying with all current and proposed air quality regulations and legislation. The most modern autodeposition process containing PVDC polymeric dispersions has the advantage of containing **no** volatile organic compounds (V.O.C.'s) as determined by the U.S.E.P.A. procedure for certifying quantity of volatile organic compounds emitted by paint, and other coatings (know as **Federal Reference Method 24**, and/or ASTM Method D-3960-92).

VOC DETERMINATION: FEDERAL REFERENCE METHOD 24 AND AUTODEPOSITION COATING (PVDC)

For the determination of VOC in a specific material, the EPA has utilized "Federal Reference Method 24" which combines several test methods published by the American Society for the Testing of Materials (ASTM). The key method employed is ASTM D 3960-92, "Standard Practice for Determining Volatile Organic Compound (VOC) Content of Paints and Related Coatings." This method provides a measure of the VOC content of solventborne and waterborne paints by determining the quantity of material released from a sample under specified bake conditions. The VOC content is calculated as a function of (1) the volume of coating less water and exempt solvents, and (2) the volume of coating solids.

A sample of the most commonly employed autodeposition coating was evaluated according to EPA Method 24. This material is supplied as a concentrated make-up/replenisher which is diluted with water prior to application.

The "as supplied" coating density, $(D_c)s$, was determined to be 9.86 lb/gal using ASTM D 1475 - "Standard Test Methods for Density of Paint, Lacquer, and Related Products." This method uses a weight-per-gallon cup. The weight percent of total volatile in the coating, $(W_v)s$, was determined to be 62.5 by ASTM D 2369 - "Standard Method for Volatile Content of Coatings." The method involves accurately weighing a paint sample before and after drying at 110C for one hour.

The weight percent water, $(W_w)s$, was determined to be 62.5 by ASTM D 3792 - "Standard Test Method for Water Content of Water Reducible Paints by Direct Injection into a Gas Chromatograph." In this procedure, the paint specimen is diluted whereby dimethylformamide, and an internal standard (2-propanol) are added, and an aliquot of the mixture is injected directly into the gas chromatograph.

The water content, in volume percent, $(V_w)s$, can be calculated by the equation:

$$(V_w)s=\frac{(W_w)s(D_c)s}{D_w}$$

Where D_w is the density of water, 8.33 lbs.gal.
In this case,

$$(V_s)s=\frac{(62.5\%)(9.86 lbs/gal)}{8.33 lb/gal}=74.0\%$$

The organic volatile content, $(W_o)s$, i.e., the VOC content expressed as a percent by weight, is determined by the following equation:

$$(Wo_s)=(W_v)s-(W_w)s=62.5-62.5=0$$

The VOC content of the "as supplied"coating, (VOC)s, is calculated and expressed in terms used by State and Federal regulations by:

$$(VOC)s=\frac{(W_o)s(D_c)s}{100\%-(V_w)s}$$

which, in the case of this PVDC based autodeposition coating is:

$$(VOC)s=\frac{(0)9.86 lb/gal)}{100\%-74\%}=0$$

It is apparent that the use of this type of autodeposition coating can eliminate any cost penalties for exhaust surcharges or the purchase/installation of pollution abatement equipment.

CONCLUSION

The autodeposition coating process reduces the complexity and capital required by competitive technologies. It requires no electric current and develops self-limiting organic coatings through a chemical reaction with the metal surface.

Because the process coats wherever it wets, it generates exceptionally uniform protective coatings even on difficult to coat parts...and does so at a fraction of the conventional energy costs.

Autodeposition coatings can be applied on the same production line for parts with many different end-use market applications. No conversion coating is required, the only pretreatment necessary is cleaning. With no volatile organic compounds, no toxic heavy metals, and low temperature curing, these environmental and operational benefits also produce a more worker-friendly environment.

The autodeposition coating process presents an opportunity to satisfy air quality requirements while still applying a high quality barrier coating. In addition, this autodeposition process saves money by generating no toxic heavy metal sludge and utilizing a low temperature (110 degree C) cure, leading to energy savings

Recent advances in the autodeposition process have resulted in better coating appearance. Improvements in both the coating uniformity and higher gloss have been achieved. Gloss values (60 degree angle) in the 5-15%, 15-25%, and 25-35% reflectance range are now possible by modifying the reaction rinse all from the same coating bath. More uniform coloring in the coating has also been demonstrated

Effects of Coating Weight and Pretreatment on the Painted Corrosion Performance of Coated Steel Sheet

Theresa C. Simpson and Jay D. Hoffman
Bethlehem Steel Corp.

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

A program was initiated to determine corrosion performance of coated sheet products. The program examined the performance of galvannealed, hot-dip galvanized and electroplated zinc coated steel sheet in a variety of cyclic laboratory corrosion tests. Both perforation and cosmetic corrosion susceptibility were evaluated. Materials were pretreated using immersion and spray phosphate systems and were also prepared without a phosphate pretreatment. Results of these studies will be presented in this paper.

INTRODUCTION

The purpose of this study was to determine the effects of coating weight and pretreatment type on the painted corrosion performance of galvannealed, hot-dip galvanized and electroplated steel sheet. Materials with coating weights ranging from 45g/m^2 - 150g/m^2 were tested. Materials were pretreated using immersion and spray phosphating systems and were also prepared in the cleaned-only (no phosphate) condition. Cosmetic corrosion resistance of these materials was evaluated using the GM9540P-Method B test, the Nissan CCT-IV test, the Volvo test, and SAE J2334[1-4]. These will be referred to as the 9540P, CCT4, Volvo and J2334 tests, respectively, for the balance of this document. Perforation corrosion resistance was evaluated using the 9540P test. Phosphatability was also evaluated for each material type prior to corrosion testing.

Results of these studies indicate some dependence of cosmetic and perforation corrosion resistance on coating weight of these materials. A stronger dependence on pretreatment type was observed. The studies also indicate some differences in cosmetic corrosion that are cyclic test dependent. Results of these studies will be presented in this paper.

EXPERIMENTAL

Materials used in these studies included galvanneal and hot dip galvanized produced via both flux and hot line processes, and electroplated zinc. A list of the material types and chemistry of each coating is given in Table 1.

The pretreatment processes used in these studies were based on standard automotive practices. Materials were cleaned with a non-etching alkaline cleaner prior to phosphate application and painting. Tri-cationic spray and immersion phosphates were applied after cleaning. A high build cathodic e-coat and a base-coat/clear coat were then applied. Samples without phosphate were alkaline cleaned prior to e-coat and topcoat application. Phosphate processing and painting was completed by ACT Laboratories, Hillsdale, MI.

Cyclic testing was completed using automatic cabinets for the 9540P and the CCT4 tests. The J2334 test was completed manually.

RESULTS AND DISCUSSION

PHOSPHATABILITY - Phosphate quality, crystal size, and uniformity was evaluated for each material type prior to corrosion testing. Materials were phosphated with tri-cationic phosphates, applied by both spray and immersion methods. Average phosphate coating weights (2 samples each) and crystal size for each material type are listed in Table 2.

COSMETIC CORROSION PERFORMANCE TEST SEVERITY EVALUATION - A number of cyclic tests were evaluated as part of this study. Since nominally identical materials were exposed in each test, it was possible to make some judgments about the relative severity of these tests. Figure 1 compares average scribe creep data for all samples as a function of pretreatment type in three cyclic tests: 9540P, CCT4, and J2334. Data are plotted for 40 cycles of 9540P, 50 cycles of CCT4, and 80 cycles of J2334. Based on this comparison the severities of these tests are similar, although CCT4 may be slightly more severe and J2334 slightly less severe than 9540P. The standard deviations of the three tests are also similar.

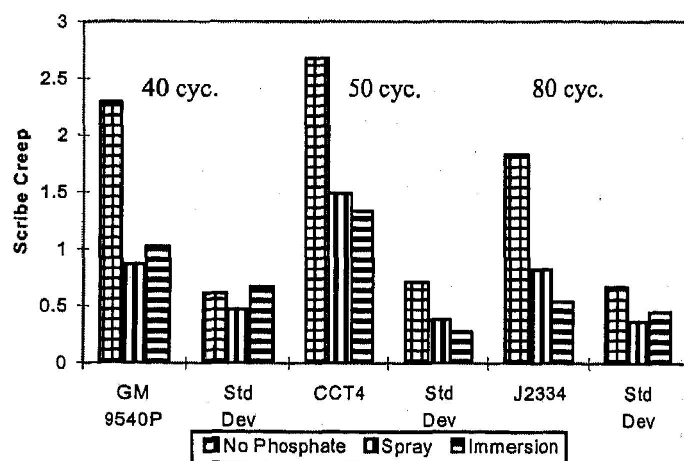

FIGURE 1-Comparison of severity of cyclic tests for various pretreatment conditions.

TEST SELECTIVITY EVALUATION, COMPARISON OF CYCLIC TEST DATA - Selectivity of each test was also evaluated. Figure 2 is a plot comparing control materials tested in the three tests. The plot shows scribe creep results for triplicate (duplicate for CCT4) samples of a cold rolled steel material (CRS) and a hot dip galvanized material (HDG) after test. Note that in both 40 cycles of the 9540P test and 50 cycles of the CCT4 test there is a relatively small difference in the scribe creep performance of these materials. In 80 cycles of J2334, however, the CRS has significantly poorer scribe creep performance than the HDG. Comparing these results to data from actual field exposures for zinc coated sheet and cold rolled steel sheet shows that the values in J2334 are much more field relevant[5]. Standard deviations for each material are also shown. The standard deviation for the CCT4 test are slightly less than for the other two tests. It should be noted that the times (# of cycles) selected for these tests were based on standard amounts of time typically used for each test. It is possible that the selectivity of the 9540P and CCT4 tests would improve if their times were extended.

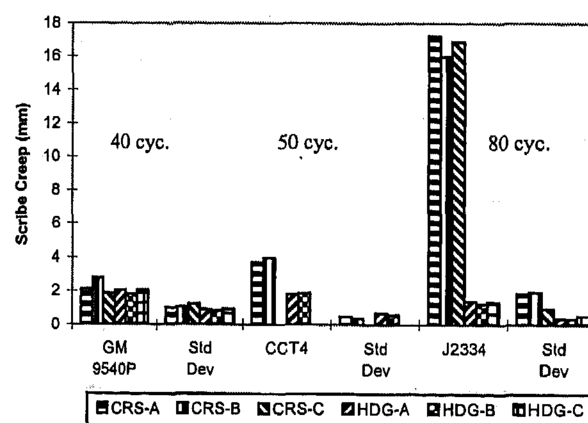

FIGURE 2-Comparison of selectivity of cyclic corrosion tests for CRS and HDG.

EFFECTS OF COATING WEIGHT ON COSMETIC CORROSION PERFORMANCE - The primary purpose of this study was to determine if coating weight and pretreatment affect the painted corrosion performance of these materials. Materials were tested in a variety of laboratory and one accelerated field test. Results are grouped according to pretreatment type. Figures 3-5 show an example of scribe creep data as a function of coating weight for materials tested in J2334. Coating weights given are zinc coating weights to enable direct comparison of galvannealed to hot dip galvanized and electroplated zinc. Note that no real trend in scribe creep as a function of coating weight occurs. Similar data were obtained for all of the cyclic tests. Figures 6-8 show the relationship

between red rust susceptibility and coating weight after 6 months of exposure in the Volvo test. Note that there is some evidence of a dependence on red rust susceptibility with coating weight. These data are early data in this test and it will be interesting to see if this dependence continues with time. No evidence for a relationship between rust susceptibility and coating weight was observed in the other tests.

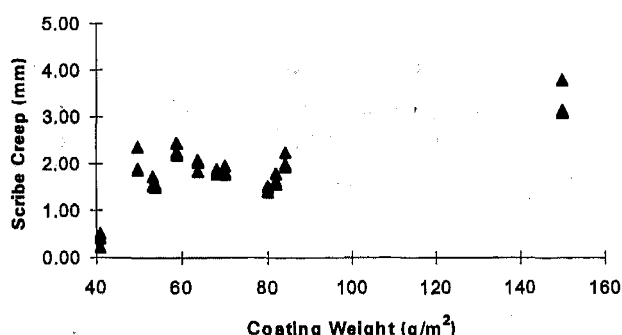

FIGURE 3-Scribe creep as a function of zinc coating weight, J2334, 80 cycles, No Phosphate Condition.

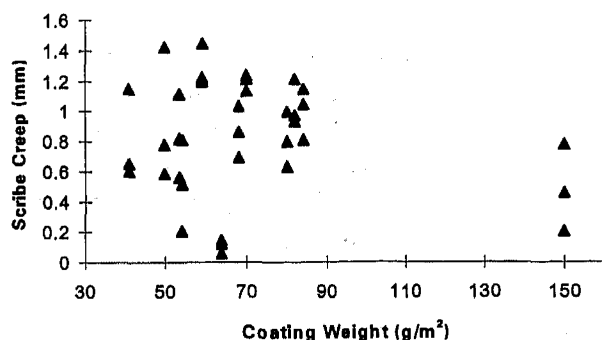

FIGURE 4-Scribe creep as a function of zinc coating weight, J2334, 80 cycles, Spray Phosphate Condition.

EFFECTS OF MATERIAL TYPE- It was also possible to compare the effects of material type on the cosmetic corrosion performance. In order to make this comparison, galvannealed, hot dip galvanized and electroplated zinc materials were selected that had coating weights of approximately 60 g/m^2 (electroplated zinc had a coating weight of ~68 g/m^2). Figure 9 compares average scribe creep for these materials. Two different galvannealed materials with similar coating weights are shown in this comparison. Data are averages of scribe creep performance in three cyclic tests - 9540P, CCT4 and J2334. Triplicate samples of each material were exposed in the 9540P test and the J2334 test; duplicates were exposed in the CCT4 test. Figure 10 compares the same materials using scribe creep information from only the J2334 test. In general, the trend in scribe creep that was shown in Figures 3-5 - no phosphate>spray phosphate>immersion phosphate - holds for these materials. All materials have good scribe creep performance and the galvannealed materials have equivalent to marginally better performance on average than the hot dip galvanized or electroplated zinc materials.

The conclusion from these studies is that cosmetic corrosion resistance is affected by the pretreatment type, and the severity of attack will differ based on the type of cyclic test performed. Cosmetic corrosion resistance has a small if any dependence on coating weight for these materials over this range of coating weights. Performance of these coated sheet products is similar; in some cases galvannealed materials have slightly better scribe creep resistance than hot dip galvanized or electroplated zinc.

PERFORATION CORROSION PERFORMANCE - Perforation corrosion resistance was also evaluated on these materials using an 80 cycle 9540P test. Pit depth was measured at the conclusion of the test. Two sample configurations were used in these studies: SAE ACAP perforation-type coupons consisting of a test specimen:cover plate sandwich with a Teflon spacer separating them and a circular uncoated region on the test specimen [6] and spot welded couples of each material to cold-rolled-steel. All perforation specimens were phosphated with a tri-cationic immersion phosphate and received a high build cathodic electrocoat.

Figures 11-13 are plots of average maximum pit depth as a function of coating weight.

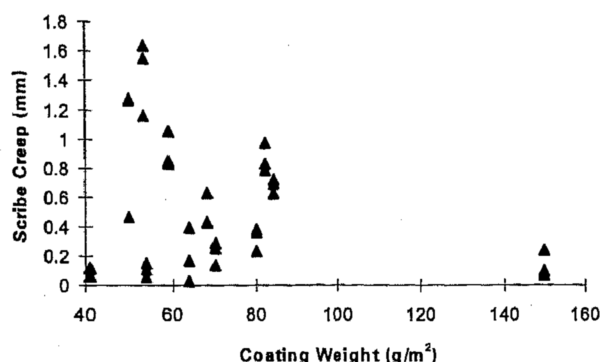

FIGURE 5-Scribe creep as a function of zinc coating weight, J2334, 80 cycles, Immersion Phosphate Condition

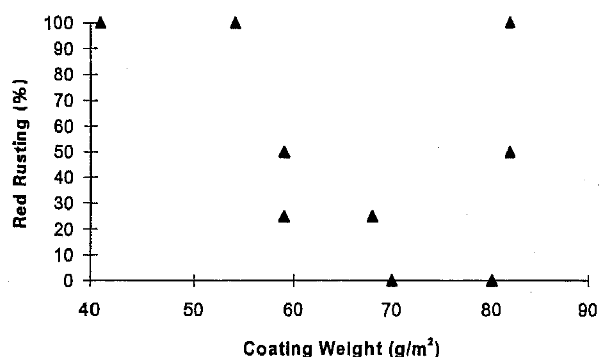

FIGURE 6-Red Rust susceptibility as a function of zinc coating weight, Volvo Test, 6 month removals, visual observation, No Phosphate Condition.

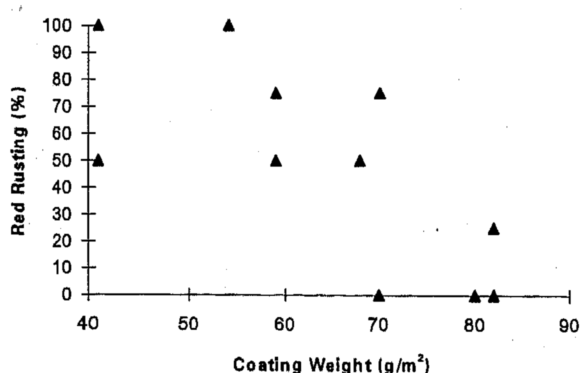

FIGURE 7-Red Rust susceptibility as a function of zinc coating weight, Volvo Test, 6 month removals, visual observations, Spray Phosphate Condition.

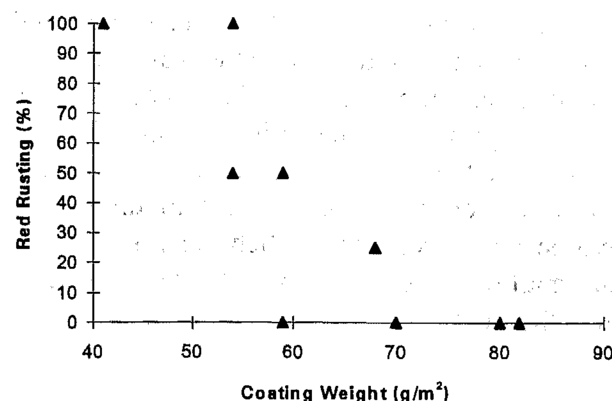

FIGURE 8-Red Rust susceptibility as a function of zinc coating weight, Volvo Test, 6 month removals, visual observations, Immersion Phosphate Condition.

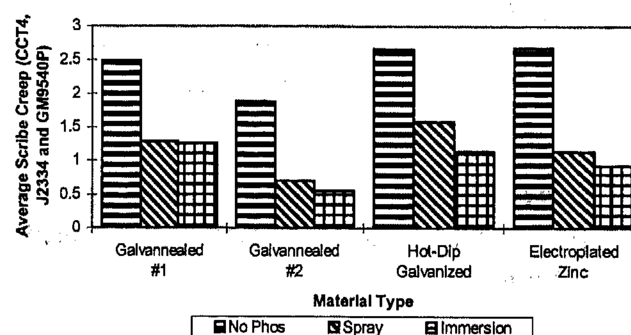

FIGURE 9-Comparison of Scribe Creep Performance as a function of material type and pretreament type. Data plotted are averages of three cyclic test results (length of test as in Figs. 1-2). All materials had ~60 g/m^2 coating weights (electroplated zinc, 68 g/m^2)

Average maximum pit depth for the spot welded couples is the average of the five deepest pits across the pitted surface. For the SAE coupons it is the average of the deepest pit in each of the four quadrants of the uncoated area of the coupon. Figures 11 and 12 are for spot welded couples; Figure 13 is for SAE perforation-type coupons. Regression lines are shown on all plots. Figure 12 includes a cold-rolled steel control material in the regression analyses; Figures 11 and 13 are for zinc coated products only. A trend in pitting susceptibility as a function of coating weight does exist, but it is only a trend and is far from a linear correlation. It is possible that this trend would have

been more pronounced if the materials were exposed for longer periods of time.

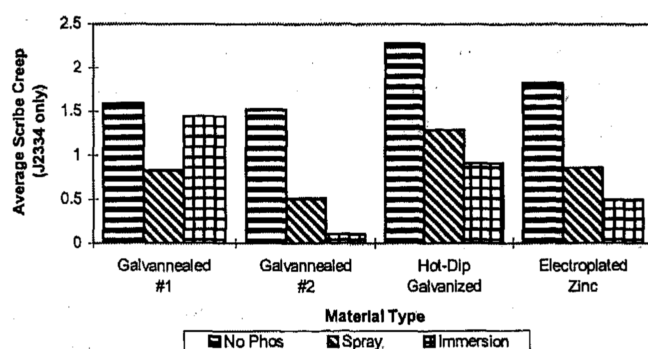

FIGURE 10-Comparison of Scribe Creep Performance as a function of material type and pretreatment type. Data plotted are averages of triplicate samples in the J2334 test (80 cycles). All materials had ~60 g/m² coating weights (electroplated zinc, 68 g/m²)

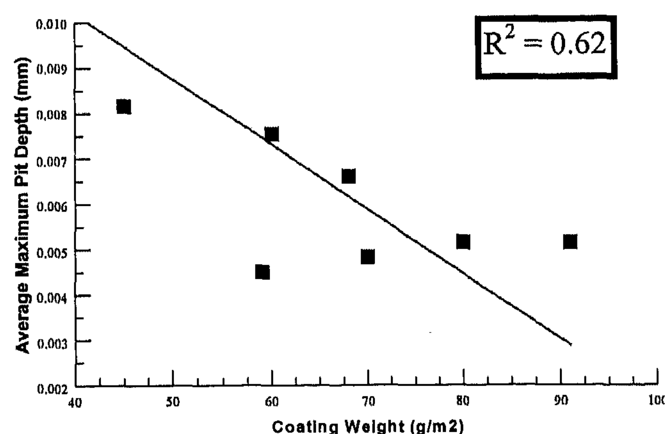

FIGURE 11-Pitting susceptibility as a function of zinc coating weight, coated products only, 80 cycles 9540P, spot welded couples of each coated product to cold rolled steel.

The conclusion from these studies is that pitting susceptibility is somewhat related to zinc coating weight and that within the range of coating weights examined it does not differ dramatically for these materials.

CONCLUSIONS

Overall, these studies showed that there appears to be a weak influence of coating weight on the cosmetic and perforation corrosion resistance of zinc coated products in the zinc coating weight range of 40-150 g/m². It should be noted that for the perforation corrosion studies the time of exposure may be one reason that a consistent effect of coating weight was not observed. Further studies need to address this by taking exposures to longer times. The early results of the Volvo test show some evidence of increased red rusting resistance with increased coating weight. Results further showed that phosphate pretreatment does influence the cosmetic corrosion resistance. The best corrosion resistance was seen with immersion phosphates.

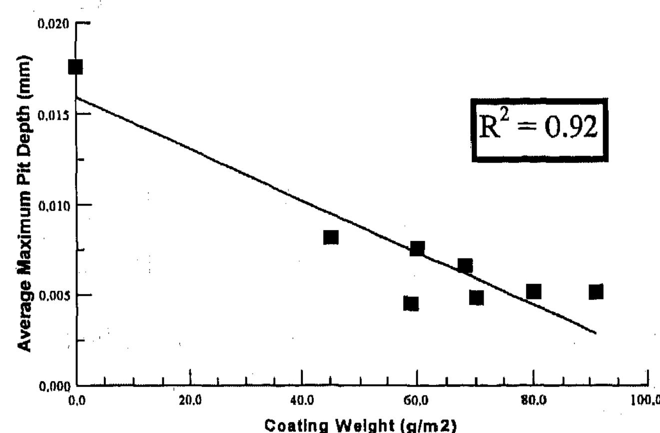

FIGURE 12-Pitting susceptibility as a function of zinc coating weight, coated products and cold rolled steel controls, 80 cycles 9540P , spot welded couples of each coated product to cold rolled steel.

Data from these studies further showed that there are significant differences in both the severity and selectivity of cyclic corrosion tests. The J2334 test appears to have the most field relevant selectivity for zinc coated vs cold rolled steel products.

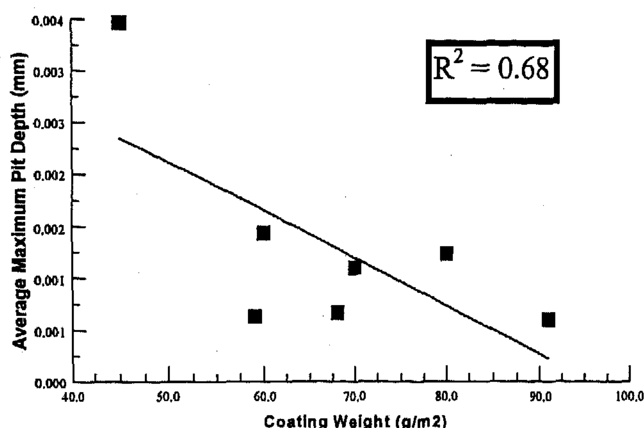

FIGURE 13-Pitting susceptibility as a function of zinc coating weight, coated products only, 80 cycles 9540P , SAE ACAP-type perforation coupons.

Automotive Corrosion Protection Practices in Europe

Horst Gehmecker
Chemetall GmbH

Copyright 1997 Society of Automotive Engineers, Inc.

ABSTRACT

A survey of the corrosion protection practices in Europe is presented. The materials in use for the construction of the carbody and the chemical pretreatment processes applied are described in detail. Trends in electrocoating are also discussed briefly. The use of precoated/prephosphated steel and aluminum is continuously increasing. In addition trials are made with magnesium and plastic hang-on parts. In pretreatment, multi-metal and environmentally friendly processes free of nickel, nitrite and chrome are increasingly used. Some twelve body lines process aluminum hang-on parts and all-aluminum carbodies, respectively. Two body lines operate with a nickel and nitrite free phosphating process and chrome free post-treatment since early 1996. Future trends are presented for conclusion.

INTRODUCTION

Automotive corrosion protection practices in Europe include the application of pre-coated steel, corrosion protection by design and construction, seam sealers, trication phosphating, cataphoretic electrocoating, underbody coating and cavity waxes. These protection practices seem to be similar to the ones employed in North America in the first run. A closer analysis reveals interesting differences, some of them being rather distinct.

The corrosion protection practices in Europe will be discussed in detail. Particular emphasis will be put on the materials used for the car body construction, chemical pretreatment and electrocoating. The protection measures associated with design and construction, sealers and waxes are beyond the scope of this paper.

CAR BODY CONSTRUCTION MATERIALS

For car body construction, the sheet materials depicted in Table 1 are used by the European vehicle manufacturers. Some of these materials are still being investigated in pre-production trials and are not yet employed in routine production.

The ranking included in Table 1 indicates the extent to which the material is used in the European vehicle industry excluding transplants. The amount of mild steel is decreasing while the amounts of pre-coated steel and aluminum are increasing. Several car models are made 100 % of pre-coated steel sheet. In addition to the production of an all-aluminum luxury car (approximately 70 units/day), several medium volume cars are being manufactured with aluminum hang-on parts. There do exist ambitious plans by several car manufacturers to use aluminum for hang-on parts, aluminum intensive vehicles and further all-aluminum cars. By 1998, the amount of aluminum to be processed in paint shops may be 35 - 50 % in several plants.

Several manufacturers have investigated the application of cast magnesium for skin parts. Problems encountered so far are the surface quality of the material having a large impact on the finish of the painted car.

The use of plastics is still discussed controversially in Europe. By the beginning of 1998 a high volume subcompact car will be introduced which will be composed of a metal frame and plastic hang-on parts.

Pre-primed pre-coated steel has been employed to some extent over many years. There are indications that the use of pre-primed electrogalvanized steel will be increased in the near future. A new compact car which will be introduced in 1997 will have the underbody coating replaced by the use of pre-primed electrogalvanized sheet in combination with a shield made of plastic.

PRE-PHOSPHATING OF COATED STEELS - Pre-phosphating of electrogalvanized steel was introduced some years ago in order to improve mainly the forming properties of the material. Initially, two cationic systems have been in use based on Zn-Mn-phosphate and Zn-Ni-phosphate, respectively. Quality constraints led to the development of a trication phosphating system based on Zn-Ni-Mn-phosphate from 1991 onwards. Details of the process and the coatings precipitated are depicted in Table 2. The coatings comply with the quality requirements of most of the automobile manufacturers.

In addition to two-sided electrogalvanized steel, one-sided electrogalvanized, Galvanneal and to some extent HDG are being pre-phosphated. In the case of one-sided EG particular emphasis must be taken to avoid excessive reaction with the steel side, leading to undesired sludge generation. Trication pre-phosphating of EG is being performed in seven lines in Europe. The material is purchased without passivating post-treatment by the OEM industry.

Several high volume cars are currently being made from pre-coated pre-phosphated steel, with a strong upwards trend for the near future. All car bodies made from pre-phosphated sheet are conducted through a chemical pretreatment line comprising degreasing, trication phosphating and post-treatment in order to treat sanded areas as well as areas where

the coating had been damaged, e. g. by forming operations etc.

With state-of-the-art pre-phosphating processes, coating weights on Galvanneal are difficult to control. This causes problems in sheet welding, especially of double layers. This led to the development of no-rinse trication phosphating systems which can be applied by spray/squeeze or roll-on methods. This latest development allows control of the coating weight in a sufficiently low and narrow range. At present, no-rinse pre-phosphated material is being investigated or evaluated at an industrial scale.

IN-LINE PRE-TREATMENT OF ALUMINIUM SHEET - Most of the aluminum sheet material employed to date is purchased by the car manufacturer in a bare surface state and either used as such or given a deoxidising/ passivating treatment prior to stamping and joining. One manufacturer uses chromated, pre-painted (Al pigmented primer, approximately 7 μm) material.

With the increasing use of aluminum, improved properties regarding stamping, welding, adhesive bonding and transport/storage are demanded by the body shops. This initiated extensive collaborative investigations, with various approaches to apply an inorganic or organic coating on the strip (see Table 3). At present, dry lubricants are being investigated or evaluated at an industrial scale.

CHEMICAL PRE-TREATMENT OF MULTI-METAL CAR BODIES

Due to strict environmental and working safety regulations, the European vehicle manufacturers are on the leading edge with respect to the use of environmentally-conscious phosphating products. The technology presently used in Europe is shown schematically in Figure 1. The various pre-treatment stages will be discussed in more detail, especially with respect to environmentally-conscious products. Depending on regulations in Europe, the priorities may be different for individual countries.

DEGREASING - Thorough degreasing is an important precondition to achieve a high quality conversion coating. The alkaline cleaners used are formulated with biodegradable and APEO (= Alkylphenolethoxylate) free surfactants. Powder cleaners and liquid cleaners are used in a ratio of approximately two to one. A considerable amount of cleaners are formulated as two component products in order to cope with the different permeability of builder and surfactants when passed through ultrafiltration devices.

ACTIVATION - Grain refining (activation) with colloidal titanium phosphate polymers is state-of-the-art world-wide. Although it is generally accepted that the grain refiners give better performance in a separate stage than in a cleaner stage, many spray and also spray/dip lines are not equipped with separate activation stages.

Most activating products still in use have very limited bath-lifetimes necessitating frequent bath make-up and replenishment. Some five years ago grain refiners with a greatly extended bath-lifetime were introduced. Currently some twenty car body lines and numerous parts lines are operated with these materials. Through their use a fair amount of process water can be saved.

Characteristic data of the liquid grain refiners are given in Table 4. An interesting feature is that they are supplied in liquid form and can be dosed directly by means of metering pumps, eliminating manual additions of powder.

NITRITE-FREE PHOSPHATING - In order to achieve fine-crystalline zinc phosphate coatings in a reasonably short time, oxidising reagents must be added to accelerate the phosphating reaction.

Two basic types of nitrite-free processes have been introduced in recent years. The accelerators used in these processes are hydrogen peroxide and hydroxylamine compounds, respectively. The formation of toxic fumes (NOx) in the plant and the contamination of effluents with NO_2^- are avoided by both of them. Peroxide-accelerated processes may be more sound due to the lack of accelerator breakdown products which could enrich in the phosphating bath and hence contribute to the rinsing water contamination. Hydroxylamine-accelerated processes may be easier to operate due to the integrated accelerator but form breakdown products such as ammonium ions.

Peroxide-accelerated processes tend to be more advantageous in spray application whereas hydroxylamine-accelerated processes give better results in immersion applications. Characteristics of interest are summarized in Table 5.

NICKEL-FREE PHOSPHATING - Trication phosphating processes contain heavy metal ions like zinc, nickel and manganese. The concentrations of heavy metals in the waste water are limited in many countries by state and also local regulations. In Germany, for example, the maximum permitted waste water concentration of nickel is 0,2 to 0,5 ppm. It is common knowledge that such low limits are difficult to reach even when applying special waste water treatment. These problems may be solved by installing a selective ion exchanger or by employing a nickel-free process. Nickel-free processes, as referenced in this paper, are also cobalt-free.

In recent years a nickel-free process has been developed using traces of Cu ions as a nickel replacement. For steel and aluminum treatment the process may be accelerated by sodium nitrite or hydroxylamine. Hydrogen peroxide seems to be less appropriate. If pre-coated steel should also be treated, hydroxylamine is most appropriate as an accelerator. This is due to the ability to control the nitrate concentration which turned out to be a critical factor with respect to the formation of white spots.

This process has been successfully employed in two vertically indexed immersion lines for car

bodies since early 1996. Materials processed are CRS, EG two-sided, EG one-sided, Al and Al pre-primed. Data of interest are compiled in Table 6.

CHROME-FREE PASSIVATION - Passivating post-treatments are still being used by most of the vehicle manufacturers throughout North America and Europe. Japanese and Korean manufacturers normally do not apply post-treatments.

Most frequently, products containing hexavalent/trivalent chromium are still being employed. Since hexavalent chromium compounds are highly toxic and carcinogenic, the maximum permitted concentrations are very low (i.e. 0,1 mg/m^3 in air and 0,1 mg/l in effluents in Europe).

Chrome-free alternatives on the basis of flourozirconates are generally accepted by the European automotive manufactureres to give equivalent paint adherence and creep resistance as chromium based products. Approximately twelve car body lines currently employ these products. The majority of these lines are located in Germany.

Unlike chrome based products, it is possible to establish either a small or large rinse cascade when using the chrome-free post treatment. In both cases considerable amounts of water can be saved (see Figure 2). Since the chrome-free process does not provide substantial protection to bare phosphated steel panels it is recommended to electrocoat the bodies wet-on-wet after chemical conversion treatment.

More recently, a trend towards the elimination of post treatments has also been observed in Europe. At present, too little data are available to discuss the long term impact of this change.

PHOSPHATING OF ALUMINIUM - Trication phosphating with controlled addition of fluoride is the current state-of-the-art pre-treatment of multi-metal car bodies with aluminum hang-on parts or all-aluminium car bodies in Europe. Approximately ten lines are currently employing this technique, with spray and dip application balancing each other. All processes do contain nickel, and the majority are accelerated by sodium nitrite. Some of the practical experience collected over the recent years is depicted in Table 7.

Spray phosphating of approximately 80 % aluminum together with steel and pre-coated steel has been operated successfully for many years. In immersion applications some preconditions have to be met in order to achieve satisfactory coating results. These are, among others, the use of intensive bath agitation and the minimization of bath contaminants. To date, less than 20 % of aluminum are being processed by immersion application. In Europe there do exist very ambitious plans to increase the amount of aluminium to app. 35 % for certain models, in some cases to 50...100 %.

CATHODIC ELECTROCOATING

With respect to electrocoating in Europe, lead-free cathodic electrocoats have been introduced in several car body lines most recently. Some of the materials in use are also tin-free. The solvent content has been decreased to under approximately two percent in most applications.

A further trend is the conversion of the electrocoat tanks to the so-called generation five materials which are said to give higher throw power at lower coating thickness. Also so-called low-density materials are being used to some extent. Most of these materials still contain lead.

In several lines the effluents from the electrocoating section have been decreased to zero due to the establishment of rinsing cascades and the employment of a final rinse with ultrafiltrate.

Low bake materials are not a topic in Europe because of the intensive use of bake-hardening steel or aluminum sheet. Bake-hardening materials need oven temperatures exceeding 180°C in order to obtain their final mechanical strengths.

SUMMARY

Trends in Europe with respect to corrosion protection practices are the increasing use of coated steel, pre-phosphated steel and aluminum. Several projects are under way to use these materials with inorganic or organic functional layers. The use of light materials like magnesium and plastic are intensively investigated. Due to environmental issues, new pretreatment products are used including cleaners with biodegradable and APEO-free surfactants, liquid activators with longer bath-lifetime, nitrite-free and/or nickel-free zinc phosphating agents and chrome-free post-treatments. Lead- and tin-free cathodic electrocoats have been introduced in several car body lines. A further trend in electrocoating is the conversion of the state-of-the -art materials to so-called generation five and low-density products.

TABLE 1: Car body construction materials employed in Europe

Cold-rolled steel	- soft, unalloyed - high strength,e.g. dual-phase, triple-phase - bake-hardening	3 2 3
Hot-dip galvanized steel	- Zn + 0.1- 0.2 % Al - Zn + ca. 10 % Fe (Galvanneal) - Zn + ca. 5 % Al + 1 % Rare Earths(Galfan) - Zn + ca. 55 % Al + 1.5 % Si (e.g.Galvalume)	3 2 0 0
Electrogalvanized steel	- Zn - Zn + ca. 10 % Ni - Zn + ca. 16 % Fe - Zn + ca. 16 % Fe / Zn + ca. 83 %Fe	3 3 0 0
Hot-dip/Electrogalvanized steel	- Zn + ca. 16 % Fe / Zn + ca. 83 % Fe	0
Pre-coated steel, pre-primed	- Zn or ZnNi (el.) + zinc rich paint (3 - 7 μm) - ZnNi (el.) + org. coating (~1 μm)	2 1
Aluminium	- AlCuMg (AA 2xxx) - AlMg, AlMgMn (AA 5xxx) - AlMgSi (AA 6xxx)	1 1 2
Aluminium, coated with primer	- AlMgSi (AA 6xxx) + org. coating paint (~7 μm)	1
Magnesium	- AZ 91 HP	0
Plastic	- thermoplastics	1

0 = not used/investigated   1 = limited application   2 = medium amounts   3 = extensive use

TABLE 2: Trication pre-phosphating process for EG strip

Treatment times:	5 - 15 sec
Treatment temperature:	60 - 62 °C (140 - 143 °F)
Coating weight:	1.6 ± 0.4 g/m^2 (two-sided EG) 1.3 ± 0.4 g/m^2 (one-sided EG)
Coating composition:	38 - 40 % Zn 30 - 33 % P_2O_5 ~ 1.0 % Ni 4 - 8 % Mn
Lines in Europe:	7

TABLE 3: Aluminum for car body construction

Surface state	**Status**
bare	in use
bare, deoxidized + passivated	in use
chromated, rinse or dry-in-place *	in use
chromated + conductive paint (~ 7 μm) *	in use
chromated + conductive paint (~ 2 μm) *	R&D
pre-treatment chrome-free, rinse or dry-in-place *	R&D
pre-treated chrome-free, with conductive paints *	R&D
anodized *	R&D
zinc phosphated *	R&D
thin Zn layer (plasma, electrolytic, zincate) *	R&D
thin Zn layer (plasma, electrolytic, zincate) + Znph *	R&D
dry lubricant *	R&D
pre-treatment chrome-free + dry lubricant *	in use
	R&D

* These pre-treatments are applied in-line onto the strip

TABLE 4: Properties of liquid activators

Supply product	• liquid • milky white • shelf life-time 6 months • Storage temperature > -7 °C (20 °F) • automatically dosable
Activation bath	• stable up to 50 °C (120 °F) • bath life-time ~ 8 weeks • constant activation • completely dispersible • only compensation of carry-over losses • consumption 50 - 200 mg/ft^2

TABLE 5: Characteristics of nitrite-free phosphating processes

Peroxide-accelerated process	• no breakdown products • more appropriate in spray application • minimum time 1,5 min for steel • separate neutralisation necessary • frequent accelerator determination • closed-loop possible
Hydroxylamine-accelerated process	• more appropriate in immersion • breakdown product are ammonium ions • accelerator contained in replenisher • rare accelerator determination • process slower than nitrite-accelerated • operates on FeII side

TABLE 6: Nickel-free phosphating process - line data

Type of line	- 2 indexed vertical immersion lines
Throughput	- approximately 700 units/day per line
Material processed	- CRS, EG, Al, Al pre-primed
Number of stages	- 11
Nickel replacement	- traces of Cu
Accelerator	- hydroxylamine
Treatment time	- 180 secs
Fell limitation	- with pressurized air
Coating weight on CRS	- 2.5 g/m^2
Crystal size on CRS	- 4 - 10 microns
Post-treatment	- fluorozirconate
Performance with CED	- similar to ZnNiMnph process

TABLE 7: Practical experience with aluminum phosphating

- Applicable by spray and immersion
- Spray process easier to operate than dip process
- Percentage of aluminum being processed to date
  - spray: < 80 %
  - dip: < 20 %
- Treatment of 35 - 50 % Al by dip expected for 1998
- Preconditions in dip application
  - high bath agitation
  - good activating pre-rinse
  - minimize bath contamination with phosphating poisons
- fluoride control with ion-sensitive electrode

Round-Robin Evaluation of a New Standard Laboratory Test for Cosmetic Corrosion

Herbert E. Townsend

ABSTRACT

A new, standard laboratory test (SAE J 2334) for evaluation of the cosmetic corrosion resistance of autobody steel sheet has been developed through the joint efforts of SAE's Automotive Corrosion Prevention Committee (SAE/ACAP) and the Auto/Steel Partnership's (A/SP) Corrosion Task Force. Results from this test give an excellent correlation with those of on-vehicle tests conducted in Montreal, Quebec, and St. John's, Newfoundland. To establish the precision of the new test, nine laboratories participated in a round-robin evaluation. Each laboratory tested ten standard, painted automotive steel sheet products. The results of this work are analyzed in terms of within-lab repeatability and lab-to-lab reproducibility, and they are an important and final milestone in the development and specification of the new test.

INTRODUCTION

In the early 1980's, the automotive and steel industries recognized that an improved laboratory test for evaluation of the cosmetic corrosion resistance of coated steel sheet products was sorely needed. The widely used salt-spray test was notoriously unreliable. Although existing cyclic tests were better than salt spray, they did not completely agree with real-world performance. Moreover, the large number of different types of cyclic tests made it difficult for auto manufacturers and their suppliers to agree on performance criteria.

To address this need, the Automotive Applications Committee of the American Iron and Steel Institute established the Corrosion Task Force in 1984 with the mission of developing an improved, standard laboratory test. This Group joined forces with the SAE/ACAP Cosmetic Corrosion Subcommittee and the two groups proceeded with the test development. The Auto/Steel Partnership added its support to the groups in 1995.

The 12-year efforts of these groups have culminated in the establishment of a new corrosion test which has been tentatively designated as SAE J 2334. Development of this test involved a number of key steps. As documented in a series of papers published during the course of this development [1-10], these steps included:

o A reservoir of standard test materials was established. These included cold rolled and coated sheet products representing a broad range of performance. The materials were phosphated and painted to give ten material variables. This reservoir made possible the evaluation of a broad range of tests with a common set of materials, thus giving a well-defined and consistent frame of reference for comparing test results.

o To establish the real-world performance of the reference materials, on-vehicle tests were conducted for a 5-year period on pickup trucks operated in Montreal, Quebec, and St. John's, Newfoundland. The results of these tests served as the real-world standard against which the results of all other tests were compared.

o License-plate test racks containing a subset of the standard materials were distributed to committee members. In 1992, fifty racks were prepared for mounting on the front license-plate brackets of cars driven in many locations throughout the USA, including Florida, Pennsylvania, and Michigan. Results from these tests will ensure that the real-world standard of results established in Montreal and St. John's is truly representative of a wide range of environments.

o The standard materials were tested in a wide variety of test environments by the committee members and other cooperating laboratories worldwide . These included 19 laboratory tests, three proving ground tests, and static exposure with twice-weekly application of salt solution at seven outdoor

sites.

o Methods were developed for comparing the results of the various tests to those of the real-world standard. These comparisons clearly showed that none of the existing test methods evaluated was completely satisfactory, see Table 1. In particular, all of the evaluated tests underestimated the performance of zinc and zinc-alloy coated sheet relative to cold rolled.

Table 1: Rating of various tests.

Test	Rating*
J 2334	97
Best existing cyclic test	80
Best outdoor test	56
Best proving ground test	52
Salt spray test	12

* Rating is based on the the R^2 + C criterion given in Reference 1, normalized to a scale of 0 (worst) to 100 (perfect correlation).

o To overcome the shortcomings of existing tests, we conducted a statistically designed experiment (Plackett-Burmann L8 matrix)[1,2]. The effects of seven variables in a typical cyclic test were evaluated. The results of these tests indicated that two of the variables are critical to obtaining a good correlation with real-world behavior. First, it was discovered that the salt solution used in most tests (typically 5%) was too concentrated. Much better results are obtained with lower concentrations, such as 0.5 to 0.85%. Second, it was found that best results are obtained when the relative humidity in the dry stage is controlled at 50%.

o Based on the above findings, the new J 2334 test cycle (see Figure 1) was designed and evaluated. As shown in Table 1, the new test shows an excellent correlation with the on-vehicle tests conducted at St. John's and Montreal, and it is a major improvement over any of the existing tests evaluated.

o To determine whether the mechanisms of corrosion occurring in the new test environment are similar to those taking place in the on-vehicle tests, Lehigh University conducted a detailed study of the test specimens. This study showed an excellent match of the corrosion products and morphologies of attack for J 2334 and the real-world[11].

o Finally, to determine the precision of the new test, a round-robin, or interlaboratory, test program was conducted in which nine laboratories conducted the J 2334 test on the standard set of ten materials. This paper describes the results of the round-robin tests.

EXPERIMENTAL PROCEDURES

TEST MATERIALS - A variety of automotive steel sheet products were sheared into 100- x 300-mm panels, and coated with a full automotive paint system, see Table 2. These materials, including bare, cold rolled as well as metallic-coated sheet, were selected to give a wide range in performance, and to be representative of the types of products in use for the construction of automobiles. Specifically, they included steel sheet with: two coating weights each of electroplated zinc, electroplated zinc-nickel alloy, and hot-dip zinc-iron alloy, plus one coating weight of hot-dip zinc. Also included are three uncoated cold rolled steels, two with different phosphate pretreatments, and one with no phosphate. These are the same ten material combinations that were used in on-vehicle and laboratory tests throughout the development of J 2334.

Also included in the tests were duplicate, preweighed 25- x 50-mm coupons of bare cold rolled steel intended to provide quantitative mass-loss data on the corrosivity of the test conditions.

TEST SPECIMENS - Painted test panels were cut in half to form 100- x 150-mm coupons. Metallic adhesive tape was applied to the single cut edge to protect it from corrosion. A diagonal scribe was made with a carbide lathe tool to scratch through the paint to expose bare, uncoated steel. All of the test panels were prepared and scribed at ACT laboratories. It was intended that the test panels would be oriented at an angle of 15 degrees to the vertical.
